cryoprecipitate, and fresh-frozen plasma is usually reserved for a patient with life-threatening hemorrhage. The concern is that one is adding "fuel to the fire" of already activated coagulation. However, it may be the only method to prevent death in some patients with severe hemorrhage. Therapy will stabilize a patient, prevent exsanguination or massive thrombosis, and permit institution of definitive therapy to treat the underlying cause.

A patient with manifestations of thrombosis is often treated by anticoagulation with heparin or low-molecular-weight heparin. However, these medications are used in the treatment of DIC only when the benefit (e.g., reduce clotting) outweighs the risk (e.g., further bleeding). Antithrombin III is sometimes used in fulminant DIC, although it increases the risk of bleeding. Chronic DIC does not respond to oral anticoagulants, but it can be controlled with long-term use of heparin.

Nursing Management Disseminated Intravascular Coagulation

Nursing Diagnoses

Nursing diagnoses for the patient with DIC may include but are not limited to the following:

- *Risk for impaired tissue integrity* as evidenced by *insufficient fluid volume* (bleeding)
- *Acute pain* related to *physical injury agent* (bleeding)
- *Decreased cardiac output* (related to fluid volume deficit)
- *Anxiety* related to *unmet needs* (fear of the unknown)

Nursing Implementation

Nurses must be alert to the possible development of DIC and especially to the precipitating factors listed in Table 33-20. The nurse must also remember that, because DIC is secondary to an underlying disease, appropriate care for managing the causative problem must be provided while also providing supportive care related to the manifestations of DIC.

Appropriate nursing interventions are essential to the survival of a patient with acute DIC. Astute, ongoing assessment, active attention to manifestations of DIC, and prompt administration of prescribed therapies are crucial. Table 33-14 and NCP 33-2 (see the Evolve website) provide assessments and interventions appropriate for the patient with DIC. Early detection of bleeding, both occult and overt, must be a primary goal. Assess for signs of external bleeding (e.g., petechiae, oozing at IV or injection sites) and signs of internal bleeding (e.g., increased heart rate, changes in mental status, increasing abdominal girth, pain) as well as indications that microthrombi may be causing significant organ damage (e.g., decreased urinary output). Tissue damage should be minimized and the patient protected from additional sources of bleeding.

An additional nursing responsibility is to administer blood products and medications correctly. (Blood product transfusion is discussed later in this chapter.)

Neutropenia

Leukopenia refers to a decrease in the total WBC count (granulocytes, monocytes, and lymphocytes). *Granulo-cytopenia* is a deficiency of granulocytes, which include neutrophils, eosinophils, and basophils. The neutrophilic granulocytes, which play a major role in phagocytizing pathogenic microbes, are closely monitored in clinical practice as an indicator of a patient's risk for infection. A reduction in neutrophils is termed *neutropenia.* (Some clinicians use the terms *granulo-cytopenia* and *neutropenia* interchangeably because neutrophils constitute the largest proportion of granulocytes.) The *absolute neutrophil count* (ANC) is determined by multiplying the total WBC count by the percentage of neutrophils. **Neutropenia** is defined as a neutrophil count of less than 1 to 1.5×10^9/L, or 1 000 to 1 500/mcL. Normally, neutrophils range from 2.2 to 7.7×10^9/L. *Severe neutropenia* is defined as an ANC less than 0.5×10^9/L.

However, in considering the clinical significance of neutropenia, it is important to know whether the decrease in the neutrophil count was gradual or rapid, as well as the degree and the duration of neutropenia. The faster the drop and the longer the duration, the greater the likelihood is of developing life-threatening infection, sepsis, and death. Other factors and comorbid conditions—such as being older than 60 years of age, having an existing infection, being in a hospital, having diabetes, and other factors—can increase the risk of a serious infection.

Neutropenia is not a disease; it is a clinical consequence that occurs with a variety of conditions or diseases (Table 33-22). It can also be a predictable or an unanticipated adverse effect of taking certain drugs. The most common cause of neutropenia is iatrogenic, resulting from widespread use of chemotherapeutic and immuno-suppressive therapy in the treatment of malignancies and autoimmune diseases.

TABLE 33-22
CAUSES OF NEUTROPENIA

Drug Therapy
• Antitumour antibiotics (daunorubicin [Cerubidine], doxorubicin [Adriamycin]) • Alkylating agents (nitrogen mustards, busulfan [Myleran]) • Antimetabolites (methotrexate, 6-mercaptopurine, cytarabine) • Anti-inflammatory drugs (phenylbutazone) • Cardiovascular drugs (captopril, procainamide) • Diuretics (furosemide [Lasix]) • Psychotropics and antidepressants (clozapine, imipramine) • Miscellaneous (gold, penicillamine) • Antimicrobial agents (ganciclovir, penicillin G, trimethoprim–sulphamethoxazole)
Hematological Disorders
• Idiopathic neutropenia • Fanconi's anemia • Congenital (cyclic neutropenia) • Aplastic anemia • Leukemia • Myelodysplastic syndrome
Autoimmune Disorders
• Systemic lupus erythematosus • Felty syndrome • Rheumatoid arthritis
Infections
• Viral (e.g., hepatitis, influenza, HIV, measles) • Fulminant bacterial infection (e.g., typhoid fever, miliary tuberculosis) • Parasitic • Rickettsial
Miscellaneous
• Severe sepsis • Bone marrow infiltration (e.g., carcinoma, tuberculosis, lymphoma) • Hypersplenism (e.g., portal hypertension, storage diseases [e.g., Gaucher's disease]) • Nutritional deficiencies (cobalamin, folic acid) • Transfusion reaction • Hemodialysis

HIV, human immunodeficiency virus.

Clinical Manifestations

The patient with neutropenia is predisposed to infection with nonpathogenic organisms that constitute normal body flora as well as opportunistic pathogens. When the WBC count is depressed or immature WBCs are present, normal phagocytic mechanisms are impaired. Also, because of the diminished phagocytic response, the classic signs of inflammation—redness, heat, and swelling—may not occur. WBCs are the major component of pus. Therefore, in the patient with neutropenia, pus formation (e.g., as a visible skin lesion or as pulmonary infiltrates on a chest radiograph) is also absent.

Safety Alert

- Presence of a low-grade fever in neutropenic patients is of great significance because it may indicate infection and quickly lead to septic shock and death.
- A fever greater than 38°C and a neutrophil count less than 0.5×10^9/L is a medical emergency.

When fever occurs in a neutropenic patient, it is assumed to be caused by infection and calls for immediate attention. The immuno-compromised, neutropenic patient has little or no ability to fight infection. Thus, minor infections can lead rapidly to sepsis. The mucous membranes of the throat and mouth, skin, perianal area, and pulmonary system are common entry points for pathogenic organisms in susceptible hosts. Clinical manifestations related to infection at these sites include complaints of sore throat and dysphagia, appearance of ulcerative lesions of the pharyngeal and the buccal mucosa, diarrhea, rectal tenderness, vaginal itching or discharge, shortness of breath, and a nonproductive cough. Any minor complaint by the patient of pain or any other symptom should be taken seriously. These seemingly minor complaints can progress to fever, chills, sepsis, and septic shock if not recognized and treated in the early stages.

Systemic infections caused by bacterial, fungal, and viral organisms are common in patients with neutropenia. The patient's own flora (normally nonpathogenic) contributes significantly to life-threatening infections such as pneumonia. Organisms that are known to be common sources of infection include Gram-positive coagulase-negative staphylococci and *Staphylococcus aureus* and Gram-negative organisms such as *Escherichia coli* and *Pseudomonas aeruginosa* (Baden, Bensinger, Angarone, et al., 2014). Fungi involved include *Candida* (usually *C. albicans*) and *Aspergillus*. Viral infections caused by reactivation of herpes simplex and herpes zoster are common following prolonged periods of neutropenia, such as in HSCT patients.

Diagnostic Studies

The primary diagnostic tests for assessing neutropenia are the peripheral WBC count and bone marrow aspiration and biopsy (Table 33-23). A total WBC count of 4×10^9/L or 4 000/mcL reflects leukopenia. However, only a differential count can confirm the presence of neutropenia (ANC of 1–1.5 ×

10^9/L or 1 000–1 500/mcL). If the differential WBC count reflects an ANC of 0.5 to 1 ×10^9/L or 500 to 1 000/mcL, the patient is at moderate risk for a bacterial infection. An ANC less than 0.5 to 1 × 10^9/L or 500 to 1 000/mcL places the patient at severe risk. Note that patients with acute leukemia who present with a high WBC may in fact have neutropenia, because the majority of the WBCs are ineffective leukemia blast cells.

TABLE 33-23

COLLABORATIVE CARE
Neutropenia

Diagnostic	Collaborative Management
• History and physical examination • Risk assessment for severity and duration of neutropenia • WBC count with differential • WBC morphology • Hct and Hb values • Reticulocyte and platelet count • Bone marrow aspiration or biopsy • Cultures of nose, throat, sputum, urine, stool, obvious lesions, blood (as indicated) • Chest radiograph or other diagnostic tests	• Identification and removal of cause of neutropenia (if possible) • Identification of site of infection (if present) and causative organism • Antimicrobial therapy • Blood cultures (prior to administration of antimicrobials) • Hematopoietic growth factors (G-CSF, and GM-CSF) • Strict adherence to handwashing and patient hygiene protocols • Single-patient room and positive-pressure or HEPA filtration, depending on risk • Community isolation and home precautions if outpatient

G-CSF, granulocyte colony–stimulating factor; *GM-CSF*, granulocyte-macrophage colony–stimulating factor; *Hb*, hemoglobin; *Hct*, hematocrit; *HEPA*, **h**igh-**e**fficiency **p**articulate **a**ir; *WBC*, white blood cell.

A peripheral blood smear is used to assess for immature forms of WBCs (e.g., bands). The Hct level, the reticulocyte count, and the platelet count are performed to evaluate bone marrow function. A review of the patient's recent past and current drug history should also be done. If the cause of neutropenia is unknown, bone marrow aspirations and biopsies are performed to examine cellularity and cell morphology. Additional studies may be done as indicated to assess spleen and liver function.

Nursing and Collaborative Management Neutropenia

The factors involved in the nursing and collaborative care of neutropenia include (a) determining the cause of the neutropenia; (b) identifying the offending organisms if an infection has developed; (c) instituting prophylactic, empirical, or therapeutic antibiotic therapy; (d) administering hematopoietic growth factors (e.g., granulocyte colony–stimulating factor [G-CSF] and granulocyte-macrophage colony–stimulating factor [GM-CSF]); and (e) instituting protective practices (e.g., strict handwashing, skin and oral hygiene) (see Table 33-23).

Occasionally, the cause of the neutropenia can be easily treated (e.g., nutritional deficiencies). However, neutropenia can also be an adverse effect that must be tolerated as a necessary step in therapy (e.g., chemotherapy, radiation therapy). In some situations, the neutropenia resolves when the primary disease is treated (e.g., tuberculosis).

The nurse must monitor the neutropenic patient for signs and symptoms of infection (any fever ≥38°C) and early septic shock. Early identification of a potentially infective organism depends on acquiring cultures from various sites. Serial blood cultures (at least two) or one from a peripheral site and one from a venous access device should be done promptly and antibiotics started immediately. In addition, cultures of sputum, throat, lesions, wounds, urine, and feces may be required. It may also be necessary to do a computed tomographic (CT) scan, tracheal aspiration, bronchoscopy with bronchial brushings, or lung biopsy to diagnose the cause of pneumonic infiltrates. Despite these many tests, the causative organism is identified in only approximately half of patients with neutropenia.

When a febrile episode occurs in a patient with neutropenia, antibiotic therapy must be initiated immediately (within 1 hour), even before the determination by culture of a specific causative organism. Broad-spectrum antibiotics are usually ordered by the IV route because of the potential lethal effects of infection. However, some oral antibiotics are highly effective and routinely used for prophylaxis against infection in some patients with neutropenia. Antibiotics are often used in combinations because of their synergistic effects and in the event that multiple organisms are responsible for the infectious symptoms. Regardless of the combination, the nurse must initiate therapy promptly and observe for

adverse effects of antimicrobial agents. Adverse effects common to aminoglycosides include nephrotoxicity and ototoxicity; adverse effects common to cephalosporins include rashes, fever, and pruritus.

The extended duration of neutropenia increases the infection risk of the patient. The longer the neutropenia lasts, the greater the risk of a fungal infection. Antifungal therapy is initiated in patients who produce a positive culture or in patients who do not become afebrile with broad-spectrum antibiotic coverage.

G-CSF (filgrastim [Neupogen]) and GM-CSF can be used to prevent neutropenia or to reduce its severity, its duration, or both. They should be considered for patients receiving chemotherapy based on their risk factors for neutropenia. G-CSF stimulates the production and function of neutrophils. GM-CSF stimulates the production and function of neutrophils and monocytes. These agents can be given by IV or subcutaneously. Keratinocyte growth factor may also be used to reduce the duration and severity of mucositis, which may contribute to infection. An important consideration in the care of a patient with neutropenia is the determination of the best means to protect the patient, whose own defences against infection are compromised. To accomplish this goal, the following principles must be kept in mind: (a) the patient's normal flora is the most common source of microbial colonization and infection; (b) transmission of organisms from humans most commonly occurs by direct contact with the hands; (c) air, food, water, and equipment provide additional opportunities for infection transmission; and (d) health care providers with transmissible illnesses and other patients with infections can also be sources of infection under certain conditions.

Handwashing is the single most important preventive measure in minimizing the risk of infection in the patient with neutropenia. Strict adherence to handwashing protocol by all people coming in contact with the compromised patient is the major method to prevent transmission of harmful pathogens.

Immuno-compromised patients should be separated from those who are infected or who have conditions that increase the probability of transmitting infections. A patient who is hospitalized, therefore, should be in a private room. Often, patients can be managed on an outpatient basis if the patient and caregivers can astutely monitor for fevers and other signs of infection and then report promptly to a nearby health care facility (Table 33-24). Although it is expensive to install, high-efficiency particulate air (HEPA) filtration, an air-handling method with a high-flow filtering system, can reduce or eliminate the number of aerosolized pathogens in

the environment. It is often used for a patient with severe, prolonged neutropenia (e.g., patients who have undergone bone marrow transplant). Care routines in a HEPA environment are essentially the same as care in any other private room. Prophylactic antibiotics and antifungals may also be used for severely immuno-compromised patients. The patient and caregiver should be instructed on a diet that restricts potentially hazardous foods, such as raw and undercooked meats and eggs and soft cheeses with moulds.

TABLE 33-24

PATIENT & CAREGIVER TEACHING GUIDE
Neutropenia

This instruction sheet for patients explains protective precautions they should take when their neutrophil count is low. Patients should ask their health care provider about specific precautions to follow related to their particular risk factors for infection.

• *Wash your hands* frequently and make sure those around you wash their hands frequently, particularly if they help with your care. An antibacterial hand gel may also be used.
• Notify your nurse or health care provider if you have any of the following:
  • A fever greater than 38°C
  • Chills or feeling hot
  • Redness, swelling, discharge, or new painful area either on the skin or deeper in your body
  • Changes in urination or bowel movements
  • A cough, sore throat, mouth sores, or blisters
• If you are at home, take your temperature as directed and follow instructions on what to do if you have a fever.
• Avoid crowds and people with colds, flu, or infections. If you are in a public area, wear a mask and use hand-sanitizing gel frequently.
• Avoid uncooked meats, seafood, eggs, and unwashed fruits and vegetables. Ask your health care provider about specific dietary guidelines for you.
• Bathe or shower daily. A moisturizer may be used to prevent skin from drying and cracking.
• Maintain some daily activity as instructed by your health care team. This may include walking and moderate exercise while avoiding crowds.
• Brush your teeth with a soft toothbrush four times daily. You may floss once daily if it does not cause excessive pain or bleeding. Avoid alcohol-based mouthwashes.
• Do not perform gardening or clean up after pets. Feeding and petting your dog or cat is fine as long as you wash your hands well after handling.

Quality-of-life issues for the patient with neutropenia should not be overlooked. Potential patient experiences of fatigue, malaise, decrease in functioning, social isolation, depression, and perceived lack of support require appropriate interventions.

Age-Related Considerations

Thrombo-Cytopenia and Neutropenia

About 55% to 60% of cancer diagnoses are currently made in individuals older than 65 years. This proportion is expected to further increase in the next 2 decades as the baby boomers move into this age group. Age-related changes of bone marrow function are rather subtle and probably not significant for the hematopoietic function of normal older individuals. These changes, however, may become clinically evident under conditions of severe hematopoietic stress, such as the administration of repeated courses of chemotherapy, radiation therapy, or both and the resultant sequelae of myelosuppression. The use of supportive therapies, such as hematopoietic growth factors, increases the likelihood that older individuals will be treated with standard and even aggressive therapies, leading to neutropenia and thrombo-cytopenia. The nurse also needs to be aware that older individuals may have signs and symptoms different from those of a younger individual. For example, the older adult may have delirium as compared with cough as a clinical manifestation of pneumonia.

Myelodysplastic Syndrome

Myelodysplastic syndrome (MDS) is a group of related hematological disorders characterized by a change in the quantity and quality of bone marrow elements. Peripheral blood cytopenias in combination with a hypercellular bone marrow exhibiting dysplastic changes is the hallmark of MDS. In MDS, hematopoiesis is disorderly and ineffective. In Canada, it is estimated that the incidence is 75 to 162 per 100 000 adults aged 65 and older (Leukemia & Lymphoma Society, 2016). Although it can occur in all age groups, the highest prevalence is in people over 80 years of age (Shead, Hanisch, Marlow, et al., 2016).

Etiology and Pathophysiology

The exact etiology of MDS is unknown. Its manifestations result from neoplastic transformation of the pluripotent hematopoietic stem cells within the bone marrow. People who have received radiation or chemotherapy or who have been exposed to industrial solvents are at higher risk for developing MDS. Rarely, genetic disorders are responsible

for the disease. Nevertheless, in 85% of MDS patients, no specific cause can be identified (Klotz, Parikh, & Battiwalla, 2013).

MDS is referred to as a *clonal disorder* because some bone marrow stem cells continue to function normally whereas others (a specific clone) do not. The abnormal clone of the stem cells is usually found in the bone marrow but eventually may be found in circulation. Occasionally, one type of MDS transforms into another. Depending on the subtype, MDS may progress to acute myelogenous leukemia (AML) (Meers, 2015). In contrast to AML, in which the leukemic cells show little normal maturation, the clonal cells in MDS always display some degree of maturity. Disease progression is slower than in AML. However, eventually, the abnormal cells replace the bone marrow. Typically, life-threatening anemia, thrombo-cytopenia, and neutropenia occur during the advanced stage of MDS.

Clinical Manifestations

MDS commonly manifests as infection and bleeding caused by inadequate numbers of ineffectively functioning circulating granulocytes or platelets. MDS is often discovered in the older adult in the course of investigating symptoms of anemia, thrombo-cytopenia, or neutropenia. It may also be diagnosed incidentally from a routine CBC.

Diagnostic Studies

Bone marrow biopsy with aspirate analysis is essential for both the diagnosis and the classification of the specific types of myelodysplasia. In MDS, the bone marrow is normocellular, hypocellular, or hypercellular, and the patient has peripheral cytopenia. Laboratory data and bone marrow studies will help rule out other causes of the dysplasia, such as nonmalignant disorders, cobalamin and folate deficiencies, and infectious causes.

Informatics in Practice

Use of Internet to Access Information on Unfamiliar Diseases

- Nurses assigned the care of a patient with a disease or disorder that they are not familiar with, such as thalassemia, can access the Internet

and perform a quick search.

- Within minutes, nurses can learn the pathophysiology of thalassemia, treatment options, possible complications that will need monitoring, and recommended medical and nursing interventions.
- Using this readily available information helps nurses deliver high-quality, evidence-informed care.

Nursing and Collaborative Management Myelodysplastic Syndrome

Treatment of MDS is based on the premise that the aggressiveness of the treatment should match the aggressiveness of the disease. The recommended treatment depends on the amount and type of dysplasia in the bone marrow as well as genetic mutations and patient's age. Low-intensity treatments consist of hematological monitoring (serial bone marrow and peripheral blood examinations) and transfusions with blood products, including iron chelators to prevent iron overload if required. Growth factors may also be used (e.g., G-CSF, erythropoietin). Low-intensity chemotherapeutic drugs may be used, such as azacitidine (Vidaza) or lenalidomide (Revlimid). High-intensity treatments include the use of chemotherapeutic drugs similar to those used to treat and cure myeloid leukemia. High-intensity treatments are not recommended for all patients, and only about one-third of high-risk patients are treated with intensive chemotherapy, HSCT, or both.

Nursing care of a patient with MDS is similar to that of a patient with manifestations of anemia (see NCP 33-1, earlier in this chapter, for patients with anemia; see NCP 33-2 for thrombo-cytopenia and NCP 33-3 for neutropenia, both available on the Evolve website).

Leukemia

Leukemia is a broad term given to a group of malignant diseases that affect the blood and blood-forming tissues of the bone marrow, lymph system, and spleen. Leukemia occurs in all age groups. It is characterized by diffuse replacement of bone marrow with proliferating leukocyte precursors. This loss of regulation in cell division results in an accumulation of dysfunctional cells. Leukemia follows a progressive course that is eventually fatal if untreated. It was estimated that, in 2017, there would be 6 200 new cases and 2 900 deaths in Canada due to leukemia and that males would account for more than 58% of new cases (Canadian Cancer Society, 2017a).

Etiology and Pathophysiology

Regardless of the specific type of leukemia, there is generally no single causative agent in the disease's development. Most leukemias result from

a combination of factors, including genetic and environmental influences. Chromosomal changes, first recognized in chronic myelogenous leukemia, have led to discoveries of how normal genes, once transformed, can result in abnormal genes *(oncogenes)* capable of causing many types of cancers, including leukemias (see Chapter 18). Chemical agents (e.g., benzene), chemotherapeutic drugs (e.g., alkylating agents), viruses, radiation, and immunological deficiencies have all been associated with the development of leukemia in susceptible hosts. The incidence of leukemia is increased in radiologists, people who have lived near nuclear bomb test sites or nuclear reactor accidents (e.g., Chernobyl), and people previously treated with radiation therapy or chemotherapy.

Although ribonucleic acid (RNA) retroviruses cause a number of leukemias in animals, a viral cause for a human leukemia has been established only for some patients with adult T-cell leukemia. This form of leukemia is endemic in southwestern Japan and parts of the Caribbean and central Africa and is caused by the human T-cell leukemia virus type 1 (HTLV-1).

Classification

Leukemia can be classified as either acute or chronic. The terms *acute* and *chronic* refer to cell maturity and the nature of the disease's onset. *Acute leukemia* is characterized by the clonal proliferation of immature hematopoietic cells. The leukemia develops following malignant transformation of a single type of immature hematopoietic cell, followed by cellular replication and expansion of that malignant clone. *Chronic leukemias* involve more mature forms of WBCs, and the disease onset is more gradual.

Leukemia can also be classified by identifying the type of leukocyte involved, that is, whether it is of myelogenous origin or of lymphocytic origin. By combining the acute and chronic categories with the cell type involved, specific types of leukemia can be identified. Four major types of leukemia are acute lymphocytic leukemia (ALL), acute myelogenous leukemia (AML), chronic myelogenous (granulocytic) leukemia (CML), and chronic lymphocytic leukemia (CLL). The defining features of these leukemic subtypes are presented in Table 33-25.

TABLE 33-25
TYPES OF LEUKEMIA

Type	Age of Onset	Clinical Manifestations	Diagnostic Findings
Acute myelogenous leukemia (AML)	Increase in incidence with advancing age; peak incidence between 60 and 70 yr of age; accounts for 15%–20% of acute leukemia in children and 80% in adults	Fatigue and weakness, headache, mouth sores, anemia, bleeding, fever, infection, sternal tenderness, gingival hyperplasia, mild hepato-splenomegaly and lymphadenopathy	Low RBC count, Hb, Hct; low platelet count; low to high WBC count with myeloblasts; high LDH; greatly hypercellular bone marrow with myeloblasts
Acute lymphocytic leukemia (ALL)	Peak prevalence between ages 2 and 5 and after age 50	Fever; pallor; bleeding; anorexia; fatigue and weakness; bone, joint, and abdominal pain; generalized lymphadenopathy; infections; weight loss; hepato-splenomegaly; headache; mouth sores; neurological manifestations, CNS involvement, increased intracranial pressure secondary to meningeal infiltration	Low RBC count, Hb, Hct; low platelet count; low, normal, or high WBC count; high LDH; transverse lines of rarefaction at ends of metaphysis of long bones on radiograph; hypercellular bone marrow with lymphoblasts; lymphoblasts also possible in cerebro-spinal fluid; presence of Philadelphia chromosome (20%–25% of patients)
Chronic myelogenous leukemia (CML)	25–60 yr of age; peak incidence around 45 yr of age	No symptoms early in disease; then fatigue and weakness, fever, sternal tenderness, weight loss, joint pain, bone pain, massive splenomegaly, increase in sweating	Low RBC count, Hb, Hct; high platelet count early, lower count later; increase in polymorphonuclear neutrophils, normal number of lymphocytes, and normal or low number of monocytes in WBC differential; low leukocyte alkaline phosphatase; presence of Philadelphia chromosome (90% of patients)
Chronic lymphocytic leukemia (CLL)	50–70 yr of age; rare below 30 yr of age; predominance in men	No symptoms frequently; detection of disease often during examination for unrelated condition; chronic fatigue, anorexia, splenomegaly and lymphadenopathy and hepatomegaly; may progress to fever, night sweats, weight loss, fatigue, and frequent infections	Mild anemia and thrombo-cytopenia with disease progression; total WBC count > 100×10^9/L; increase in peripheral lymphocytes; increase in presence of lymphocytes in bone marrow; hypo-gammaglobulinemia; may have autoimmune hemolytic anemia (4%–11%), idiopathic thrombo-cytopenia purpura (2%–4%)

CNS, central nervous system; *Hb,* hemoglobin; *Hct,* hematocrit; *LDH,* lactic dehydrogenase; *RBC,* red blood cell; *WBC,* white blood cell.

Acute Myelogenous Leukemia.

AML represents only one-fourth of all leukemias, but it makes up approximately 80% of the acute leukemias in adults. Its onset is often abrupt and dramatic. A patient may have serious infections and abnormal bleeding from the onset of the disease (Figure 33-12).

FIGURE 33-12 Complications of acute leukemia. Spreading cellulitis of the neck and chin in this woman with acute myelogenous leukemia results from streptococcal and candidal infection. She is at risk because of previous chemotherapy and prolonged neutropenia.
Source: Skarin, A. T. (1996). *Atlas of diagnostic oncology* (2nd ed.). London: Mosby-Wolfe.

AML is characterized by uncontrolled proliferation of myeloblasts, the precursors of granulocytes. There is hyperplasia of the bone marrow and the spleen. The clinical manifestations are usually related to replacement of normal hematopoietic cells in the marrow by leukemic myeloblasts and, to a lesser extent, to infiltration of other organs (see Table 33-25.)

Acute Lymphocytic Leukemia.

ALL is the most common type of leukemia in children and accounts for about 20% of acute leukemia in adults. In ALL, immature, small lymphocytes proliferate in the bone marrow; most are of B-cell origin. Fever is present in the majority of patients at the time of diagnosis. Signs and symptoms may appear abruptly with bleeding or fever, or they may be insidious with progressive weakness, fatigue, and bleeding tendencies.

Central nervous system (CNS) manifestations are especially common in ALL and represent a serious problem. Leukemic meningitis caused by arachnoid infiltration occurs in many patients with ALL (Cooper & Brown, 2015).

Chronic Myelogenous Leukemia.

CML is caused by excessive development of mature neoplastic granulocytes in the bone marrow. The excess neoplastic granulocytes move into the peripheral blood in massive numbers and ultimately infiltrate the liver and the spleen. These cells contain a distinctive cytogenetic abnormality, the *Philadelphia chromosome*, which serves as a disease marker and results from translocation of genetic material between the *BCR* gene on chromosome 22 and the *ABL* gene on chromosome 9. The protein that is encoded by the newly created *BCR–ABL* gene on the Philadelphia chromosome interferes with normal cell cycle events, such as the regulation of cell proliferation.

The natural history of CML is a chronic stable phase followed by the development of a more acute, aggressive phase referred to as the *blastic phase.* The chronic phase of CML can last for several years and can usually be well controlled with treatment. Even with treatment, the chronic phase of the disease will eventually progress to the accelerated phase, ending in a blastic phase. Once CML transforms to an acute or blastic phase, it must be treated aggressively, similar to an acute leukemia.

Chronic Lymphocytic Leukemia.

CLL is the most common leukemia in adults. CLL is characterized by the production and accumulation of functionally inactive but long-lived, mature-appearing lymphocytes. The type of lymphocyte involved is usually the B cell. The lymphocytes infiltrate the bone marrow, spleen, and liver. Lymph node enlargement (lymphadenopathy) is present throughout the body, and there is an increased incidence of infection because of T-cell deficiencies or hypo-gammaglobulinemia. Complications from early-stage CLL are rare but may develop as the disease advances. Pressure on nerves from enlarged lymph nodes causes pain and even paralysis. Mediastinal node enlargement leads to pulmonary symptoms. Because CLL is usually a disease of older adults, treatment decisions must be made by considering the progression of the disease and the adverse effects of treatment. Many individuals in the early stages of CLL require no treatment. Others may be followed closely and receive treatment only when the disease progresses.

Other Leukemias.

Occasionally, the subtype of leukemia cannot be identified. The malignant leukemic cells may have lymphoid, myeloid, or mixed characteristics. Frequently, these patients do not respond to treatment and have a poor prognosis. Other rare types include hairy cell and biphenotypic leukemias.

Clinical Manifestations

The clinical manifestations of leukemia are varied (see Table 33-25). Essentially, they relate to problems caused by bone marrow failure and the formation of leukemic infiltrates. Bone marrow failure results from (a) bone marrow overcrowding by abnormal cells and (b) inadequate production of normal marrow elements. The patient is predisposed to anemia, thrombo-cytopenia, and decreased number and function of WBCs.

As leukemia progresses, fewer normal blood cells are produced. The abnormal WBCs continue to accumulate because they do not go through the normal cell life cycle to death *(apoptosis).* The leukemic cells infiltrate the patient's organs, leading to problems such as splenomegaly, hepatomegaly, lymphadenopathy, bone pain, meningeal irritation, and oral lesions. Solid masses called *chloromas* can result from collections of leukemic cells. A high leukemia WBC count in the peripheral blood can cause the blood to thicken and potentially block circulatory pathways. This is called *leukostasis* and can be life-threatening.

Diagnostic Studies

Peripheral blood evaluation and bone marrow examination are the primary methods of diagnosing and classifying the subtypes of leukemia. Morphological, histochemical, immunological, and cytogenetic methods are all used to identify cell subtypes and the stage of development of leukemic cell populations. This is important because different subtypes have different natural histories, prognoses, and chemotherapeutic regimens. Other studies such as lumbar puncture and CT scan can determine the presence of leukemic cells outside of the blood and the bone marrow.

The malignant cells in most patients with leukemia have specific cytogenetic abnormalities that are associated with distinct subsets of the disease. These cytogenetic abnormalities have diagnostic, prognostic, and therapeutic importance. For example, in CML, the finding of the Philadelphia chromosome has a good prognostic significance, but not so in ALL.

Collaborative Care

Once a diagnosis of leukemia has been made, collaborative care is focused on the initial goal of attaining remission. Age and cytogenetic analysis often help form the basis of important treatment decisions. Because chemotherapy is the mainstay of the treatment, the nurse must understand the principles of cancer chemotherapy, including cellular kinetics, the use

of multiple medications rather than single drugs, and the cell cycle. (See the section on chemotherapy in Chapter 18.)

In some cases, such as with asymptomatic patients who have CLL, watchful waiting with active supportive care may be appropriate. Although a patient may not be cured, attaining remission or disease control is a realistic option for the majority of patients. In *complete remission,* there is no evidence of overt disease on physical examination, and the bone marrow and peripheral blood appear normal. A lesser state of control is known as *partial remission.* It is characterized by a lack of symptoms and a normal peripheral blood smear, but there is still evidence of disease in the bone marrow. *Minimal residual disease* is defined as tumour cells that cannot be detected by morphological examination but can be detected by molecular testing. *Molecular remission* indicates that all molecular studies are negative for residual leukemia. The patient's prognosis is directly related to the ability to maintain a remission and becomes more unfavourable with each relapse. Each time there is a relapse, the succeeding remission may be more difficult to achieve and shorter in duration.

Sometimes patients have such a high WBC count that initial emergent treatment may include the use of leukapheresis and hydroxyurea administration. The purpose of these treatments is to reduce the WBC count and the risk of leukemia-induced thrombosis.

The chemotherapeutic treatment of acute leukemia is divided into stages. The first stage, *induction therapy,* is the attempt to induce or bring about a remission. Induction is aggressive treatment that seeks to destroy leukemic cells in the tissues, peripheral blood, and bone marrow in order to eventually restore normal hematopoiesis on bone marrow recovery. During induction therapy, a patient may become critically ill because the bone marrow is severely depressed by the chemotherapeutic drugs. Throughout the induction phase, nursing interventions focus on neutropenia, thrombo-cytopenia, and anemia as well as on providing psychosocial support to the patient and family. Common chemotherapeutic drugs for induction of AML include cytarabine (Cytosar) and antitumour antibiotics (anthracyclines) such as daunorubicin (Cerubidine), idarubicin (Idamycin), or mitoxantrone. After one course of induction therapy, approximately 70% of newly diagnosed patients achieve complete remission. There is one subtype of AML, called *promyelocytic leukemia* (M3), for which tretinoin (Vesanoid) and arsenic trioxide (Trisenox) may also be used to induce a remission. It is generally assumed that leukemia cells persist undetected after induction therapy. As

a result, relapse is possible within a few months if no further therapy is administered.

Terms used to describe postinduction or postremission chemotherapy include *intensification, consolidation,* and *maintenance. Intensification therapy,* or high-dose therapy, may be given immediately after induction therapy for several months. This therapy may use the same drugs as those used in induction, but at higher dosages. Other drugs that target the cell in a different way than those administered during induction may also be added.

Consolidation therapy is started after a remission is achieved. It may consist of one or two additional courses of the same drugs given during induction or involve high-dose therapy *(intensive consolidation).* The purpose of consolidation therapy is to eliminate remaining leukemic cells that may not be clinically or pathologically evident.

Maintenance therapy is treatment with lower doses of the same drugs used in induction or other drugs given every 3 to 4 weeks for a prolonged period of time. Like consolidation or intensification, the goal is to keep the body free of leukemic cells. Each leukemia calls for different maintenance therapy. In AML, maintenance therapy is rarely effective and, therefore, rarely administered.

In addition to chemotherapy, corticosteroids and radiation therapy can also have a role in the complex therapeutic plans for the patient with leukemia. Total body radiation may be used to prepare a patient for bone marrow transplantation, or radiation may be restricted to certain areas (fields) such as the liver and spleen or other organs affected by infiltrates. In ALL, prophylactic intrathecal methotrexate is given to decrease the chance of CNS involvement, which is common in this particular type of leukemia. When CNS leukemia does occur, cranial radiation may be given. Biological therapy may be indicated for specific leukemias. (Biological therapy is discussed in Chapter 18.)

Drug Therapy Regimens.

Therapeutic drugs used to treat leukemia vary. Table 33-26 gives examples of treatment regimens used in various types of leukemia.

TABLE 33-26

DRUG THERAPY
Treatments Used in Leukemia*

Drug Therapy	Other Therapy
Acute Myelogenous Leukemia Cytarabine (Cytosar), daunorubicin (Cerubidine),† idarubicin (Idamycin),† mitoxantrone, tretinoin (Vesanoid),† etoposide (Vepesid),† clofarabine (Clolar), arsenic trioxide (Trisenox), fludarabine (Fludara), azacitidine (Vidaza) Combination chemotherapy of cytarabine and antitumour antibiotic (most common)	Autologous or allogeneic hematopoietic stem cell transplant (see Chapter 18)
Acute Lymphocytic Leukemia Doxorubicin (Adriamycin), vincristine sulphate, prednisone, dexamethasone, L-asparaginase (Kidrolase) ponatinib (Iclusig), dasatinib (Sprycel), cyclophosphamide (Procytox), methotrexate, 6-mercaptopurine (Purinethol), cytarabine, imatinib (Gleevec), rituximab (Rituxan), clofarabine (Clolar) Combination chemotherapy of several agents is common	Cranial radiation therapy, intrathecal methotrexate or cytarabine, allogeneic hematopoietic stem cell transplant (see Chapter 18)
Chronic Myelogenous Leukemia Imatinib (Gleevec), dasatinib (Sprycel), ponatinib (Iclusig), nilotinib (Tasigna), bosutinib (Bosulif), hydroxyurea (Hydrea) Combination chemotherapy including any of the following: cytarabine, daunorubicin, methotrexate, prednisone, vincristine, L-asparaginase, 6-mercaptopurine, busulfan (Myleran)	Radiation, hematopoietic stem cell transplant, interferon alfa, leukapheresis
Chronic Lymphocytic Leukemia Chlorambucil (Leukeran), cyclophosphamide (Procytox), prednisone, vincristine, fludarabine (Fludara), rituximab (Rituxan), alemtuzumab (MabCampath), bendamustine (Treanda), oxaliplatin (Eloxatin), methotrexate, ofatumumab (Arzerra), idelalisib (Zydelig), obinutuzumab (Gazyva), ibrutinib (Imbruvica), lenalidomide (Revlimid)	Radiation, splenectomy, colony-stimulating factors, allogeneic hematopoietic stem cell transplant

*The classification and mechanism of action of these drugs are presented in Table 18-8 (Drug Therapy Classification of Chemotherapeutic Drugs).

†Used for acute promyelocytic leukemia.

Combination chemotherapy is the mainstay of treatment for leukemia. The three purposes for using multiple drugs are to (a) decrease drug resistance, (b) minimize the drug toxicity to the patient by using multiple drugs with varying toxicities, and (c) interrupt cell growth at multiple points in the cell cycle.

Some therapeutic drugs are aimed at affecting small molecules that promote the growth and differentiation of leukemic cells. For example, arsenic trioxide (Trisenox), which is used to treat acute promyelocytic leukemia (a type of AML), causes DNA fragmentation and cell death. In addition, it inhibits cell proliferation and angiogenesis. Imatinib mesylate (Gleevec) and other tyrosine-kinase inhibitors target *BCR–ABL* protein that is present in nearly all patients with CML. Thus, this drug kills only cancer cells, leaving healthy cells alone.

The use of specific targeted therapy in the form of monoclonal antibodies is an exciting new treatment modality in hematopoietic

malignancies, but cures with these therapies alone are rare. Rituximab (Rituxan) binds to the B-cell antigen (CD20) and has been used with CLL. Alemtuzumab (MabCampath) binds to CD52, a panlymphocyte antigen present on both T and B cells, and is used to treat CLL.

Hematopoietic Stem Cell Transplantation.

HSCT is another type of therapy used for patients with different forms of leukemia. The goal of HSCT is to totally eliminate leukemic cells from the body using combinations of chemotherapy with or without total body irradiation. This treatment also eradicates the patient's hematopoietic stem cells, which are then replaced with those of an HLA-matched sibling or volunteer donor (allogeneic), with those of an identical twin (syngeneic), or with the patient's own (autologous) stem cells that were removed (harvested) before the intensive therapy. (Hematopoietic stem cell transplantation is discussed in Chapter 18.)

The primary complications of patients who undergo allogeneic HSCT are graft-versus-host (GVH) disease, relapse of leukemia (especially ALL), and infection (especially interstitial pneumonia). GVH disease is discussed in Chapter 16. Because HSCT has serious associated risks, the patient must weigh the significant risks of treatment-related death or treatment failure (relapse) with the hope of cure.

Nursing Management Leukemia

Nursing Assessment

Subjective and objective data that should be obtained from a patient with leukemia are presented in Table 33-27.

TABLE 33-27

NURSING ASSESSMENT
Leukemia

Subjective Data
Important Health Information
Past health history: Exposure to chemical toxins (e.g., benzene, arsenic), radiation, or viruses (Epstein-Barr, HTLV-1); chromosome abnormalities (Down, Klinefelter's, and Fanconi's syndromes); immunological deficiencies; organ transplantation; frequent infections; bleeding tendencies; family history of leukemia *Medications:* Chemotherapy *Surgery or other treatments:* Radiation exposure; prior radiation and chemotherapy for cancer
Symptoms
• Weight loss, chills, night sweats • Fatigue with progressive weakness; bone pain, joint pain; muscle cramps • Dyspnea, cough • Nausea, vomiting, anorexia, dysphagia, early satiety; mouth sores, sore throat • Hematuria, decreased urine output • Diarrhea, dark or bloody stools • Headaches, confusion, numbness, tingling, visual disturbances • Easy bruising; epistaxis; prolonged menses; menorrhagia; erectile dysfunction
Objective Data
General
Fever, generalized lymphadenopathy, lethargy
Integumentary
Pallor or jaundice; petechiae, ecchymoses, purpura, reddish-brown to purple cutaneous infiltrates, macules, and papules
Cardiovascular
Tachycardia, systolic murmurs
Gastro-Intestinal
Gingival bleeding and hyperplasia; oral ulcerations, herpes and *Candida* infections; perirectal irritation and infection; hepatomegaly, splenomegaly
Neurological
Seizures, disorientation, confusion, decreased coordination, cranial nerve palsies, papilledema
Musculo-Skeletal
Muscle wasting, bone pain, joint pain
Possible Findings
Low, normal, or high WBC count with shift to the left (blast cells); anemia, ↓ hematocrit and hemoglobin, thrombo-cytopenia, Philadelphia chromosome; hypercellular bone marrow aspirate or biopsy with myeloblasts, lymphoblasts, and markedly ↓ normal cells

HTLV-1, human T-cell leukemia virus, type 1; *WBC*, white blood cell.

Nursing Diagnoses

Nursing diagnoses for the patient with leukemia include those appropriate for anemia, thrombo-cytopenia, and neutropenia (see NCP 33-1 in this chapter and NCPs 33-2 and 33-3 on the Evolve website).

Planning

The overall goals are that the patient with leukemia will (a) understand and follow the treatment plan, (b) experience minimal adverse effects and complications associated with both the disease and its treatment, and (c) establish realistic hopes and goals, and feel supported during the periods of treatment, relapse, or remission.

Nursing Implementation

Acute Intervention.

The nursing role during acute phases of leukemia is extremely challenging because the patient has many physical and psychosocial needs. As with other forms of cancer, the diagnosis of leukemia can evoke great fear and be equated with death. It may be viewed as a hopeless, horrible disease with many painful and undesirable consequences. The treatment and prognosis of each patient with leukemia are driven by many factors, such as age and type of leukemia. For each patient, it is important that the nurse has an understanding of the patient's type of leukemia, prognosis, treatment plan, and goals. With this information, the nurse can help the patient realize that, although the future may be uncertain, one can have a meaningful quality of life while in remission or with disease control and that, in some cases, there is reasonable hope for cure. The family also needs help adjusting to the stress of this abrupt onset of serious illness (e.g., with the patient's dependence, withdrawal, changes in role responsibilities, and alterations in body image) and the losses imposed by the sick role. The diagnosis of leukemia often brings with it the need to make difficult decisions at a time of profound stress for the patient and family.

Patients may have comorbid conditions that affect treatment decisions. Important nursing interventions include (a) maximizing the patient's physical functioning, (b) teaching patients that acute adverse effects of treatment are usually temporary, and (c) encouraging patients to discuss their quality-of-life issues. The nurse is an important advocate in helping the patient and family understand the complexities of treatment decisions and manage the adverse effects and toxicities. A patient may require long

hospitalization or may need to temporarily relocate to an appropriate treatment centre. These situations can lead a patient to feel deserted and isolated at a time when support is most needed. The nurse has contact with the patient many hours a day and can help reverse feelings of abandonment and loneliness by balancing the demanding technical needs with a humanistic, caring approach. The needs of the patient with leukemia are best met by a multidisciplinary team (e.g., psychiatric and oncology clinical nurse specialists, case managers, dietitians, chaplains, and social workers).

From a physical care perspective, the challenge is to make astute assessments and plan care to help the patient manage the severe adverse effects of chemotherapy. The life-threatening results of bone marrow suppression (neutropenia, thrombo-cytopenia, and anemia) require aggressive nursing interventions (see NCP 33-1, earlier in this chapter, and NCPs 33-2 and 33-3 on the Evolve website). These patients may be at risk for oncological emergencies such as tumour lysis syndrome, DIC, and leukostasis. Additional complications of chemotherapy may affect the patient's GI tract, nutritional status, skin and mucosa, cardiopulmonary status, liver, kidneys, and neurological system. (Nursing interventions related to chemotherapy are discussed in Chapter 18 and NCP 18-2 on the Evolve website.)

The nurse must be knowledgeable about all medications being administered. This knowledge must include mechanism of action, purpose, routes of administration, usual doses, potential adverse effects, safe-handling considerations, and toxic effects of the medications. In addition, the nurse must know how to assess laboratory data reflecting the effects of the medications. Patient survival and comfort during aggressive chemotherapy are significantly affected by the quality of nursing care.

Ambulatory and Home Care.

Ongoing care for the patient with leukemia is necessary to monitor for signs and symptoms of disease control or relapse. For a patient requiring long-term or maintenance chemotherapy, long-term chronic disease management can become discouraging. Therefore, the patient and the family must be taught to understand the importance of the continued diligence in disease management and the need for follow-up care. Teachings must also include information about the medications and self-care measures and when to seek medical attention.

The goals of rehabilitation for long-term survivors of leukemia are to manage the physical, psychological, social, and spiritual consequences and delayed effects from the disease and its treatment. (Delayed effects from treatment are discussed in Chapter 18.) The patient may need assistance re-establishing some relationships, and friends and family may need help learning how to interact with the patient. The patient and the family must learn to regain attitudes of health and life while facing the real fear of relapse of disease. Involving the patient in survivor networks and support groups may help the patient adapt to living after a life-threatening illness. Exploring community resources (e.g., Canadian Cancer Society) may reduce the financial burden and the feelings of dependence. Spiritual support may give the patient inner strength and peace.

Vigilant follow-up care helps to ensure that the cancer survivor's unique needs are recognized and treated. Often, these needs require referral or consultation. For example, physiotherapists may be asked to develop an exercise program to prevent post-treatment deficits caused by drug-induced peripheral neuropathy. Some patients' needs may include, for instance, growth and development concerns for childhood survivors, vocational retraining, and reproductive concerns for a patient of child-bearing age. The long-term recovery following treatment for leukemia affects the quality of the patient's life.

Evaluation

The expected outcomes are that the patient with leukemia will (a) cope effectively with diagnosis, treatment regimen, and prognosis; (b) experience no complications related to the disease or its treatment; and (c) feel comfortable and supported throughout treatment.

Lymphomas

Lymphomas are malignant neoplasms originating in the bone marrow and lymphatic structures resulting in the proliferation of lymphocytes. Two major types of lymphoma—Hodgkin's disease and non-Hodgkin's lymphoma (NHL)—are discussed in this chapter. NHL is the fourth most common type of cancer in Canada (Leukemia and Lymphoma Society of Canada, 2016). A comparison of these two types of lymphoma is presented in Table 33-28.

TABLE 33-28

COMPARISON OF HODGKIN'S DISEASE AND NON-HODGKIN'S LYMPHOMA

	Hodgkin's Disease	Non-Hodgkin's Lymphoma
Cellular origin	B lymphocytes	B lymphocytes (88%) T or natural killer lymphocytes (12%)
Extent of disease	Localized to regional, but may be more widespread	Disseminated
B symptoms*	Common	Uncommon
Extranodal involvement	Rare	Common

*B symptoms include fever, night sweats, and weight loss.

Hodgkin's Lymphoma

Hodgkin's lymphoma, also called *Hodgkin's disease*, makes up about 11% of all lymphomas (Ansell, 2015). It is a malignant condition characterized by proliferation of abnormal, giant, multinucleated cells, called *Reed–Sternberg cells*, which are located in lymph nodes. The disease has a bimodal age-specific incidence, occurring most frequently in people from 15 to 30 years of age and older than 55 years (Hoppe, Advani, Ai, et al., 2015). In adults, it is twice as prevalent in men than in women. It was estimated that, in 2017, 990 people would be diagnosed with Hodgkin's lymphoma in Canada (Canadian Cancer Society, 2017b).

Etiology and Pathophysiology

Although the cause of Hodgkin's lymphoma remains unknown, several key factors are thought to play a role in its development. The main interacting factors include infection with Epstein-Barr virus (EBV), genetic predisposition, and exposure to occupational toxins. The incidence of Hodgkin's lymphoma is increased in patients with HIV.

Normally, the lymph nodes are composed of connective tissues that surround a fine mesh of reticular fibres and cells. In Hodgkin's lymphoma, the normal structure of lymph nodes is destroyed by hyperplasia of monocytes and macrophages. The main diagnostic feature of Hodgkin's disease is the presence of Reed–Sternberg cells in lymph node biopsy specimens. The disease is believed to arise in a single location (it originates in cervical lymph nodes in 80% of patients) and then spread along adjacent lymphatics. However, in recurrent disease, it may be more diffuse, and not necessarily contiguous. It eventually infiltrates other organs, especially the lungs, spleen, and liver. When the disease begins above the diaphragm, it

remains confined to lymph nodes for a variable time. Disease originating below the diaphragm frequently spreads to extralymphoid sites such as the liver.

Clinical Manifestations

The onset of symptoms in Hodgkin's lymphoma is usually insidious. The initial development is most often enlargement of cervical, axillary, or inguinal lymph nodes (Figure 33-13); a mediastinal node is the second most common location. This lymphadenopathy affects discrete nodes that remain movable and nontender. The enlarged nodes are not painful unless they exert pressure on adjacent nerves.

FIGURE 33-13 Enlarged cervical lymph node in the neck of a man with Hodgkin's lymphoma. Source: Howard, M. R., & Hamilton, P. J. (2013). *Haematology: An illustrated colour atlas* (4th ed.). London: Churchill Livingston.

The patient may notice weight loss, fatigue, weakness, fever, chills, tachycardia, or night sweats. A group of initial findings including fever, night sweats, and weight loss (termed *B symptoms*) correlates with a worse prognosis. After the ingestion of even small amounts of alcohol, individuals with Hodgkin's disease may complain of a rapid onset of pain at the site of disease. The cause for the alcohol-induced pain is unknown. Generalized pruritus without skin lesions may develop. Cough, dyspnea, stridor, and dysphagia may all reflect mediastinal node involvement.

In more advanced disease, there is hepatomegaly and splenomegaly. Anemia results from increased destruction and decreased production of erythrocytes. Other physical signs vary depending on where the disease is located; for example, (a) intrathoracic involvement may lead to superior vena cava syndrome, (b) enlarged retroperitoneal nodes may cause

palpable abdominal masses or interfere with renal function, (c) jaundice may occur from liver involvement, (d) spinal cord compression leading to paraplegia may occur with extradural involvement, and (e) bone pain may occur as a result of bone involvement.

Diagnostic and Staging Studies

Peripheral blood analysis, excisional lymph node biopsy, bone marrow examination, and radiological evaluation are important means of evaluating Hodgkin's lymphoma. Peripheral blood analysis often reveals a microcytic hypochromic anemia; neutrophilic leukocytosis (15–28 × 10^9/L), which may be associated with lymphopenia; and an increased platelet count. Leukopenia and thrombo-cytopenia may develop, but they are usually a consequence of treatment, advanced disease, or superimposed hypersplenism. Other blood studies may show an elevated erythrocyte sedimentation rate, hypoferremia caused by excessive iron uptake by the liver and spleen, elevated leukocyte alkaline phosphatase from liver and bone involvement, hypercalcemia from bone involvement, and hypoalbuminemia from liver involvement.

Excisional lymph node biopsy offers a definitive means of diagnosis. The removed peripheral lymph node is examined for the presence of the diagnostic Reed–Sternberg cells. Bone marrow biopsy is performed as an important aspect of staging. Reed–Sternberg cells may also be found in the patient's bone marrow.

Radiological evaluation can help define all sites and determine the clinical stage of the disease. CT or MRI scans are used as initial staging tools. These scans may show mediastinal lymphadenopathy; renal displacement caused by retroperitoneal node enlargement; abdominal lymph node enlargement; and liver, spleen, bone, and brain infiltration. Gallium scans may also be used to monitor response to treatment.

Nursing and Collaborative Management Hodgkin's Lymphoma

The information from the various diagnostic studies is used to determine the stage of the disease (Figure 33-14). The nomenclature used in staging includes a Roman numeral (I to IV) that reflects the location and extent of the disease, followed by an *A* or *B* classification (meaning B symptoms are absent or present, respectively). Treatment depends on the nature and the extent of the disease.

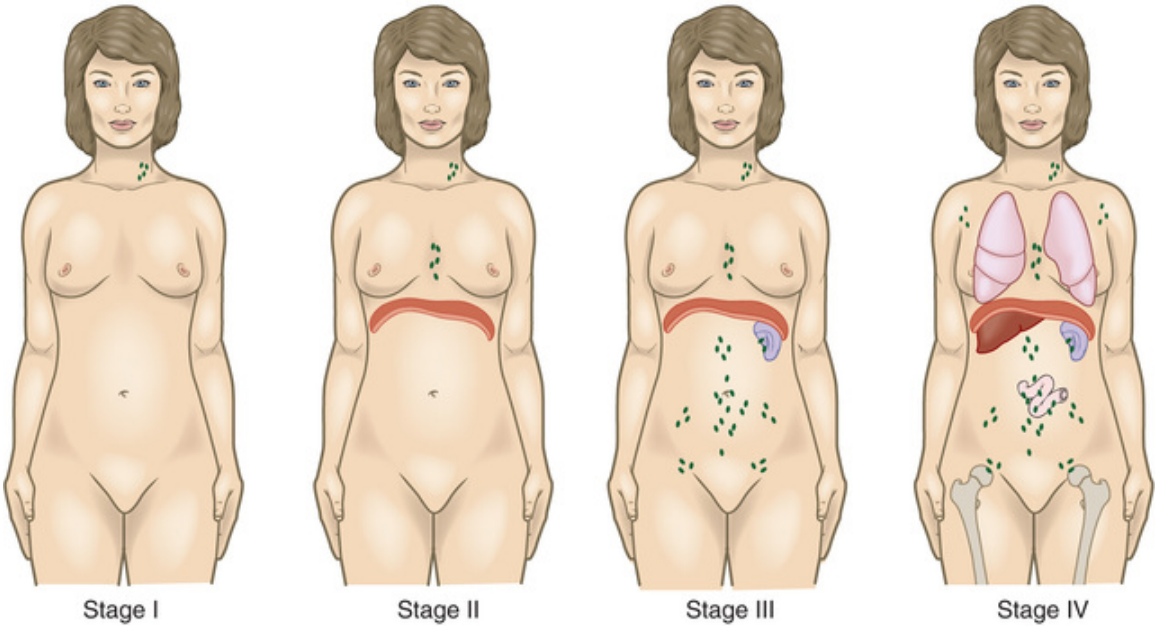

FIGURE 33-14 Staging system for Hodgkin's lymphoma and non-Hodgkin's lymphoma. **Stage I,** involvement of single lymph node (e.g., cervical node). **Stage II,** involvement of two or more lymph nodes on one side of diaphragm. **Stage III,** lymph node involvement above and below the diaphragm. **Stage IV,** involvement outside the lymph nodes (e.g., liver, bone marrow). The stage is followed by the letter A (absence) or B (presence) to indicate significant systemic symptoms (e.g., fever, night sweats, weight loss).

Once the stage of Hodgkin's lymphoma is established, management focuses on selecting a treatment plan. The standard for chemotherapy is the ABVD regimen: doxorubicin (**A**driamycin), **b**leomycin, **v**inblastine, and **d**acarbazine. Patients with early-stage disease with favourable

characteristics will receive two to four cycles of chemotherapy. Patients with early-stage but unfavourable prognostic features (e.g., the presence of B symptoms) or intermediate-stage disease will be treated with four to six cycles of chemotherapy. Advanced-stage Hodgkin's lymphoma is treated more aggressively using six to, potentially, eight cycles of chemotherapy. A more aggressive chemotherapy regimen is BEACOPP (**b**leomycin, **e**toposide, doxorubicin [**A**driamycin], **c**yclophosphamide, vincristine (former trade name **O**ncovin), **p**rocarbazine, and **p**rednisone) (Hoppe, Advani, Ai, et al., 2015). The role of radiation as a supplement to chemotherapy varies depending on sites of disease and the presence of resistant disease after chemotherapy.

A variety of chemotherapy regimes and newer drugs, such as brentuximab vedotin (Adcetris), are used to treat patients with relapsed or refractory disease. Ideally, once remission is achieved, a curative option may be intensive chemotherapy with the use of autologous or allogeneic HSCT. HSCT has allowed patients to receive higher, potentially curative doses of chemotherapy while reducing life-threatening leukopenia. Combination chemotherapy works well because, as with leukemia, drugs are used that have an additive antitumour effect without increased adverse effects. As with leukemia, therapy must be aggressive. Thus, potentially life-threatening problems are risked for the sake of attempting to achieve a remission.

Maintenance chemotherapy does not contribute to increased survival once a complete remission is achieved. Occasionally, single medications may be administered palliatively to patients who cannot tolerate intensive combination therapy. A serious consequence of the treatment for Hodgkin's lymphoma is the later development of secondary malignancies (see Chapter 18) as well as potential long-term toxicities from the treatment, such as endocrine, cardiac, and pulmonary dysfunction (Kanate, Craig, Abraham, et al., 2013). Secondary cancers often occur 10 years after treatment for Hodgkin's lymphoma, the most common of which are breast cancer and lung cancer. Patients should have screening for early detection of these problems.

The nursing care for patients with Hodgkin's lymphoma is largely focused on managing problems related to the disease (e.g., pain caused by the tumour), pancytopenia, and other adverse effects of therapy. Because the survival of patients with Hodgkin's lymphoma depends on their response to treatment, supporting the patient through the immuno-suppressive state is extremely important.

Psychosocial considerations are just as important as they are with leukemia. However, the prognosis for Hodgkin's lymphoma is better than that for many other forms of cancer. The physical, psychological, social, and spiritual consequences of the patient's disease must be addressed. Fertility issues may be of particular concern because this disease is frequently seen in adolescents and young adults. The nurse must help ensure that these issues are addressed soon after diagnosis. Evaluation of patients for long-term effects of therapy is important because delayed consequences of disease and treatment may not be apparent for many years. (Secondary malignancies and delayed effects of treatment are discussed in Chapter 18.)

Non-Hodgkin's Lymphoma

Non-Hodgkin's lymphomas (NHLs) are a heterogeneous group of malignant neoplasms of primarily B-, T-, or natural killer (NK)–cell origin that can affect people of all ages. B-cell lymphomas constitute about 88% of all NHLs. They are classified by the level of differentiation, cell of origin, and rate of proliferation. A variety of clinical presentations and courses are recognized, from indolent (slowly developing) to rapidly progressive disease. NHL is the most commonly occurring hematological cancer. It was estimated that, in 2017, there would be 8 300 new cases of NHL diagnosed in Canada and approximately 2 700 deaths due to NHL (Canadian Cancer Society, 2017c).

Etiology and Pathophysiology

As with Hodgkin's lymphoma, the cause of NHL is usually unknown. It may result from chromosomal translocations, infections, environmental factors, or immunodeficiency states. Chromosomal translocations have an important role in the pathogenesis of many NHLs. Some viruses and bacteria are implicated in the pathogenesis of NHL, including HTLV-1, EBV, human herpesvirus 8, hepatitis B and C, *Helicobacter pylori, Chlamydophila psittaci, Campylobacter jejuni,* and *Borrelia burgdorferi.* Environmental factors linked to the development of NHL include chemicals such as pesticides, herbicides, solvents, organic chemicals, and wood preservatives. NHL is also more common in individuals who have inherited immunodeficiency syndromes and who have used immuno-suppressive medications or received chemotherapy or radiation.

There is no hallmark feature in NHL that parallels the Reed–Sternberg cell of Hodgkin's lymphoma. However, all NHLs involve lymphocytes

arrested in various stages of development. For example, lymphoblastic lymphoma and lymphoblastic leukemia (which has a majority of disease within the bone marrow rather than in the lymph nodes) result from malignant proliferation of small, immature B lymphocytes. Diffuse large B-cell lymphoma, the most common aggressive lymphoma in adults, is a neoplasm that originates in the lymph nodes. Burkitt's lymphoma is a highly aggressive disease thought to originate from B-cell blast cells in the lymph nodes.

Clinical Manifestations

NHLs can originate outside the lymph nodes, the method of spread can be unpredictable, and the majority of patients have widely disseminated disease at the time of diagnosis (Figure 33-15). The primary clinical manifestation is painless lymph node enlargement. Because the disease is usually disseminated when it is diagnosed, other symptoms will be present depending on where the disease has spread (e.g., hepatomegaly with liver involvement or neurological symptoms with CNS disease). NHL can also manifest in nonspecific ways, such as an airway obstruction, hyperuricemia, renal failure or acute kidney injury from tumour lysis syndrome, pericardial tamponade, or GI complaints.

FIGURE 33-15 Non-Hodgkin's lymphoma involving the spleen. The presence of an isolated mass is typical. Source: Kumar, V., Abbas, A. K., Fausto, N., et al. (2010). *Robbins and Cotran pathologic basis of disease* (8th ed., p. 607). Philadelphia: Saunders.

Patients with high-grade lymphomas may have lymphadenopathy and constitutional symptoms (B symptoms) such as fever, night sweats, and weight loss. The peripheral blood is usually normal, but some lymphomas manifest in a “leukemic” phase.

Diagnostic and Staging Studies

Diagnostic studies used for NHL resemble those used for Hodgkin's disease. However, because NHL is more often in extranodal sites, more diagnostic studies may be done, such as an MRI to rule out CNS or bone marrow infiltration or a barium enema or CT to visualize suspected GI involvement. Clinical staging, as described for Hodgkin's lymphoma, is used to help guide therapy (see Figure 33-14), but establishment of the precise histological subtype is extremely important. Lymph node biopsy establishes the cell type and the pattern. NHL is classified based on morphological, genetic, immunophenotypic (i.e., cell surface antigens, CD20, CD52), and clinical features.

The World Health Organization has categorized more than 30 unique types of NHL. A simple modification of the classification system is presented in Table 33-29.

TABLE 33-29
CLASSIFICATION OF NON-HODGKIN'S LYMPHOMA*

B-Cell Lymphomas
• Diffuse large B-cell lymphoma (DLBCL) • Follicular lymphoma • Marginal zone B-cell lymphoma (MALT) • Small lymphocytic lymphoma/chronic lymphocytic leukemia • Mantle cell lymphoma • Burkitt's lymphoma • Plasmablastic lymphoma • AIDS-related B-cell lymphomas
T-Cell and NK-Cell Lymphomas
• Lymphoblastic lymphoma • T-cell lymphoma • Mycosis fungoides and Sézary syndrome • Anaplastic large T-cell lymphoma • NK-cell lymphomas
Post-Transplant Lymphoproliferative Disorders (PTLD)

*This is only a partial list.

AIDS, acquired immune deficiency syndrome; *MALT*, mucosa-associated lymphoid tissue; *NK*, natural killer.

Treatment is guided by cell type, cytogenetic studies, and clinical behaviour: *indolent* (low grade), *aggressive* (high grade), or *highly aggressive* (very high grade). Additional factors, known as the International Prognostic Index (IPI), may be considered for each subtype to help select the appropriate treatment for each patient. Factors considered may include the clinical stage, number of extranodal sites, age, serum LDH level, WBC count, Hb, and performance status. Immunological, cytogenetic, and

molecular studies are also useful for making therapeutic decisions and assessing prognoses.

Nursing and Collaborative Management Non-Hodgkin's Lymphoma

Treatment for NHL involves chemotherapy and sometimes radiation (Table 33-30). Ironically, more aggressive lymphomas are more responsive to treatment and more likely to be cured. In contrast, indolent lymphomas have a naturally long course but are difficult to treat effectively.

TABLE 33-30
TREATMENT OF NON-HODGKIN'S LYMPHOMA*

Recommended Therapies	Common Chemotherapy Combinations
Indolent (Low Grade) (e.g., follicular lymphoma, marginal zone B-cell lymphoma [MALT])	
• Observation until disease progression for asymptomatic patients with low-volume tumours and normal blood counts • External beam irradiation for local, limited disease • Single-agent rituximab (Rituxan) • Single-agent chemotherapy (chlorambucil, cyclophosphamide, bendamustine, or idelalisib) • Rituximab with another agent (bendamustine, cyclophosphamide, fludarabine, cladribine, lenalidomide, chlorambucil) • Combination chemotherapy (R-CHOP or other) • Radioimmunotherapy • Hematopoietic stem cell transplant (HSCT)	• **R-CHOP: r**ituximab, **c**yclophosphamide, doxorubicin **h**ydrochloride, vincristine (former trade name **O**ncovin), **p**rednisone • **FCMR: f**ludarabine, **c**yclophosphamide **m**itoxantrone, **r**ituximab • **R-CVP: r**ituximab, **c**yclophosphamide, **v**incristine, **p**rednisone • **RFND: r**ituximab, **f**ludarabine, mitoxantrone (former trade name **N**ovantrone), **d**examethasone ± rituximab • **FC: f**ludarabine, **c**yclophosphamide
Aggressive (Intermediate or High Grade) (e.g., mantle cell, diffuse large B-cell, peripheral T-cell, natural killer–cell lymphomas)	
• Combination chemotherapy with localized radiation if needed • Aggressive combination chemotherapy for 3–8 cycles with rituximab with local radiation if needed • Intrathecal chemotherapy if needed • Single agent or other combination treatment, depending on subtype and response (e.g., bendamustine, bortezomib, cladribine, ibrutinib, lenalidomide, gemcitabine, alemtuzumab, oxaliplatin, romidepsin) • HSCT	• **R-CHOP** (see above) • **ICE** (or "RICE" with **r**ituximab): **i**fosfamide, **c**yclophosphamide, **e**toposide • **R-EPOCH: r**ituximab, **e**toposide, **p**rednisone, vincristine (former trade name **O**ncovin), **c**yclophosphamide, doxorubicin **h**ydrochloride • **ESHAP ± R: e**toposide, methylprednisolone (**S**olu-Medrol), **h**igh-dose cytarabine (former trade name **A**ra-C), cisplatin (former trade name **P**latinol), with or without **r**ituximab • **Hyper-CVAD ± R:** hyperfractionated **c**yclophosphamide, **v**incristine, doxorubicin hydrochloride (**A**driamycin), **d**examethasone alternating with high-dose methotrexate and cytarabine with or without rituximab • **DHAP ± R: d**examethasone, **h**igh-dose cytarabine (former trade name **A**ra-C), cisplatin (former trade name **P**latinol), with or without **r**ituximab • **SMILE: s**teroids, **m**ethotrexate, **i**fosfamide, **L**-asparaginase, **e**toposide • High-dose cytarabine and high-dose methotrexate with leucovorin rescue
Highly Aggressive (e.g., Burkitt's lymphoma, AIDS-related B-cell lymphomas)	
• Aggressive combination chemotherapy for 3–8 cycles • HSCT	• Hyper-CVAD ± R (see above) • CODOX-M: **c**yclophosphamide, vincristine (former trade name **O**ncovin), **dox**orubicin, high-dose **m**ethotrexate, with or without **r**ituximab (includes intrathecal methotrexate)

*Not all-inclusive.

MALT, mucosa-associated lymphoid tissue.

Patients with low-grade (indolent) lymphoma may live 10 years or more without treatment. However, some initial therapies can be well tolerated and have been shown to extend the time to progression of the disease. Therapy would be indicated if the patient has local symptoms from

progressive, bulky, or painful disease or a compromise of normal organ function. Lymphomas that have an infectious basis, such as *H. pylori* gastric lymphomas, may be treated with antibiotic or antiviral therapy. HSCT may have some benefit in certain subtypes of aggressive or refractory lymphomas.

Rituximab, a genetically engineered monoclonal antibody against the CD20 antigen on the surface of normal and malignant B lymphocytes, is also used to treat NHL. Once bound to the cells, rituximab causes lysis and cell death. Numerous chemotherapy combinations have been used to try to overcome the resistant nature of this disease. Complete remissions are uncommon, but the majority of patients will respond with improvement in adenopathy and symptoms.

Drug Alert

rituximab (Rituxin)

- Patients must be monitored for signs of severe hypersensitivity or reaction to rituximab (Rituxan), especially with the first infusion.
- Manifestations may include hypotension, bronchospasm, dysrhythmias, angioedema, and cardiogenic shock.
- Patients should be screened for history of hepatitis because rituximab may reactivate the disease.

Another therapy for NHL is the monoclonal antibody ibritumomab tiuxetan (Zevalin). This antibody is linked to a radioactive isotope (yttrium-90) (see Chapter 18, Table 18-16). The monoclonal antibody targets the CD20 antigen, which is on the surface of mature B cells and B-cell tumours. This targeting allows for the delivery of radiation directly to the malignant cells. Adverse effects of these medications include pancytopenia. Nurses must be aware of the precautions to take in caring for these patients and must educate patients about safety issues to minimize the risk of radiation exposure to staff and others.

In general, T-cell lymphomas are more difficult to treat and are often treated aggressively up front followed by an HSCT. Cutaneous T-cell lymphomas may be treated with topical corticosteroids or topical chemotherapy for limited-stage disease. For more diffuse disease,

treatment may include phototherapy, interferon alfa, vorinostat (Zolinza), or others.

The nursing care for NHL is similar to that for Hodgkin's lymphoma. Nursing care is largely focused on managing problems related to the disease (e.g., pain caused by the tumour, spinal cord compression, tumour lysis syndrome), pancytopenia, and other adverse effects of therapy. However, because NHL can be more extensive and involve specific organs (e.g., CNS, spleen, liver, GI tract, bone marrow), it is important that the nurse have an understanding of the subtype and the extent of the disease. For example, a patient with known involvement of the colon may complain of acute abdominal pain. The patient most likely would have abdominal guarding and an enlarged and tympanic abdomen. This could indicate a bowel perforation and be considered a medical emergency. A patient with Burkitt's NHL starting chemotherapy would be at high risk for tumour lysis syndrome and would require frequent laboratory studies and monitoring, as well as strict documentation of intake and output. (For oncological problems, refer to Chapter 18.) Because most of these patients receive therapy that is potentially myelosuppressive, NCP 33-1, NCP 33-2, and NCP 33-3 would apply to these patients as well.

A patient undergoing radiation therapy has special nursing needs. The skin in the radiation field requires attention. In addition, the nurse must understand the concepts related to administration of and safety issues regarding radiation therapy (see Chapter 18 and NCP 18-1 on the Evolve website).

Psychosocial considerations are very important. Helping the patient and the family understand the disease, the treatment, and expected and potential adverse effects is paramount in enlisting their help in ensuring the patient's well-being and safety. Some aggressive treatments require close follow-up and even inpatient admission. In young patients, fertility concerns may need to be addressed. As with Hodgkin's lymphoma, evaluation of patients with NHL for long-term effects of therapy is important because delayed consequences of disease and treatment may not be apparent for many years. (Secondary malignancies and delayed effects of treatment are discussed in Chapter 18.)

Evidence-Informed Practice

Translating Research Into Practice

A nurse is caring for Gerard Robineault, a 59-year-old male with non-Hodgkin's lymphoma who is receiving chemotherapy. Due to a decrease in red blood cells and platelets, he was advised to rest and avoid the high level of physical exercise he once enjoyed. He misses his active lifestyle and now admits to the nurse that he is "somewhat depressed."

Best Available Evidence	**Clinician Expertise**	**Patient Preferences and Values**
Aerobic exercise, especially walking and stretching, to maintain mobility may improve physical functioning, fatigue, and depression in patients with hematological cancers.	The nurse knows that recommendations to decrease intensive physical exercise may result in a diminished quality of life for many patients, especially for individuals who are used to being physically active.	Gerard is considering joining a neighbourhood bicycling club so that he can "feel better."

Decision and Action

1. Why is intensive or extreme exercise contraindicated in someone who is receiving chemotherapy or who is acutely ill?
2. What precautions should the nurse suggest Gerard take before he increases his exercise level?
3. How should the nurse involve Gerard in monitoring his fatigue?
4. As Gerard seeks ways to improve his quality of life, how should the nurse support him?

Reference for Evidence

Bergenthal N, Will A, Streckmann F, et al. Aerobic physical exercise for adult patients with haematological malignancies. *The Cochrane Database of Systematic Reviews*. 2014;11; 10.1002/14651858.CD009075.pub2.

Multiple Myeloma

Multiple myeloma, or *plasma cell myeloma,* is a condition in which neoplastic plasma cells infiltrate the bone marrow and destroy bone. The disease is more common in men than in women and usually develops after 40 years of age, with an average age at onset of 69 years (Röllig, Knop, & Bornhäuser, 2015). Myeloma has a higher incidence in Black ethnic groups than in White people. It was estimated that, in 2017, 2 900 new cases of multiple myeloma would be diagnosed in Canada (Canadian Cancer Society, 2017d).

Etiology and Pathophysiology

The cause of multiple myeloma is unknown. Exposure to radiation, organic chemicals (such as benzene), herbicides, and insecticides may play a role. Genetic factors, viral infection, and obesity may also influence the risk of developing multiple myeloma.

The disease process involves excessive production of plasma cells. Plasma cells are activated B cells, which produce immunoglobulins (antibodies) that normally protect the body. However, in multiple myeloma, instead of a variety of plasma cells producing antibodies to fight different infections, myeloma tumours produce monoclonal antibodies. *Monoclonal* means they are all of one kind, making them ineffective and even harmful. Not only do they not fight infections, but they also infiltrate the bone marrow. *Bence Jones proteins* are the light chain part of these monoclonal antibodies. They show up in the urine in many patients with multiple myeloma.

Furthermore, plasma-cell production of excessive amounts of cytokines (interleukins [ILs]; IL-4, IL-5, and IL-6) also plays an important role in the pathological process of bone destruction. As myeloma protein increases, normal plasma cells are reduced, a decrease that further compromises the body's normal immune response. Proliferation of malignant plasma cells and the overproduction of immunoglobulin and proteins result in the end-

organ effects of myeloma to the bone marrow, bone, and kidneys and possibly the spleen, lymph nodes, liver, and even heart muscle.

Clinical Manifestations

Multiple myeloma develops slowly and insidiously. The patient often does not manifest symptoms until the disease is advanced, at which time skeletal pain is the major manifestation. Pain in the pelvis, spine, and ribs is particularly common and is triggered by movement. Diffuse osteoporosis develops as the myeloma protein destroys bone. Osteolytic lesions are seen in the skull, vertebrae, and ribs (Figure 33-16). Vertebral destruction can lead to collapse of vertebrae with ensuing compression of the spinal cord. Loss of bone integrity can lead to the development of pathological fractures.

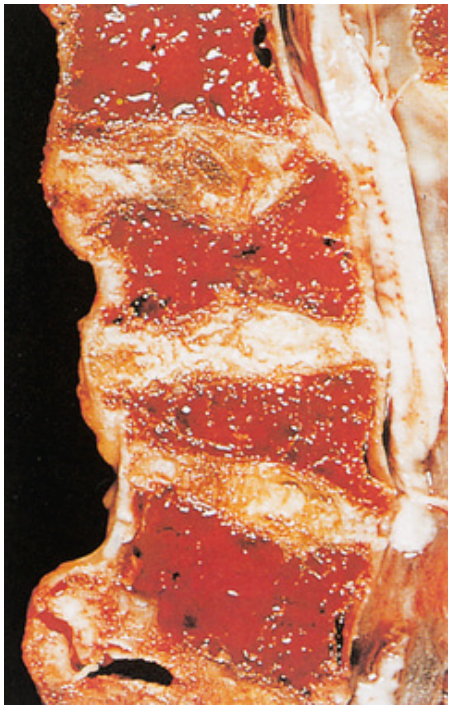

FIGURE 33-16 Multiple myeloma. This segment of the lower thoracic spine has been sectioned to show the extensive replacement of the bone and the marrow with red gelatinous tissue.
Source: Skarin, A. T. (1996). *Atlas of diagnostic oncology* (2nd ed.). London: Mosby-Wolfe.

Bony degeneration also causes calcium to be lost from bones, eventually causing hypercalcemia. Hypercalcemia may cause renal, GI, or neurological manifestations such as polyuria, anorexia, confusion, and ultimately seizures, coma, and cardiac problems. A serum *hyperviscosity*

syndrome can occur in some patients, leading to cerebral, pulmonary, renal, and other organ dysfunction. Even without hyperviscosity, high protein levels caused by the presence of the myeloma protein can result in renal tubular obstruction, interstitial nephritis, and renal failure. The patient may also display manifestations of anemia, thrombo-cytopenia, and granulo-cytopenia (recurrent infections), all of which are related to the replacement of normal bone marrow with plasma cells. Neurological abnormalities may be caused by regional myeloma cell growth that compresses the spinal cord or cranial nerves or by perineuronal or perivascular deposition.

Diagnostic Studies

Evaluating multiple myeloma involves laboratory, radiological, and bone marrow examination. M protein can be found in the blood and urine. Pancytopenia, hypercalcemia, the presence of Bence Jones protein in the urine, and an elevated serum creatinine are possible findings.

Skeletal bone surveys; MRI, PET scan, or both; and CT scan show distinct lytic areas of bone erosions, generalized thinning of the bones, or fractures, especially in vertebrae, ribs, pelvis, and bones of the thigh and the upper arms. Bone marrow analysis shows significantly increased numbers of plasma cells in the bone marrow. The simplest criteria for prognosis in multiple myeloma are the blood levels of two markers: β_2-microglobulin and albumin. In general, higher levels of β_2-microglobulin and lower levels of albumin are associated with a poorer prognosis.

Collaborative Care

Collaborative care involves managing both the disease and its symptoms. The current treatment options include corticosteroids, chemotherapy, immunotherapy, targeted therapy, and HSCT (Röllig, Knop, & Bornhäuser, 2015). Multiple myeloma is seldom cured, but treatment can relieve symptoms, produce remission, and prolong life. Ambulation and adequate hydration are used to treat hypercalcemia, dehydration, and potential renal damage. Weight bearing helps the bones reabsorb some calcium, and fluids dilute calcium and prevent protein precipitates from causing renal tubular obstruction. Control of pain and prevention of pathological fractures are other goals of management. Analgesics, orthopedic supports, and localized radiation help reduce the skeletal pain.

Kyphoplasty is sometimes used to control spinal vertebral disease. *Kyphoplasty* is a minimally invasive procedure that injects cement to stabilize the vertebral compression (Terpos, Berenson, Raje, et al., 2014).

Bisphosphonates, such as pamidronate and zoledronic acid (Zometa), inhibit bone breakdown and are used for the treatment of skeletal pain and hypercalcemia. They inhibit bone resorption without inhibiting bone formation and mineralization. They are given monthly by IV infusion and are recommended for all patients with symptomatic multiple myeloma.

Drug Alert

zoledronic acid (Zometa)

- Patients must be adequately hydrated prior to administering zoledronic acid (Zometa).
- Renal toxicity may occur if IV zoledronic acid is infused in less than 15 minutes.

Chemotherapy with corticosteroids is often recommended for multiple myeloma. It is used to reduce the number of plasma cells. Initial treatment depends on whether the patient is a future bone marrow transplant candidate and on anticipated tolerance of therapy. The treatment usually includes a corticosteroid plus one or two chemotherapy agents, such as melphalan (Alkeran), cyclophosphamide, doxorubicin (Adriamycin), and bendamustine (Treanda). High-dose chemotherapy followed by autologous HSCT has evolved as the standard of care in eligible patients.

Immunotherapy and targeted therapy are also used to treat multiple myeloma. Immuno-modulator drugs include thalidomide (Thalomid), lenalidomide (Revlimid), and pomalidomide (Pomalyst). Proteasome inhibitors include bortezomib (Velcade).

Drugs may be used to treat complications of multiple myeloma. For example, allopurinol (Zyloprim) may be given to reduce hyperuricemia, and IV furosemide (Lasix) promotes renal excretion of calcium. In some patients, the levels of plasma proteins are so high that it causes a hyperviscosity syndrome leading to neurological changes, renal insufficiency, and other problems related to the lack of blood flow. In this instance, plasmapheresis is used.

Nursing Management Multiple Myeloma

A major focus of care relates to the bone involvement and the sequelae from bone breakdown. Maintaining adequate hydration is a primary nursing consideration to minimize problems from hypercalcemia. Fluids are administered to attain a urinary output of 1.5 to 2 L/day if the patient does not have renal compromise. In addition, weight bearing helps bones reabsorb some of the circulating calcium, and corticosteroids may augment the excretion of calcium. Once chemotherapy is initiated, the uric acid levels may rise because of the increased cell destruction. Hyperuricemia is treated by ensuring adequate hydration and using allopurinol to prevent any renal damage. Because of the myeloma proteins, the patient is at additional risk for renal dysfunction. The nurse must monitor electrolytes and fluid balance.

Because of the potential for pathological fractures, the nurse must be careful when moving and ambulating the patient. A slight twist or strain in the wrong area (e.g., a weak area in the patient's bones) may be sufficient to cause a fracture. In addition, the development of peripheral neuropathy is common with several therapies for multiple myeloma and can contribute to discomfort, the inability to perform basic activities of daily living, and the risk for injury from falling.

Pain management requires innovative and knowledgeable nursing interventions. Analgesics, such as nonsteroidal anti-inflammatory drugs, acetaminophen, or an acetaminophen–opioid combination, may be more effective than opioids alone in diminishing bone pain. Braces, especially for the spine, may also help control pain. As in any situation necessitating pain management, the nurse is responsible for assessing the patient and for implementing necessary measures to alleviate the pain. (Pain management is discussed in Chapter 10.) Patients may also be at risk for deep-vein thrombosis related to chemotherapy and immobility and should have preventive measures employed.

Assessment and prompt treatment of infection are important in the care of patients with multiple myeloma. Recurrent infections may be caused by a decrease in the production of normal immunoglobulins, the ineffectiveness of the overproduced and abnormal immunoglobulins, neutropenia that results from the bone marrow infiltration or as an adverse effect of treatment, or a combination of these. NCP 33-1 for anemia, NCP 33-2 for thrombo-cytopenia, and NCP 33-3 for neutropenia

apply to the patient with multiple myeloma. (NCPs 33-2 and 33-3 are available on the Evolve website.)

The patient's psychosocial needs require sensitive, skilled management. It is important to help the patient and significant others adapt to changes fostered by chronic sickness and adjust to the losses related to the disease process while helping to maximize functioning and quality of life. The symptoms of multiple myeloma go through remission and exacerbation periods. Consequently, acute care is needed at various times during the course of the illness. The final acute phase is unresponsive to treatment and usually short. The way in which patients and families deal with confronting death may be affected by the manner in which they learned to accept and live with the chronic nature of the disease.

Disorders of the Spleen

The spleen can be affected by many illnesses, most of which cause some degree of *splenomegaly* (enlarged spleen) (Table 33-31). The term *hypersplenism* refers to the occurrence of splenomegaly and peripheral cytopenias (anemia, leukopenia, and thrombo-cytopenia). The degree of splenic enlargement varies with the disease. For example, massive splenic enlargement occurs with chronic myelogenous leukemia, hairy cell leukemia, and thalassemia major. Mild splenic enlargement occurs with HF and systemic lupus erythematosus.

TABLE 33-31
CAUSES OF SPLENOMEGALY

Infections and Inflammations
• Bacterial infections: endocarditis, salmonella • Mycobacterial infections: tuberculosis • Spirochetes: syphilis, Lyme disease • Viral infections: hepatitis, human immunodeficiency virus, cytomegalovirus, mononucleosis • Parasitic infections: malaria, trypanosomiasis, schistosomiasis, leishmaniasis, toxoplasmosis • Rickettsial infections: Rocky Mountain spotted fever, typhoid fever • Fungal infections: histoplasmosis • Autoimmune diseases: systemic lupus erythematosus, rheumatoid arthritis
Infiltrative Diseases and Tumours or Cysts
• Acute and chronic leukemia • Lymphomas • Polycythemia vera • Multiple myeloma, amyloidosis • Other primary or secondary neoplasms and cysts • Sarcoidosis • Gaucher's disease
Congestion
• Cirrhosis of the liver • Heart failure (portal hypertension) • Portal or splenic vein thrombosis • Sickle cell disease • Thalassemia • Acquired hemolytic anemia • Immune thrombo-cytopenia

When the spleen enlarges, its normal filtering and sequestering capacity increases. Consequently, there is often a reduction in the number of circulating blood cells. In addition, there are unusual findings in the peripheral smear, such as pitted or pocked erythrocytes or Howell–Jolly bodies. These findings assist with diagnosing a malfunctioning spleen. A slight to moderate enlargement of the spleen is usually asymptomatic and found during a routine examination of the abdomen. Even massive splenomegaly can be well tolerated, but the patient may complain of abdominal discomfort and early satiety. In addition to physical examination, other techniques to assess the size of the spleen include radionuclide colloid liver–spleen scan, CT scan, MRI, and ultrasound scan.

Occasionally, laparotomy and splenectomy are indicated in the evaluation or treatment of splenomegaly. Splenectomy can have a dramatic effect in increasing peripheral RBC, WBC, and platelet counts. Another major indication for splenectomy is splenic rupture. The spleen may rupture from trauma, inadvertent tearing during other surgical procedures, and diseases such as mononucleosis, malaria, and lymphoid neoplasms.

Nursing responsibilities for the patient with spleen disorders vary depending on the nature of the problem. Splenomegaly may be painful

and may necessitate analgesic administration; care in moving, turning, and positioning; and evaluation of lung expansion because spleen enlargement may impair diaphragmatic excursion. If anemia, thrombo-cytopenia, or leukopenia develops from splenic enlargement, nursing measures must be instituted to support the patient and prevent life-threatening complications. If splenectomy is performed, observation for hemorrhage and shock is required.

After splenectomy, immunological deficiencies may develop. Patients who have had splenectomy have a lifelong risk for infection, especially from encapsulated organisms such as pneumococcus (Weledji, 2014). This risk is reduced by immunization with pneumococcal vaccine (e.g., Pneumovax).

Blood Component Therapy

Blood component therapy is frequently used in managing hematological diseases. Many therapeutic and surgical procedures depend on blood product support. However, blood component therapy supports the patient only temporarily so is used in the interim until the underlying problem is resolved. Because transfusions are not free from hazards, they should be used only if necessary.

Nurses must be careful to avoid developing a complacent attitude about this common but potentially dangerous therapy. Nurses also must make sure that the physician has discussed the risks, benefits, and alternatives with the patient and that this conversation is documented in the patient's medical record.

Traditionally, the term *blood transfusion* meant the administration of whole blood. Blood transfusion now has a broader meaning because of the ability to administer specific components of blood such as platelets, packed red blood cells (PRBCs), or plasma. Usually, a specific component is ordered, although whole blood may be used rarely with massive hemorrhage or for an exchange transfusion (Table 33-32).

TABLE 33-32
BLOOD PRODUCTS*

Description	Special Considerations	Indications for Use
Packed Red Blood Cells		
Packed RBCs are prepared from whole blood by sedimentation or centrifugation. One unit contains 250–350 mL. They can be stored up to 35 days depending on processing.	Use of RBCs for treatment allows remaining components of blood (e.g., platelets, albumin, plasma) to be used for other purposes. There is less danger of fluid overload. • Leukocyte depletion (by the blood bank or with a filter) may be used to reduce hemolytic febrile reactions in patients who receive frequent transfusions.	Severe or symptomatic anemia; acute blood loss. In general, one unit of packed red blood cells can be expected to increase a patient's Hb level by 10 g/L or Hct by 3%. One unit of RBCs can replace a blood loss of 500 ml.
Frozen Red Blood Cells		
Frozen RBCs are prepared using glycerol for protection. They can be stored for 10 years.	They must be used within 24 hr of thawing. Successive washings with saline solution remove the majority of WBCs and plasma proteins.	Autotransfusion; stockpiling; or rare donors for patients with allobodies. Infrequently used because filters remove most WBCs.
Platelets		
Platelets are prepared from fresh whole blood. Platelets may be pooled from multiple donors. A single donation by apheresis is usually 200–400 ml in volume.	Multiple units of platelets can be obtained from one donor by platelet pheresis. They can be kept at room temperature for 1–5 days depending on type of collection and storage. For patients who receive frequent transfusions or who have not responded to previous platelet transfusions, platelets that are leukocyte-reduced or HLA- or type-specific may be given to prevent alloimmunization to HLA antigens.	Bleeding caused by thrombo-cytopenia or platelet levels <10–20 × 10^9/L; use may be contraindicated in the presence of thrombo-cytopenic purpura, thrombotic thrombo-cytopenic purpura, and heparin-induced thrombo-cytopenia except for life-threatening hemorrhage. Expected increase is 10 000 mcL per unit. Failure to obtain a rise may be caused by fever, sepsis, splenomegaly, or DIC.
Fresh-Frozen Plasma		
Liquid portion of whole blood is separated from cells and frozen. One unit contains 200–250 mL. Plasma is rich in clotting factors but contains no platelets. It may be stored for >1 year, depending on storage, but must be used within 24 hr after thawing.	Use of plasma in treating hypovolemic shock is being replaced by use of pure preparations such as albumin plasma expanders.	Bleeding caused by deficiency in clotting factors (e.g., DIC, hemorrhage, massive transfusion, liver disease, vitamin K deficiency, excess warfarin).
Albumin		
Albumin is prepared from plasma. It is available in 5% or 25% solution. It can be stored for 5 years.	Albumin 25 g/100 mL is osmotically equal to 500 mL of plasma. Hyperosmolar solution acts by moving water from extravascular to intravascular space. It is heat treated and does not transmit viruses.	Hypovolemic shock, hypoalbuminemia.
Cryoprecipitates and Commercial Concentrates		
Cryoprecipitate is prepared from fresh-frozen plasma, with 10–20 mL/bag. Once thawed, it must be used.	See Table 33-19.	Replacement of clotting factors, especially factor VIII, von Willebrand factor, and fibrinogen.

*Component therapy has replaced the use of whole blood, which accounts for <10% of all transfusions. Granulocyte transfusions are not included here because they are rarely

used.

DIC, disseminated intravascular coagulation; *Hb,* hemoglobin; *Hct,* hematocrit; *HLA,* human leukocyte antigen; *RBCs,* red blood cells; *WBCs,* white blood cells.

After the Canadian blood supply was found to be tainted with viruses in the 1980s, a government inquiry known as the Krever Commission (1997) led to a new federally mandated and regulated system (Ministry of Health, 1997). For example, in Canada, all blood is tested for viruses such as HIV and hepatitis as well as other infectious organisms. Strict donor screening now takes place to reduce the risk for transfusion-transmitted infection. Although the blood supply in Canada is very safe, the Krever Commission recommended recipients be informed of the benefits, risks, and alternatives to receiving donor blood products. The new federal standards on blood and blood components are relevant to nursing policy and practice because they highlight critical areas such as proper patient and product identification as well as careful monitoring of patients receiving blood products.

Administration Procedure

Blood components may be administered with a 22-gauge IV needle, cannula, or catheter. However, larger needles (e.g., 18- or 16-gauge) may be preferred if rapid transfusions are given or if the infusion is sluggish. Smaller needles can be used for platelets, albumin, and clotting factor replacement. Whatever type of venous access used, it is important to assess patency prior to requesting the blood component from the blood bank. Most blood product administration tubing is of a "Y type" with a microaggregate filter (which filters out particulate) with one branch of the Y for the isotonic saline solution and the other branch for the blood product. Infusion pumps may be used if approved for blood administration and according to institutional policy.

Safety Alert

- Dextrose solutions or lactated Ringer's solution must not be used for administering blood because they will cause RBC hemolysis.
- Additives (including medications) must not be given via the same tubing as the blood unless the tubing is first cleared with saline solution.

When the blood or blood components have been obtained from the blood bank, positive identification of the blood donor and the recipient must be made. Improper product-to-patient identification causes 90% of hemolytic transfusion reactions, thus placing a great responsibility on nursing personnel to carry out the identification procedure appropriately. The nurse must follow the policy and procedures of the institution where care is being provided; many institutions have implemented a dual-checking system with two licensed individuals checking patient identification with the labelled blood component. The blood bank is responsible for typing and crossmatching the donor's blood with the recipient's blood; the result of the compatibility testing should be noted on the product bag or tag, if pertinent.

ABO compatibility is not a prerequisite for platelet transfusions. However, after multiple platelet transfusions, a patient may develop anti-HLA antibodies to the transfused platelets. With the use of lymphocyte typing to match HLA types of the donor and the recipient, multiple platelet transfusions can be given with fewer complications to those who develop antibodies to platelets. Patients with a history of reactions to platelet transfusions may be premedicated with an antihistamine and hydrocortisone to decrease the possibility of reaction.

The nurse takes the patient's vital signs before the beginning of the transfusion to obtain a baseline measure; if the patient has abnormal vital signs, such as an elevated temperature, the health care provider is called to clarify when the blood component may be administered. The blood should be administered as soon as it is brought to the patient. No blood products are to be refrigerated on the nursing unit in food or drug refrigerators because the temperature does not meet the temperature-range requirements for safe storage. Products that are not used right away (i.e., within 30 minutes of being issued) should be returned to the blood bank. During the first 15 minutes or 50 mL of blood infusion, the nurse should remain with the patient. If there are any untoward reactions, they are most likely to occur at this time. The rate of infusion during this period should be no more than 2 mL/min. PRBCs should not be infused quickly unless an emergency exists. Rapid infusion of cold blood may cause the patient to become chilled. If rapid replacement of large amounts of blood is necessary, a blood-warming device may be used. Other blood components, such as fresh-frozen plasma and platelets, may be infused over 15 to 30 minutes. Refer to your institution's policy and procedure.

After the first 15 minutes, vital signs are usually retaken, and the rate of infusion is governed by the clinical condition of the patient and the

product being infused. The nurse should observe the patient periodically throughout the transfusion (e.g., every 30 minutes) and up to 1 hour after the transfusion. Most patients not in danger of fluid overload can tolerate the infusion of 1 unit of PRBCs over 2 hours. The transfusion should not take more than 4 hours to administer because of the increased risk for bacterial growth in the product once it is out of refrigeration.

Blood Transfusion Reactions

A *blood transfusion reaction* is an adverse reaction to blood transfusion therapy that can range in severity from mild symptoms to a life-threatening condition. Because complications of transfusion therapy may be significant, judicious evaluation of the patient is required. Blood transfusion reactions can be classified as acute or delayed (Tables 33-33 and 33-34).

TABLE 33-33
ACUTE TRANSFUSION REACTIONS

Cause	Clinical Manifestations	Management	Prevention
Acute Hemolytic Reaction			
Infusion of ABO-incompatible whole blood, RBCs, or components containing 10 mL or more of RBCs. Antibodies in the recipient's plasma attach to antigens on transfused RBCs causing RBC destruction.	Reaction usually occurs in first 15 minutes. Fever with or without chills; low back, abdominal, chest or flank pain; flushing, tachycardia, dyspnea, tachypnea, hypotension, vascular collapse, hemoglobinuria, acute jaundice, dark urine, bleeding, acute kidney injury, shock, cardiac arrest, DIC, death.	Treat shock and DIC if present. Draw blood samples—slowly to avoid hemolysis—for serological testing. Send urine specimen to the laboratory. Maintain BP with IV colloid solutions. Give diuretics as prescribed to maintain urine flow. Insert in-dwelling urinary catheter or measure voided amounts to monitor hourly urine output. Dialysis may be required if renal failure occurs. Do not transfuse additional RBC-containing components until blood bank has provided newly crossmatched units.	Meticulously verify and document patient identification at each step from sample collection to component infusion.
Febrile, Nonhemolytic Reaction (Most Common)			
Sensitization to donor WBCs, platelets, or plasma proteins.	Sudden chills and fever (rise in temperature of >1°C), headache, flushing, anxiety, vomiting, muscle pain.	Give antipyretics as prescribed—avoid ASA in patients with thrombo-cytopenia. *Do not restart transfusion* unless physician orders it.	Consider leukocyte-poor blood products (filtered, washed, or frozen) for patients with a history of two or more such reactions. Give acetaminophen or diphenhydramine 30 min before transfusion.
Mild Allergic Reaction			

Cause	Clinical Manifestations	Management	Prevention
Sensitivity to foreign plasma proteins. More common in people with history of allergies.	Flushing, itching, pruritus, urticaria (hives).	Give antihistamine, corticosteroid, epinephrine as directed. If symptoms are mild and transient, transfusion may be restarted slowly with health care provider's order. Do not restart transfusion if fever or pulmonary symptoms develop.	Treat prophylactically with antihistamines and steroids. Consider using washed RBCs and platelets.
Anaphylactic and Severe Allergic Reaction			
Sensitivity to donor plasma proteins. Infusion of IgA proteins to IgA-deficient recipient who has developed IgA antibody.	Anxiety; urticaria; dyspnea, wheezing, progressing to cyanosis; bronchospasm; hypotension, shock, and possible cardiac arrest.	Initiate CPR if indicated. Administer O_2. Have epinephrine ready for injection. Antihistamines, corticosteroids, β_2-agonists may also be prescribed. *Do not restart transfusion.*	Transfuse extensively washed RBC products, from which all plasma has been removed. Use blood from IgA-deficient donor. Use autologous components.
Circulatory Overload Reaction			
Fluid administered faster than the circulation can accommodate. People with cardiac or renal disease at risk.	Cough, dyspnea, pulmonary congestion, adventitious breath, headache, hypertension, tachycardia, distended neck veins.	Place patient upright with feet in dependent position. Obtain chest radiograph stat if ordered. Administer prescribed diuretics, O_2, and/or morphine. Phlebotomy may be indicated.	Adjust transfusion volume and flow rate based on patient size and clinical status. Have blood bank divide unit into smaller aliquots for better spacing of fluid input.
Sepsis Reaction			
Transfusion of bacterially infected blood components.	Rapid onset of chills, high fever, vomiting, diarrhea, marked hypotension, or shock.	Obtain culture of patient's blood and send bag with remaining blood and tubing to blood bank for further study. Treat septicemia as directed—administration of antibiotics, IV fluids, and/or vasopressors.	Collect, process, store, and transfuse blood products according to blood banking standards, and infuse within 4 hr of starting time.
Transfusion-Related Acute Lung Injury (TRALI) Reaction			

Cause	Clinical Manifestations	Management	Prevention
Reaction between transfused antileukocyte antibodies and recipient's leukocytes, causing pulmonary inflammation and capillary leak.	Fever, chills, hypotension, tachypnea, frothy sputum, dyspnea, hypoxemia, respiratory failure. Noncardiogenic pulmonary edema. Leading cause of transfusion-related deaths. Arises within 1–6 hours of transfusion.	Send bag with remaining blood and tubing to blood bank for further study; draw blood to analyze ABGs and HLA or antileukocyte antibodies; obtain chest radiograph stat. Provide O_2 and administer corticosteroids (diuretics of no value). Initiate CPR if needed, and provide ventilatory and blood pressure support if needed.	Provide leukocyte-reduced products. Identify donors who are implicated in TRALI reactions, and do not allow them to donate.
Massive Blood Transfusion Reaction			
Can occur with replacement of 10 or more RBC units within 24 hours. RBC transfusions do not contain clotting factors, albumin, and platelets.	Hypothermia and cardiac dysrhythmias (from massive infusion of large quantities of cold blood). Citrate toxicity and hypocalcemia (from the use of citrate as a storage solution). Hyperkalemia (from potassium leaking from stored RBCs).	When patients receive massive transfusions of blood products, monitor clotting status and electrolyte levels.	Use blood-warming equipment. Infusion of 10% calcium gluconate. Because of dilution effect on coagulation due to massive RBC transfusion, platelets and plasma will also be administered.

ABGs, arterial blood gases; *ASA,* acetylsalicylic acid (Aspirin); *BP,* blood pressure; *CPR,* cardiopulmonary resuscitation; *DIC,* disseminated intravascular coagulation; *HLA,* human leukocyte antigen; *IgA,* immunoglobulin A; *IV,* intravenous; O_2, oxygen; *RBC,* red blood cell; *WBC,* white blood cell.

TABLE 33-34
DELAYED TRANSFUSION REACTIONS

Manifestations	Prevention and Management
Delayed Hemolytic	
Fever, mild jaundice, decreased hemoglobin. Occurs as early as 3 days or as late as several months post-transfusion as the result of destruction of transfused RBCs by alloantibodies not detected during crossmatch.	Generally, no acute treatment is required. Hemolysis may be severe enough to warrant further transfusions.
Hepatitis B*	
Elevated liver enzymes (AST and ALT), anorexia, malaise, nausea and vomiting, fever, dark urine, jaundice. Usually resolves spontaneously within 4–6 wk. Chronic carrier state can develop and result in permanent damage to the liver.	Hepatitis B virus can be detected in donated blood by the presence of hepatitis B surface antigen (HBsAg). Treat symptomatically (see Chapter 46).
Hepatitis C*	
Similar to hepatitis B, but symptoms are usually less severe. Chronic liver disease and cirrhosis may develop.	Before anti-HCV testing of donated blood began, this accounted for 90%–95% of all post-transfusion hepatitis. Treat symptomatically (see Chapter 46).
Iron Overload	
Excess iron is deposited in heart, liver, pancreas, and joints, causing dysfunction. Heart failure, dysrhythmias, impaired thyroid and gonadal function, diabetes, arthritis, cirrhosis. Occurs in patients receiving >100 units for chronic anemia (e.g., sickle cell anemia, beta thalassemia) over time.	Treat symptomatically. Deferoxamine (Desferal), which chelates and removes accumulated iron via the kidneys, administered IV or subcutaneously. Deferasirox (Exjade) and deferiprone (Ferriprox) are oral agents that chelate iron and should be started before more than 50 units of red cells are transfused.
Other	
CMV, HIV, HSV-6, Epstein-Barr virus, HTLV-1, and malaria. Most recent threats have been agents that primarily affect animals but have been transmitted to the blood supply through the food supply, or vectors such as mosquitoes or ticks. These include *Plasmodium* species (malaria), dengue fever virus, West Nile virus, *Trypanosoma cruzi* (Chagas's disease), *Babesia* species (babesiosis), human herpesvirus 8 (KS virus), and variant Creutzfeldt-Jakob disease ("mad cow disease").	Treatment is based on the cause. Ways of detecting some of these agents are now available and required, such as the nucleic acid test for West Nile virus, HIV, and *T. cruzi*. Donor screening has been the only available method to reduce the risk for donor-contaminated blood for others.

*New cases of transfusion-related hepatitis B and C are not common.

ALT, alanine aminotransferase; *AST,* aspartate aminotransferase; *CMV,* cytomegalovirus; *HCV,* hepatitis C virus; *HIV,* human immunodeficiency virus; *HSV-6,* human herpesvirus, type 6; *HTLV-1,* human T-cell leukemia virus, type 1; *KS,* Kaposi sarcoma.

If an *acute transfusion reaction* occurs, the following steps should be taken: (a) stop the transfusion; (b) maintain a patent IV line with saline solution; (c) notify the blood bank and the health care provider immediately; (d) recheck identifying tags and numbers; (e) monitor vital signs and urine output; (f) treat symptoms as per physician order; (g) save and return the blood bag and tubing to the blood bank for examination; (h) collect blood and urine samples at intervals as stipulated by hospital policy to evaluate for hemolysis; and (i) document the incident (and steps

a–h) on a transfusion reaction form and the patient's chart. The blood bank and laboratory are responsible for identifying the type of reaction.

Acute Transfusion Reactions

Acute Hemolytic Reactions.

The most common cause of hemolytic reactions is transfusion of ABO-incompatible blood (see Table 33-33). This is an example of a type II cytotoxic hypersensitivity reaction (see Chapter 16). Severe hemolytic reactions are rare. Mislabelling specimens and administering blood to the wrong individual cause most acute hemolytic reactions. This again points to the importance of using proper patient identifiers when drawing blood samples and when administering medications and blood products.

When an acute hemolytic reaction occurs, antibodies in the recipient's serum react with antigens on the donor's RBCs. This reaction results in agglutination of cells, which can obstruct capillaries and block blood flow. Hemolysis of the RBCs releases free Hb into the plasma. The Hb is filtered by the kidney and may be found in the urine (hemoglobinuria). Hb may obstruct the renal tubules, leading to acute kidney injury, DIC, and death (see Chapter 49).

The clinical manifestations of an acute hemolytic reaction may be mild or severe and usually develop within 15 minutes of transfusion. Free Hb in blood and urine specimens obtained at the onset of the reaction will provide evidence of an acute hemolytic reaction. Delayed transfusion reactions are defined as those occurring 24 hours to 14 days after the administration of blood.

Febrile Reactions.

Febrile reactions are most commonly caused by leukocyte incompatibility. Many individuals who receive five or more transfusions develop circulating antibodies to the small amount of WBCs in the blood product. Febrile reactions can often be prevented by using additional filters in the tubing to leukocyte-deplete RBCs and platelets. Donated blood in Canada is processed to reduce the number of circulating WBCs (i.e., leuko-depleted), a process that has helped decrease the incidence of the febrile nonhemolytic and minor allergic reactions. Medications such as acetaminophen (Tylenol) and diphenhydramine (Benadryl) may be ordered and given 30 minutes before blood administration to reduce these reactions.

Allergic Reactions.

Allergic reactions result from the recipient's sensitivity to plasma proteins of the donor's blood. These reactions are more common in an individual with a history of allergies. Administration of antihistamines may help prevent allergic reactions. Epinephrine or corticosteroids may be used to treat a severe reaction.

Circulatory Overload.

An individual with cardiac or renal insufficiency is at risk for developing circulatory overload, especially if a large quantity of blood is infused in a short period, particularly in an older adult. PRBCs can be split by the blood bank, allowing for one-half of a unit to be given over a time frame of up to 4 hours. A fluid balance assessment, including baseline auscultation of the patient's lungs, is performed. Complaints of shortness of breath and the presence of adventitious breath sounds may indicate fluid overload in a patient.

Sepsis.

Blood products can become infected from improper handling and storage. Bacterial contamination of blood products can result in bacteremia, sepsis, or septic shock.

Transfusion-Related Acute Lung Injury.

Transfusion-related acute lung injury (TRALI) is characterized by the sudden development of noncardiogenic pulmonary edema (acute lung injury). It usually occurs within hours of the transfusion of blood products. With the reduction of clerical errors, leukocyte-reduced products, more effective screening, and the prevention of the transmission of infectious agents, TRALI has surpassed hemolytic reactions as the leading cause of transfusion-related death. It is thought to be caused by an antibody-mediated reaction between the recipient's leukocytes and antileukocyte antibodies from donors who were sensitized during pregnancy or by previous transfusions. TRALI causes pulmonary capillary inflammation and increased permeability, leading to respiratory distress and potentially death.

Massive Blood Transfusion Reaction.

An acute complication of transfusing large volumes of blood products is termed *massive blood transfusion reaction*. Massive blood transfusion reactions can occur when replacement of RBCs or blood exceeds the total

blood volume within 24 hours. In this situation, an imbalance of normal blood elements results because clotting factors, albumin, and platelets are not found in RBC transfusions. Thus, appropriate monitoring of hemostatic laboratory parameters must be done concurrently.

Additional problems such as hypothermia, citrate toxicity, hypocalcemia, and hyperkalemia may occur when massive blood transfusions are given. Hypothermia and cardiac dysrhythmias can result from rapid infusion of large quantities of cold blood. Blood-warming equipment prevents this problem. Citrate toxicity can occur when large quantities of blood products are used because citrate is part of the storage solution; calcium binds to the citrate. Citrate toxicity is likely to develop when blood is transfused at a rate of 1 unit in 10 minutes (or 8–10 units of RBCs within a few hours). Manifestations such as muscle tremors and ECG changes may be observed with hypocalcemia but can be prevented or reversed by the infusion of 10% calcium gluconate (10 mL with every litre of citrated blood). Hyperkalemia results when potassium leaks from RBCs in stored blood. Mild to severe signs and symptoms can occur, including nausea, muscle weakness, diarrhea, paresthesias, flaccid paralysis of the cardiac or respiratory muscles, and cardiac arrest. Electrolyte monitoring is an important aspect of the care of the patient receiving massive transfusions of blood products.

Delayed Transfusion Reactions.

Delayed transfusion reactions include delayed hemolytic reactions (discussed previously), infections, and iron overload (see Table 33-34).

Infection.

Infectious agents transmitted by blood transfusion include hepatitis B and C viruses, HIV, human herpesvirus type 6 (HSV-6), EBV, HTLV-1, cytomegalovirus (CMV), and malaria. Hepatitis is still the most common viral infection transmitted, although its incidence is decreasing. Hepatitis B virus can be detected in the blood by the presence of hepatitis B surface antigen (HBsAg). A test for hepatitis C antibodies in donor blood is used to exclude the use of any donated blood testing positive for hepatitis C. Therefore, the risk for transmission of hepatitis C has been reduced. Leukocyte-reduced blood products drastically decrease the risk for blood transfusion–associated viral infections, including CMV.

In the past, transmittal of HIV by contaminated blood and blood products posed a serious problem for individuals who received infected transfusions. Patients with hemophilia who received antihemophilic

factors that had been prepared from pooled plasma of a large number of donors, some of whom were HIV-infected, have a high rate of HIV infection from transfusion sources. At present, the use of recombinant antihemophilic factors, donor education, donor screening, and HIV-antibody testing have greatly reduced the transmission of HIV by blood transfusion or factor replacement therapy.

Autotransfusion

Autotransfusion, or autologous transfusion, involves removing whole blood from a person and transfusing that blood back into the same person. Through this method, the problems of incompatibility, allergic reactions, and transmission of disease can be avoided. Methods of autotransfusion include the following:

- *Autologous donation* or *elective phlebotomy* (predeposit transfusion). A person donates blood before a planned surgical procedure. The blood can be frozen and stored for up to 10 years. Usually, the blood is stored without being frozen and is given to the person within a few weeks of donation. This technique is especially beneficial to the patient with a rare blood type or for any patient who might be expected to require limited blood product support during a major surgical procedure (e.g., elective orthopedic surgery).
- *Autotransfusion.* A newer method for replacing blood volume involves safely and aseptically collecting, filtering, and returning the patient's own blood that is lost during a major surgical procedure or from a traumatic injury. This system was originally developed in response to patients' concerns about the safety of blood from blood products. However, today it provides an important way to safely replace volume and stabilize the condition of bleeding patients. Collection devices are most often used during

surgeries. Some systems allow blood to be automatically and continuously reinfused; others require collection for some period (usually no longer than 4 hours), after which the blood is reinfused. Hospitals in Canada are now required to have a blood conservation program in place.

Case Study

Leukemia

Source: Shutterstock.com

Patient Profile

Andeep Singh, a 35-year-old man, went to the emergency department because of severe bruising caused by a fall while hiking.

Subjective Data

- Complains of oral pain and white patches covering his tongue
- Has had a 2-month history of fatigue, malaise, and flu symptoms
- Complains of shortness of breath while doing activities that previously required no exertion
- Has taken numerous prescribed antibiotics and increased rest and sleep in the past 2 months without relief of symptoms

Objective Data

Physical Examination

- Has bruises and ecchymoses from fall
- Gingiva has petechiae and patchy white spots
- Temperature 39°C, respiratory rate 26/min, pulse 110
- Has splenomegaly

Laboratory Results

- Hematocrit 0.2
- White blood cell (WBC) count 120 × 10^9/L
- Hemoglobin (Hb) 69 g/L
- Platelet count 25 × 10^9/L

Bone Marrow Biopsy

- Multiple myeloblasts (>50%)

Discussion Questions

1. What components of the laboratory test results suggest acute leukemia?
2. How is acute myelogenous leukemia treated?
3. What is the prognosis for Mr. Singh?
4. What are the life-threatening problems that can occur as a result of this disease and treatment? How can the nurse anticipate and assess for these problems?
5. ***Priority decision:*** What are the priority nursing interventions?
6. ***Priority decision:*** What are the priorities for patient teaching of a newly diagnosed young adult with leukemia?
7. ***Priority decision:*** Based on the assessment data presented, what are the priority nursing diagnoses? Are there any collaborative problems?
8. ***Evidence-informed practice:*** Mr. Singh becomes very fatigued after starting chemotherapy. He wants to know if he can still exercise even if he is so fatigued. What should the nurse tell him?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. In a severely anemic client, what would the nurse expect to find?
   a. Dyspnea and tachycardia
   b. Cyanosis and pulmonary edema
   c. Cardiomegaly and pulmonary fibrosis
   d. Ventricular dysrhythmias and wheezing

2. When obtaining assessment data from a client with a microcytic, hypochromic anemia, what would the nurse question the client about?
   a. Folic acid intake
   b. Dietary intake of iron
   c. History of gastric surgery
   d. History of sickle cell anemia

3. Nursing interventions for a client with severe anemia related to peptic ulcer disease include which of the following? (*Select all that apply)*
   a. Giving instructions in high-iron diet
   b. Taking vital signs every 8 hours
   c. Monitoring stools for occult blood
   d. Teaching self-injection of erythropoietin
   e. Administering cobalamin (vitamin B_{12}) injections

4. Which nursing management actions apply for a client in sickle cell crisis? (*Select all that apply)*
   a. Monitoring CBC
   b. Providing optimal pain management and O_2 therapy
   c. Doing blood transfusions if required and iron chelation
   d. Recommending rest as needed and deep-vein thrombosis prophylaxis
   e. Administering IV iron and a diet high in iron content

5. Which is a complication of the hyperviscosity of polycythemia?
   a. Thrombosis
   b. Cardiomyopathy
   c. Pulmonary edema

d. Disseminated intravascular coagulation (DIC)

6. When caring for a client with thrombo-cytopenia, the patient teaching should include which instruction?
   a. To wipe her or his nose gently instead of blowing
   b. To be careful when shaving with a safety razor
   c. To continue with physical activities to stimulate thrombopoiesis
   d. To avoid acetylsalicylic acid because it may mask the fever that occurs with thrombo-cytopenia
7. The nurse would anticipate that a client with von Willebrand disease who is undergoing surgery would be treated with administration of von Willebrand factor (vWF) and which of the following?
   a. Thrombin
   b. Factor VI
   c. Factor VII
   d. Factor VIII
8. What physiological process occurs in a person with DIC?
   a. The coagulation pathway is genetically altered, leading to thrombus formation in all major blood vessels.
   b. An underlying disease depletes hemolytic factors in the blood, leading to diffuse thrombotic episodes and infarcts.
   c. A disease process stimulates coagulation processes with resultant thrombosis, as well as depletion of clotting factors, leading to diffuse clotting and hemorrhage.
   d. An inherited predisposition causes a deficiency of clotting factors that leads to overstimulation of coagulation processes in the vasculature.
9. Which of the following is (are) a priority nursing action when caring for a hospitalized client with a new-onset temperature of 39°C and severe neutropenia? *(Select all that apply)*
   a. Administering the prescribed antibiotic immediately
   b. Drawing peripheral and central line blood cultures
   c. Ensuring ongoing monitoring of the client's vital signs for septic shock
   d. Taking a full set of vital signs and notifying the physician immediately
   e. Administering transfusions of WBCs to decrease immunogenicity

10. Because myelodysplastic syndrome arises from the pluripotent hematopoietic stem cell in the bone marrow, which laboratory results would the nurse expect to find?
    a. An excess of T cells
    b. An excess of platelets
    c. A deficiency of granulocytes
    d. A deficiency of all cellular blood components
11. Which is the most common type of leukemia in older adults?
    a. Acute myelocytic leukemia
    b. Acute lymphocytic leukemia
    c. Chronic myelocytic leukemia
    d. Chronic lymphocytic leukemia
12. Why are multiple drugs often used in combinations to treat leukemia and lymphoma?
    a. There are fewer toxic and adverse effects.
    b. The chance that one drug will be effective is increased.
    c. The drugs are more effective and cause fewer adverse effects.
    d. The drugs work by different mechanisms to maximize killing of malignant cells.
13. What is the major difference between Hodgkin's lymphoma and non-Hodgkin's lymphoma?
    a. Hodgkin's lymphoma occurs only in young adults.
    b. Hodgkin's lymphoma is considered potentially curable.
    c. Non-Hodgkin's lymphoma can manifest in multiple organs.
    d. Non-Hodgkin's lymphoma is treated only with radiation therapy.
14. A client with multiple myeloma becomes confused and lethargic. What indications would the nurse expect from the diagnostic results?
    a. Indications of hyperkalemia
    b. Indications of hyperuricemia
    c. Indications of hypercalcemia
    d. Indications of central nervous system myeloma
15. What would the nurse expect to find when reviewing a client's hematological laboratory values after a splenectomy?

a. Leukopenia

b. Red blood cell abnormalities

c. Decreased hemoglobin

d. Increased platelet count

16. Which complications of transfusions can be decreased by the use of leukocyte depletion or reduction of red blood cell transfusion?

a. Chills and hemolysis

b. Leukostasis and neutrophilia

c. Fluid overload and pulmonary edema

d. Transmission of cytomegalovirus and fever

1. a; 2. b; 3. a, c; 4. a, b, c, d; 5. a; 6. a; 7. d; 8. c; 9. a, b, c, d; 10. d; 11. d; 12. d; 13. c; 14. c; 15. d; 16. d.

SECTION 7

Problems of Oxygenation: Perfusion

OUTLINE

Introduction

Source: Christopher Gardiner/Shutterstock.com.

CHAPTER 34

Nursing Assessment

Cardiovascular System

Written by, Angela DiSabatino Herman, Linda Bucher

Adapted by, Sandra Goldsworthy

LEARNING OBJECTIVES

1. Differentiate the anatomical locations and functions of the following cardiac structures: pericardial layers, atria, ventricles, semilunar valves, and atrioventricular valves.
2. Explain the relation between the coronary circulation and the areas of heart muscle supplied by each blood vessel.
3. Explain the normal sequence of events involved in the conduction pathway of the heart.
4. Differentiate the structures and functions of arteries, capillaries, and veins.
5. Describe the mechanisms involved in blood pressure regulation.
6. Select essential assessment data related to the cardiovascular system that should be obtained from a patient or caregiver.
7. Select the appropriate techniques used in the physical assessment of the cardiovascular system.
8. Discuss the differences between normal and common abnormal findings of a physical assessment of the cardiovascular system.
9. Explain the links between age-related changes of the cardiovascular system and differences in assessment findings.
10. Describe the purpose of, significance of, and nursing responsibility related to diagnostic studies of the cardiovascular system.

11. Explain the relationship of the various waveforms on an electrocardiogram with the associated cardiac event.

KEY TERMS

action potential, p. 767
afterload, p. 769
arterial blood pressure (BP), p. 770
cardiac index, p. 769
cardiac output (CO), p. 769
cardiac reserve, p. 769
coronary angiography, p. 786
diastole, p. 769
diastolic blood pressure (DBP), p. 770
ejection fraction, p. 783
heaves, p. 776
Korotkoff sounds, p. 770
mean arterial pressure, p. 770
murmurs, p. 776
point of maximal impulse (PMI), p. 776
preload, p. 769
pulse pressure, p. 770
systole, p. 769
systolic blood pressure (SBP), p. 770

Structures and Functions of the Cardiovascular System

Heart

Structure.

The heart is a four-chambered, hollow, muscular organ normally about the size of a fist. It lies within the thorax in the mediastinal space that separates the right and left pleural cavities. The heart is composed of three layers: a thin inner lining, the *endocardium;* a layer of muscle, the *myocardium;* and an outer layer, the *epicardium.* The heart is covered by a fibroserous sac called the *pericardium.* This sac consists of two layers: the inside *(visceral)* layer of the pericardium (part of the epicardium) and the outer *(parietal)* layer. A small amount of pericardial fluid (approximately 10–15 mL) lubricates the space between the pericardial layers *(pericardial space)* and prevents friction between the surfaces as the heart contracts (Patton & Thibodeau, 2016).

The heart is divided vertically by the septum. The interatrial septum divides the right and left atria, and the interventricular septum divides the right and left ventricles. The thickness of the wall of each chamber is different. The atrial myocardium is thinner than that of the ventricles, and the left ventricular wall is two or three times thicker than the right ventricular wall (Patton & Thibodeau, 2016). The left ventricle must be thick in order to produce the force needed to pump the blood into the systemic circulation.

Blood Flow Through the Heart.

The blood flow through the heart is illustrated in Figure 34-1.

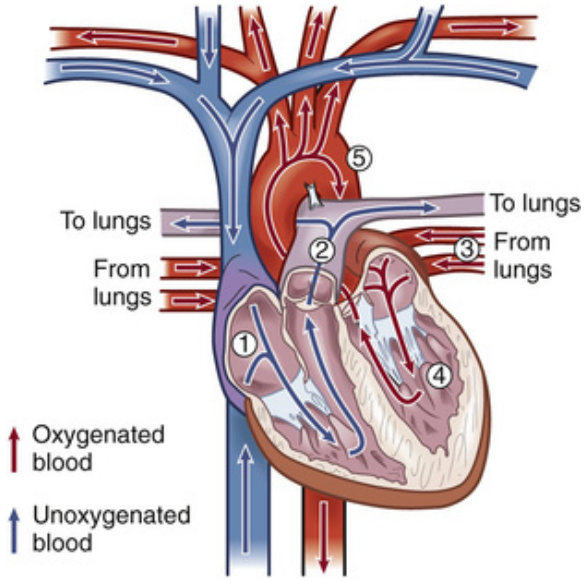

FIGURE 34-1 Schematic representation of blood flow through the heart. *Arrows* indicate direction of flow. *1,* The right atrium receives venous blood from the inferior and superior venae cavae and the coronary sinus. The blood then passes through the tricuspid valve into the right ventricle. *2,* With each contraction, the right ventricle pumps blood through the pulmonic valve into the pulmonary artery and to the lungs. *3,* Oxygenated blood flows from the lungs to the left atrium by way of the pulmonary veins. *4,* It then passes through the mitral valve and into the left ventricle. *5,* As the heart contracts, blood is ejected through the aortic valve into the aorta and thus enters the systemic circulation.

Cardiac Valves.

The four valves of the heart serve to keep blood flowing in a forward direction. The cusps of the mitral and tricuspid valves are attached to thin strands of fibrous tissue termed *chordae tendineae* (Figure 34-2). Chordae are anchored in the papillary muscles of the ventricles. This support system prevents the eversion of the leaflets into the atria during ventricular contraction. The pulmonic and aortic valves (also known as *semilunar valves*) prevent blood from regurgitating into the ventricles at the end of each ventricular contraction.

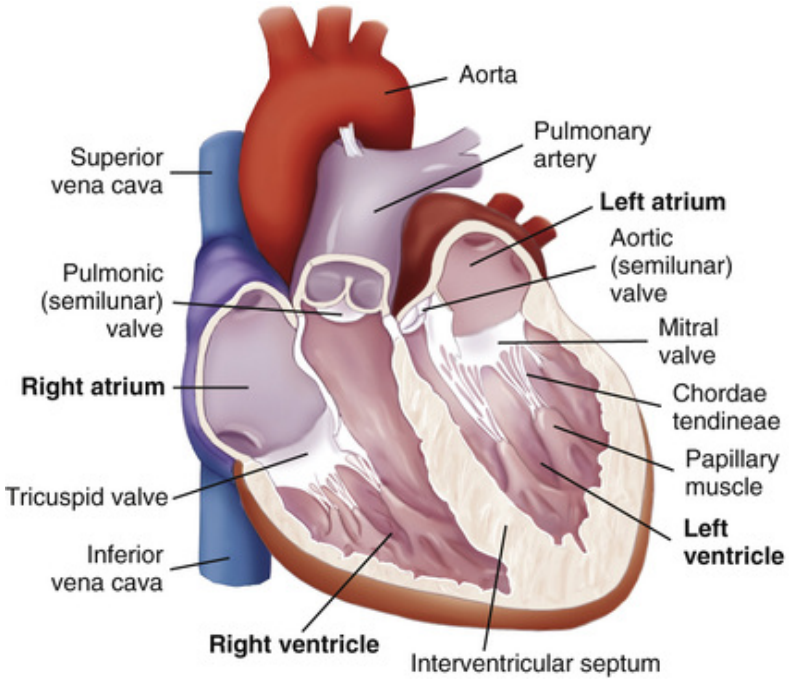

FIGURE 34-2 Anatomical structures of the atrioventricular valves.

Blood Supply to the Myocardium.

The myocardium has its own blood supply, the *coronary circulation* (Figure 34-3). Blood flow into the coronary arteries occurs primarily during diastole. The right coronary artery and its branches usually supply the right atrium, the right ventricle, and a portion of the posterior wall of the left ventricle. The left coronary artery and its branches (left anterior descending artery and left circumflex artery) supply the left atrium and the left ventricle. In 90% of people, the atrioventricular node and the bundle of His (part of the cardiac conduction system) receive blood supply from the right coronary artery. For this reason, obstruction of this artery often causes serious defects in cardiac conduction.

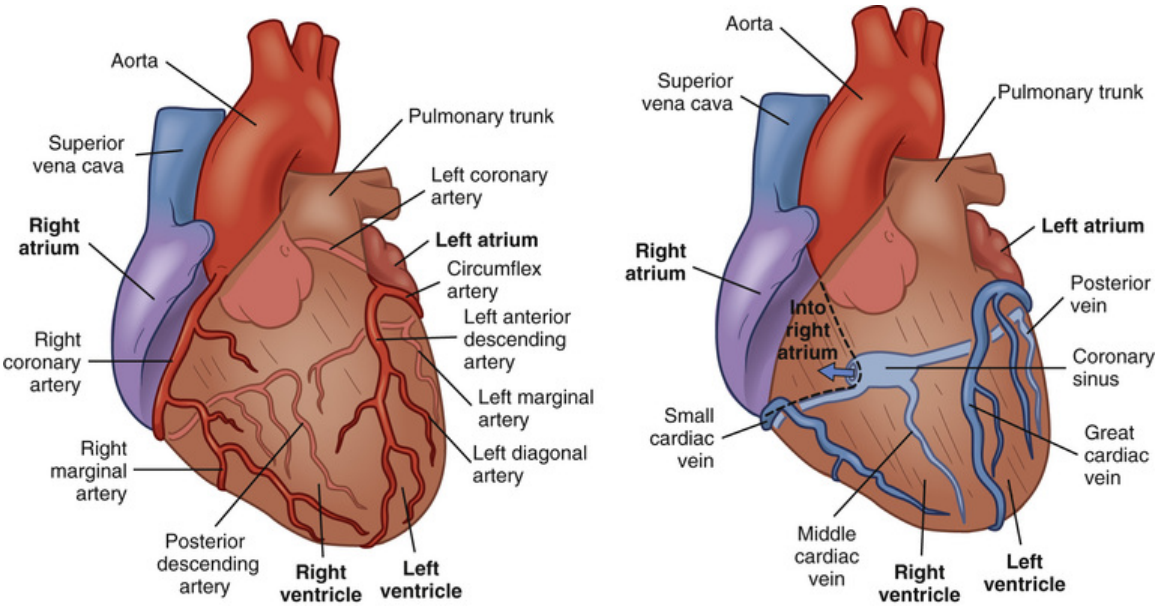

FIGURE 34-3 Coronary arteries and veins.

The divisions of coronary veins parallel the coronary arteries. Most of the blood from the coronary system drains into the coronary sinus, which empties into the right atrium near the entrance to the inferior vena cava (see Figure 34-3).

Conduction System.

The conduction system is specialized nerve tissue responsible for creating and transporting the electrical impulse; this impulse is called the **action potential.** This impulse initiates depolarization and, subsequently, cardiac contraction. The electrical impulse is initiated by the sinoatrial node (the pacemaker of the heart; Figure 34-4). Each impulse generated at the sinoatrial node travels swiftly through the muscle fibres of the atria by internodal pathways and cell-to-cell conduction. Mechanical contraction of the atria follows the depolarization of the cells.

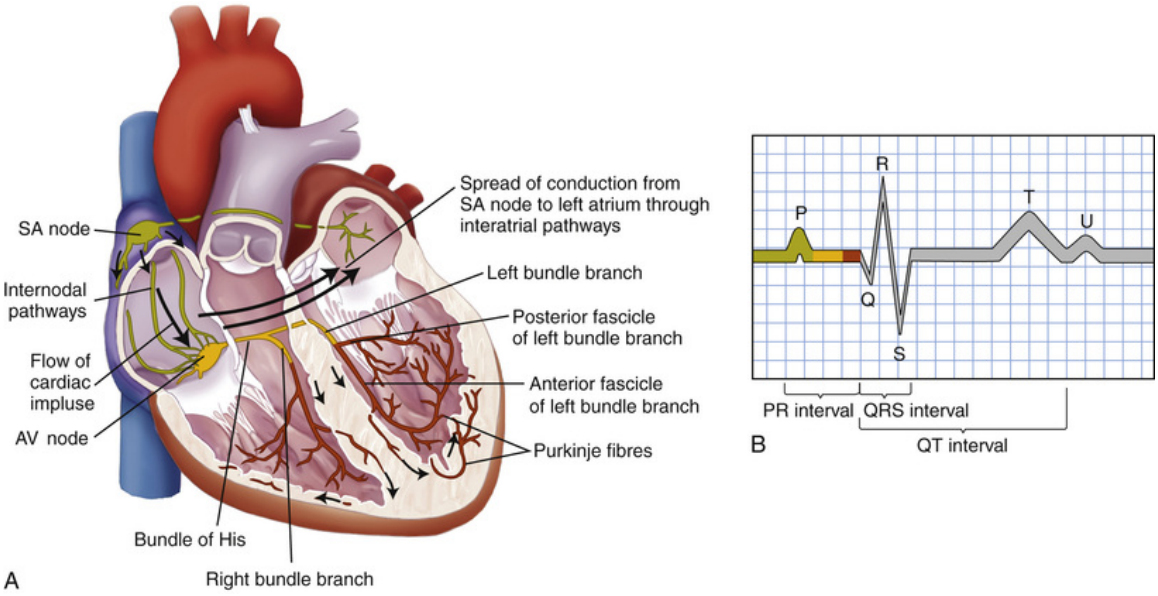

FIGURE 34-4 **A,** Conduction system of the heart. *AV,* atrioventricular; *SA,* sinoatrial. **B,** The normal electrocardiogram pattern. The P wave represents depolarization of the atria. The QRS complex indicates depolarization of the ventricles. The T wave represents repolarization of the ventricles. The U wave, if present, may represent repolarization of the Purkinje fibres or may be associated with hypokalemia. The PR, QRS, and QT intervals reflect the length of time it takes for the impulse to travel from one area of the heart to another.

The electrical impulse travels from the atria to the atrioventricular node. The excitation then moves through the bundle of His and the left and right bundle branches. The left bundle branch has an anterior and a posterior fascicle. The action potential diffuses widely through the walls of both ventricles by means of *Purkinje fibres.* The efficient ventricular conduction system delivers the impulse within 0.12 second. This triggers a uniform ventricular contraction.

The cardiac cycle starts with depolarization of the sinoatrial node. The cycle's climax is ejection of blood into the pulmonary and systemic circulations. It ends with repolarization, when the contractile fibre cells and the conduction pathway cells regain their resting polarized condition. Cardiac muscle cells have a compensatory mechanism that makes them unresponsive or refractory to re-stimulation during the action potential. During systole, there is an absolute refractory period during which cardiac muscle does not respond to any stimuli. After this period, cardiac muscle gradually recovers its excitability and a relative refractory period occurs by early diastole.

Electrocardiography.

The electrical activity of the heart can be detected on the body surface and recorded on an electrocardiogram (ECG). The letters *P, QRS, T,* and *U* are used to identify the separate waveforms (see Figure 34-4, *B*). The first wave, P, begins with the firing of the sinoatrial node and represents depolarization of the fibres of the atria. The QRS wave represents depolarization from the atrioventricular node throughout the ventricles. There is a delay of impulse transmission through the atrioventricular node that accounts for the time sequence between the end of the P wave and the beginning of the QRS wave. The T wave represents repolarization of the ventricles. The U wave, if present, represents delayed ventricular repolarization and may be associated with electrolyte imbalance (i.e., hypokalemia, hypomagnesemia, hypercalcemia) and is most typically observed in different types of bradycardia.

Intervals between these waves (PR, QRS, and QT intervals) reflect the length of time it takes for the impulse to travel from one area of the heart to another. These time intervals have been referenced, and deviations from these time references often indicate the presence of pathological conditions (Aehlert, 2013).

Mechanical System.

Depolarization triggers mechanical activity. **Systole,** contraction of the myocardium, results in ejection of blood from the cardiac chamber. Relaxation of the myocardium, **diastole,** allows for filling of the chamber. **Cardiac output (CO)** is the measurement of the heart's mechanical efficiency. CO is the amount of blood pumped by each ventricle in 1 minute. To calculate CO, the amount of blood ejected from the ventricle with the heartbeat—the stroke volume (SV)—is multiplied by the heart rate (HR) per minute:

$$CO = SV \times HR$$

For a normal adult at rest, CO is maintained in the range of 4 to 8 L/minute. **Cardiac index** is the CO divided by the body mass index (BMI). A measure of the CO of a patient per square metre of body surface area, the cardiac index adjusts the CO to the body size. The normal cardiac index is 2.8 to 4.2 L/minute/m^2.

Factors Affecting Cardiac Output.

Numerous factors can affect either the HR or the SV and thus the CO. The HR is regulated primarily by the autonomic nervous system. The factors affecting the SV are preload, contractility, and afterload (Huether & McCance, 2012). Increases in preload, contractility, and afterload increase the workload of the myocardium, which results in increased oxygen demand.

The volume of blood in the ventricles at the end of diastole, before the next contraction, is called **preload.** Preload determines the amount of stretch placed on myocardial fibres. According to Starling's law, to a point, the more the fibres are stretched (i.e., the greater the preload), the greater is their force of contraction, or contractility.

Contractility can be increased by norepinephrine, released by the sympathetic nervous system, as well as by epinephrine. Increasing contractility raises the SV by increasing ventricular emptying.

Afterload is the peripheral resistance against which the left ventricle must pump. Afterload is affected by the size of the ventricle, the wall tension, and the arterial blood pressure. If the arterial blood pressure is elevated, the ventricles meet increased resistance to ejection of blood, which increases the work demand. Eventually, this results in ventricular hypertrophy (enlargement of the cardiac muscle tissue without an increase in the size of cavities).

Cardiac Reserve.

The cardiovascular system must respond to numerous situations in health and illness (e.g., exercise, stress, hypovolemia). The ability of the heart to respond to these demands by increasing CO as much as three-fold or four-fold is termed **cardiac reserve.**

The increase in CO results from an increase in HR or SV. The HR can increase to as high as 180 beats per minute for short periods without deleterious effects. The SV can be increased by an increase in either preload or contractility.

Vascular System

Blood Vessels.

The three major types of blood vessels in the vascular system are the arteries, the veins, and the capillaries. Arteries carry blood away from the heart and, except for the pulmonary artery, carry oxygenated blood. Veins

carry blood toward the heart and, except for the pulmonary veins, carry deoxygenated blood. Small branches of arteries and veins are arterioles and venules, respectively. Blood circulates from the heart into arteries, arterioles, capillaries, venules, and veins and back to the heart.

Arteries and Arterioles.

The arterial system differs from the venous system by the amount and type of tissue that makes up arterial walls (Figure 34-5). The large arteries have thick walls that are composed mainly of elastic tissue. This elastic property cushions the vessels against the impact of the pressure created by ventricular contraction, and it provides recoil that propels blood forward into the circulation. Large arteries also contain some smooth muscle. Examples of large arteries are the aorta and the pulmonary artery.

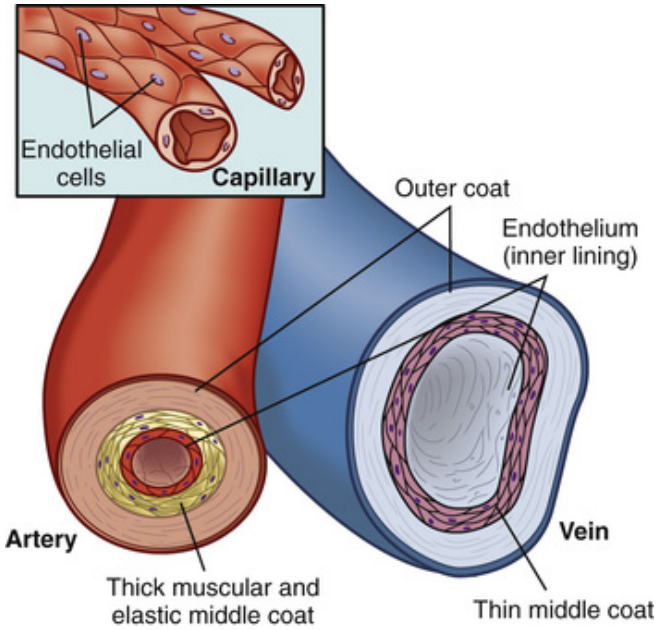

FIGURE 34-5 Comparative thicknesses of layers of an artery, a vein, and a capillary.

Arterioles have relatively little elastic tissue and more smooth muscle. Arterioles serve as the major control of arterial blood pressure and distribution of blood flow. They respond readily to local conditions, such as low O_2 and increasing levels of CO_2, by dilating or constricting.

Capillaries.

The thin capillary wall is made up of endothelial cells, with no elastic or muscle tissue (see Figure 34-5). There are many kilometres of capillaries in an adult. The exchange of cellular nutrients and metabolic end products takes place through these thin-walled vessels.

Veins and Venules.

Veins are large-diameter, thin-walled vessels that return blood to the right atrium (see Figure 34-5). The venous system is a low-pressure, high-volume system. The larger veins contain semilunar valves at intervals to maintain the blood flow toward the heart and to prevent backward flow. The amount of blood in the venous system is affected by a number of factors, including arterial flow, compression of veins by skeletal muscles, alterations in thoracic and abdominal pressures, and right atrial pressure.

The largest veins are the superior vena cava, which returns blood to the heart from the head, neck, and arms, and the inferior vena cava, which returns blood to the heart from the lower part of the body. These large-diameter vessels are affected by the pressure in the right side of the heart. Elevated right atrial pressure can cause neck veins to become distended or the liver to become engorged as a result of resistance to blood flow.

Venules are relatively small vessels made up of a small amount of muscle and connective tissue. Venules collect blood from various capillary beds and channel it to the larger veins.

Regulation of the Cardiovascular System

Autonomic Nervous System.

The autonomic nervous system consists of the sympathetic nervous system and the parasympathetic nervous system.

Effect on the Heart.

Stimulation of the sympathetic nervous system increases the HR, the speed of impulse conduction through the atrioventricular node, and the force of atrial and ventricular contractions. This effect is mediated by specific sites in the heart called *β-adrenergic receptors* that are receptors for norepinephrine and epinephrine.

In contrast, stimulation of the parasympathetic system (mediated by the vagus nerve) causes a decrease in HR by the action on the sinoatrial node and slows conduction through the atrioventricular node.

Effect on the Blood Vessels.

The source of neural control of blood vessels is the sympathetic nervous system. The α-adrenergic receptors are located in vascular smooth muscles. Stimulation of the α-adrenergic receptors results in vasoconstriction. Decreased stimulation to the α-adrenergic receptors causes vasodilation. (Sympathetic nervous system receptors that influence blood pressure are presented in Chapter 35, Table 35-1.)

The parasympathetic nerves have selective distribution in the blood vessels. Blood vessels in skeletal muscle do not receive parasympathetic input.

Baroreceptors.

Baroreceptors in the aortic arch and the carotid sinus (at the origin of the internal carotid artery) are sensitive to stretch or pressure within the arterial system. Stimulation of these receptors sends information to the vasomotor centre in the brainstem. This results in temporary inhibition of the sympathetic nervous system and enhancement of the parasympathetic influence, which cause a decrease in HR and peripheral vasodilation. Decreased arterial pressure causes the opposite effect.

Chemoreceptors.

Chemoreceptors are located in the aortic arch and the carotid bodies. They are capable of initiating changes in HR and arterial pressure in response to decreased arterial O_2 pressure, increased arterial CO_2 pressure, and decreased plasma pH. When the chemoreceptor reflexes in the medulla are triggered, they stimulate the vasomotor centre to increase blood pressure and, in turn, to increase cardiac activity (Huether & McCance, 2012).

Blood Pressure

The **arterial blood pressure (BP)** is a measure of the pressure exerted by blood against the walls of the arterial system. The **systolic blood pressure (SBP)** is the peak pressure exerted against the arteries when the heart contracts. The **diastolic blood pressure (DBP)** is the residual pressure of the arterial system during ventricular relaxation. BP is usually expressed as the ratio of SBP to DBP.

The two main factors influencing BP are CO and systemic vascular resistance (SVR):

$$BP = CO \times SVR$$

SVR is the force opposing the movement of blood. This force is created primarily in small arteries and arterioles.

Measurement of Arterial Blood Pressure.

BP can be measured by invasive and noninvasive techniques. The invasive technique consists of catheter insertion into an artery. The catheter is attached to a recording device, and the pressure is measured directly (see Chapter 68).

Noninvasive, indirect measurement of BP can be done with a sphygmomanometer and a stethoscope. The sphygmomanometer consists of an inflatable cuff and a pressure gauge or an electronic cuff. The examiner measures BP externally by listening for sounds of turbulent blood flow through a compressed artery (termed **Korotkoff sounds**). The brachial artery is the usual site for measuring BP (Jarvis, Browne, MacDonald-Jenkins, et al., 2014).

After the appropriate-size cuff is placed on the extremity, the cuff is inflated to a pressure in excess of the SBP. This causes blood flow in the artery to cease. As the pressure in the cuff is lowered, the artery is auscultated for Korotkoff sounds. There are five phases of Korotkoff sounds. The first phase is a tapping sound caused by the spurt of blood into the constricted artery as the pressure in the cuff is gradually deflated. The pressure when this sound is heard is considered the SBP. The fifth phase occurs when the sound disappears, and this pressure is known as the DBP (Jarvis, Browne, MacDonald-Jenkins, et al., 2014). Clinically, the BP is recorded as SBP/DBP (e.g., 120/80 mm Hg). On occasion, an auscultatory gap is heard. An auscultatory gap is a loss of sound between the SBP and the DBP. The BP could be measured incorrectly if the cuff is not inflated to exceed the true SBP.

In addition to the manual technique, another noninvasive way to measure BP indirectly is to use automatic BP monitors (see Chapter 35). The monitor consists of a BP cuff and a lightweight microprocessing unit. This system, which records a patient's BP at preset intervals during routine activities over 24 to 48 hours, enables ambulatory BP monitoring and may help clinicians diagnose hypertension more accurately in some patients.

Pulse Pressure and Mean Arterial Pressure.

Pulse pressure is the difference between the SBP and the DBP. Normally it is approximately one-third of the SBP. If the BP is 120/80 mm Hg, the normal pulse pressure is 40 mm Hg. The pulse pressure may be elevated during exercise or in individuals with atherosclerosis of the larger arteries because of increased SBP. The pulse pressure may be decreased in cardiac failure or hypovolemia.

Another measurement related to BP is **mean arterial pressure.** It is not the average of the DBP and SBP because the duration of diastole exceeds that of systole at normal HRs. To calculate mean arterial pressure, the DBP is added to one-third of the pulse pressure:

$$\text{Mean arterial pressure} = \text{DBP} + \tfrac{1}{3}\ \text{Pulse pressure}$$

A person with a BP of 120/60 mm Hg has a mean arterial pressure of 80 mm Hg.

Age-Related Considerations

Effects of Aging on the Cardiovascular System

One of the greatest risk factors for cardiovascular disease is age. Cardiovascular disease remains the leading cause of death in adults older than 85 years. It is the most common cause of hospitalization and the second leading cause of death in adults younger than age 85. The most common cardiovascular problem is coronary artery disease (CAD) secondary to atherosclerosis. It is difficult to distinguish normal aging changes from the pathophysiological changes of atherosclerosis. Many of the physiological changes in the cardiovascular system of older adults are a result of the combined effects of the aging process, disease, environmental factors, and lifetime health behaviours, rather than just age alone (North & Sinclair, 2012).

Age-related changes in the cardiovascular system and differences in assessment findings are presented in Table 34-1. With increased age, the amount of collagen in the heart increases and that of elastin decreases. These changes affect the myocardium's ability to stretch and contract. One of the major changes in the cardiovascular system is the response to physical or emotional stress. In times of increased stress, CO and SV decrease because of reduced contractility and HR response. The resting supine HR is not markedly affected by aging. When an older adult changes positions (e.g., sits upright), the sympathetic nerve pathway may be affected by fibrous tissue and fatty deposits, manifested as a blunted HR response (North & Sinclair, 2012).

TABLE 34-1

AGE-RELATED DIFFERENCES IN ASSESSMENT
Cardiovascular System

Changes	Differences in Assessment Findings
Chest Wall	
Kyphosis	Altered chest landmarks for palpation, percussion, and auscultation; distant heart sounds
Heart	
Myocardial hypertrophy, ↑ collagen and scarring, ↓ elastin	↓ Cardiac reserve, slight ↓ HR
Downward displacement	Difficulty in isolating apical pulse
↓ CO, HR, and SV in response to exercise or stress	Slowed, ↓ response to stress; slowed recovery from activity
Cellular aging changes and fibrosis of conduction system	↓ Amplitude of QRS complex and lengthening of PR, QRS, and QT intervals; left axis deviation; irregular cardiac rhythms
Valvular rigidity from calcification, sclerosis, or fibrosis, impeding complete closure of valves	Systolic murmur (aortic or mitral) possible without being indication of cardiovascular disease
Blood Vessels	
Arterial stiffening caused by loss of elastin in arterial walls, thickening of intima of arteries, and progressive fibrosis of media	Elevation in systolic and possibly diastolic BP (e.g., 160/90 mm Hg); possibly, widened pulse pressures; more pronounced arterial pulses; diminished pedal pulses

BP, blood pressure; *CO*, cardiac output; *HR*, heart rate; *SV*, stroke volume.

Cardiac valves become thicker and stiffer from lipid accumulation, degeneration of collagen, and fibrosis. The aortic and mitral valves are most frequently affected. These changes result in either regurgitation of blood when the valve should be closed or narrowing of the orifice of the valve (stenosis) when the valve should be open. The turbulent blood flow across the affected valve results in a murmur.

The number of pacemaker cells in the sinoatrial node decreases with age. By age 75, a person may have only 10% of the normal number of pacemaker cells. Although this is compatible with adequate sinoatrial node function, it may account for the frequency of some sinus dysrhythmias in older adults. Similar decreases also occur in the number of conduction cells in the internodal tracts, bundle of His, and bundle branches. These changes contribute to the development of atrial dysrhythmias and heart blocks. The autonomic nervous system control of the cardiovascular system changes with aging. The number and function of β-adrenergic receptors in the heart decrease with age. So the older adult not only has a decreased response to physical and emotional stress, but also is less sensitive to β-adrenergic agonist drugs. The lower maximum HR during exercise results in only a two-fold increase in CO, in contrast to the three- or four-fold increase observed in younger adults.

Arterial and venous blood vessels thicken and become less elastic with age. Arteries increase their sensitivity to vasopressin (antidiuretic hormone). With aging, both of these changes contribute to a progressive increase in SBP and a decrease or no change in DBP. Thus an increase in the pulse pressure is found. Hypertension is not a normal consequence of aging and should be treated. Valves in the large veins in the lower extremities have a reduced ability to return the blood to the heart, which often results in dependent edema.

Orthostatic hypotension, which is estimated to be present in more than 30% of patients older than 70 years with systolic hypertension, may be related to medications, decreased baroreceptor function, or both. *Postprandial hypotension* (decrease in BP of at least 20 mm Hg that occurs within 75 minutes after eating) may also occur in about a third of otherwise healthy older adults. Both orthostatic and postprandial hypotension may be related to falls in older adults. Despite the changes associated with aging, the heart is able to function adequately under most circumstances.

Age-related changes in the cardiovascular system and differences in assessment findings are presented in Table 34-1.

Case Study

Patient Introduction

Source: ESB Professional/Shutterstock.com.

Lawrence Tan, a 63-year-old man, is brought to the emergency department by ambulance at 0600 hours after calling 911 with complaints of chest pain, shortness of breath, palpitations, and dizziness. The paramedics have started an intravenous infusion and administered

oxygen at 2 L/min via nasal cannula. They also administered four chewable baby acetylsalicylic acid (ASA) and a nitroglycerin tablet, and they obtained a 12-lead ECG. Mr. Tan is pain free on arrival but still complains of palpitations and dizziness.

Critical Thinking

Throughout this assessment chapter, think about Mr. Tan's symptoms with the following questions in mind:

1. What are the possible causes of Mr. Tan's chest pain, shortness of breath, palpitations, and dizziness?
2. What would be the nurse's priority assessment of Mr. Tan?
3. What questions would the nurse ask Mr. Tan?
4. What should be included in the physical assessment? What would the nurse be looking for?
5. What diagnostic studies would the nurse expect to be ordered?

See pp. 777 and 786 for more information on Mr. Tan.

Assessment of the Cardiovascular System

Subjective Data

A careful health history and physical examination (Table 34-2) should aid the nurse in distinguishing symptoms that reflect a cardiovascular problem from those that reflect problems of other body systems. For instance, it is important to determine whether weight gain results from overeating or is a manifestation of fluid retention.

TABLE 34-2

HEALTH HISTORY
Cardiovascular System—Questions for Obtaining Subjective Data

Chest Pain
• Do you have any chest pain or discomfort? Please show me where it is. • Is the pain in one spot, or does it move around? • How long have you had this pain? • Does it come and go, or is it constant? Does it get worse before or after meals? When is the pain worst (e.g., with a certain position or activity, with stress)? • Can you describe how it feels (e.g., burning, stabbing, aching, heaviness, squeezing)? • What brings the pain on (e.g., activity, stress)? • Do any other symptoms occur when you get the pain (e.g., shortness of breath, weakness, nausea, vomiting)?* • What works to relieve the pain (e.g., rest, change of position, medication)?*
Dyspnea
• Have you experienced any shortness of breath? If yes, what kind of activity precipitates your shortness of breath? • Is your shortness of breath dependent on your position (e.g., lying down)?* • How does the shortness of breath affect your daily activities?*
Orthopnea
• How many pillows do you sleep on at night? Has this number changed recently?*
Cough
• Do you have a cough? If yes, describe the duration, the frequency, and the kind of cough (e.g., dry, hoarse, congested). • Do you cough up mucus? If yes, describe the colour and the amount. • Is coughing associated with any activity such as talking, lying down, stress, and so on?* • Is the coughing relieved by anything (e.g., walking, exercise, rest, medication)?*
Fatigue
• Do you tire easily?* If yes, when did you notice a change in your level of fatigue? • Is your energy level related to the time of the day?*
Cyanosis or Pallor
• Have you ever noticed a bluish or ashen colour to your face?*
Edema
• Have you ever noticed any swelling in your feet and legs?* • When did you first experience swelling, and have there been any recent changes?* • Are both feet swollen to the same degree?*
Nocturia
• How many times a night do you awaken to urinate?*
Cardiac History
• Do you have any past history of hypertension, elevated cholesterol or triglycerides, heart murmur, congenital heart diseases, rheumatic fever or unexplained joint pains in your youth, recurrent tonsillitis, or anemia? • Do you have any history of heart disease?* • When was your last ECG, serum cholesterol blood work, or other heart-related tests?*
Family History
• Do you have any family history of heart disease, high blood pressure, obesity, diabetes, or sudden death at a young age?*
Self-Care History
• Describe your usual daily diet, including sodium and fluid intake. What is your current weight? What was your weight 1 year ago? • Have you ever used tobacco? If yes, in what form, how much, and for how long? Have you ever tried to quit? If yes, what methods have you tried? • How often do you drink alcohol, and how much? Have you ever been told that you have a problem with alcohol?* • What is your usual amount of exercise per week? • Do you take any cardiac medications (e.g., antihypertensives, diuretics, aspirin, anticoagulants), over-the-counter medications, herbal products, or street drugs?*

*If yes, describe.

ECG, electrocardiogram.

Source: Adapted from Jarvis, C., Browne, A. J., MacDonald-Jenkins, J., & Luctkar-Flude, M. (2014). *Physical examination & health assessment* (2nd Canadian ed., pp. 303–305). Toronto: Elsevier Canada.

Important Health Information

History of Current Illness.

The nurse should ask the patient what problem has brought him or her to the health care facility or provider and should fully explore all symptoms the patient is experiencing.

Past Health History.

Many illnesses affect the cardiovascular system directly or indirectly. The patient should be questioned about a history of chest pain, shortness of breath, alcoholism or excessive drinking, anemia, rheumatic fever, streptococcal sore throat, congenital heart disease, stroke, syncope, hypertension, thrombo-phlebitis, intermittent claudication, varicosities, obesity, and edema.

Medications.

An assessment of the patient's current and past use of medications should be made. This includes both over-the-counter drugs and prescription drugs. For example, acetylsalicylic acid (ASA; Aspirin), which prolongs the blood clotting time, is contained in many drugs used to alleviate cold symptoms.

A medication assessment should list the name of the drug and the patient's understanding of its purpose and adverse effects. Drugs that may adversely affect the cardiovascular system should also be assessed. Some of these and examples of their effects on the cardiovascular system are listed in Table 34-3.

TABLE 34-3

CARDIOVASCULAR EFFECTS OF NONCARDIAC DRUGS*

Drug Classification	Examples	Cardiovascular Effects
Anticancer agents	Daunorubicin (Cerubadine) Doxorubicin (Caelyx)	Dysrhythmias, cardiomyopathy
Antipsychotics	Chlorpromazine Haloperidol	Dysrhythmias, orthostatic hypotension
Corticosteroids	Cortisone Prednisone	Hypotension, edema, potassium depletion
Hormone therapy, oral contraceptives	Estrogen + progestin (Climara Pro)	Myocardial infarction, thrombo-embolism, stroke, hypertension
Nonsteroidal anti-inflammatory drugs (NSAIDs)†	Ibuprofen (Motrin) Celecoxib (Celebrex)	Hypertension, myocardial infarction, stroke
Psychostimulants	Cocaine Amphetamines	Tachycardia, angina, myocardial infarction, hypertension, dysrhythmias
Tricyclic antidepressants	Amitriptyline (Elavil) Doxepin (Sinequan, Silenor)	Dysrhythmias, orthostatic hypotension

*List is not all-inclusive.

†Second-generation NSAIDs, known as cyclo-oxygenase 2 (COX-2) inhibitors, have been linked to an increased risk of serious adverse cardiovascular events.

Surgery or Other Treatments.

The patient should also be asked about specific treatments, past surgical procedures, and hospital admissions related to cardiovascular problems. Any hospitalizations for diagnostic workups or cardiovascular symptoms should be explored. It should be noted whether an ECG or a chest radiograph was obtained for baseline data.

Case Study

Subjective Data

Source: ESB Professional/Shutterstock.com.

A focused subjective assessment of Lawrence Tan revealed the following information:

- ***Past Medical History:*** History of hypertension, mitral valve prolapse with mild regurgitation, heart failure, and type 2 diabetes mellitus.
- ***Medications:*** Lisinopril (Prinivil), 10 mg/day PO; metoprolol (Lopresor), 50 mg PO bid; ASA, 325 mg/day PO; furosemide (Lasix), 40 mg/day PO; and metformin (Glucophage), 500 mg PO qid.
- ***Current History:*** Mr. Tan denies any previous history of chest pain or CAD. He was feeling fine until this morning, when he awoke and experienced shortness of breath, chest pain, palpitations, and dizziness while walking to the bathroom. He became frightened that he was having a heart attack, so he called 911. Denies smoking or alcohol intake. Shortness of breath and chest pain are now gone, but he continues to feel palpitations and dizziness when he sits up.
- Denies any edema. States he takes Lasix in the morning and typically "pees until lunchtime." Denies nocturia.

See pp. 777 and 786 for more information on Mr. Tan.

Objective Data

Physical Examination

Vital Signs.

After the patient's general appearance has been observed, vital signs—including BP, heart and respiratory rate, and temperature—are measured. The BP should be measured while the patient is sitting, lying, and standing. An appropriate cuff size should be used for accurate readings. Normally, there is a reduction of up to 15 mm Hg in the SBP and 3 to 5

mm Hg in the DBP in the standing position. BP measurements should be taken in both arms. These readings may vary by 5 to 15 mm Hg. BP in the lower extremities is expected to be about 10 mm Hg higher than in the upper extremities.

Peripheral Vascular System

Inspection.

The skin colour, hair distribution, and venous blood flow provide information about arterial blood flow and venous return. The extremities should be inspected for conditions such as edema, thrombo-phlebitis, varicose veins, and lesions such as stasis ulcers. Edema in the extremities can be caused by gravity, interruption of venous return, or elevation of right atrial pressure.

A measure used for assessing arterial flow to the extremities is the *capillary filling time.* The patient's nail beds are squeezed to produce blanching and are observed for the return of colour. When arterial capillary perfusion is normal, the colour returns within 3 seconds.

The large veins in the neck (internal and external jugular) should be inspected while the patient is gradually elevated to an upright position. Distension and prominent pulsations of these neck veins can be caused by right atrial pressure elevation.

Palpation.

Palpation of the pulses in the neck and extremities also provides information on arterial blood flow. The pulses should be palpated to assess the volume and pressure within each vessel. Characteristics of the arteries on the right and left sides of the body should be compared. It is important to palpate each carotid pulse separately to avoid vagal stimulation and subsequent dysrhythmias.

When palpating the arteries identified in Figure 34-6, the assessor should note the pressure of the pulse wave, or how far the vessel wall distends when the pulse occurs. This judgement of the pulsation volume is recorded as normal, bounding, thready, or absent. A scale may be used to document pulse volume or amplitude (Jarvis, Browne, MacDonald-Jenkins, et al., 2014):

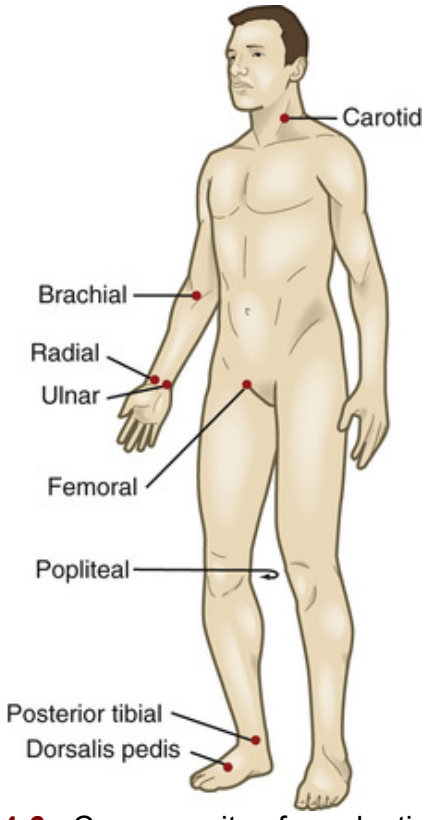

FIGURE 34-6 Common sites for palpating arteries.

0: Absent
1+: Weak, thready
2+: Normal
3+: Full, bounding

The *rigidity* (hardness) of the vessel should also be noted. The normal pulse feels as if it is tapping, whereas a vessel wall that is narrowed or bulging vibrates. A term for a palpable vibration is *thrill.*

Auscultation.

An artery that has a narrowed or bulging wall may cause blood flow to be turbulent. This abnormal flow can sound like a buzzing or humming, termed a *bruit.* It can be heard with a stethoscope placed over the vessel. Auscultation of major arteries such as the carotid arteries, the abdominal aorta, and the femoral arteries should be part of the initial cardiovascular assessment. Abnormalities of the cardiovascular system are described in Table 34-4.

TABLE 34-4

ASSESSMENT ABNORMALITIES
Cardiovascular System

Finding	Description	Possible Etiology and Significance*
Inspection		
Distended neck veins	Vertical distance between intersection of angle of Louis and level of jugular distension >3 cm with patient sitting at 30- to 45-degree angle	Elevated right atrial pressure; right-sided heart failure
Central cyanosis	Bluish or purplish tinge in central areas such as tongue, conjunctivae, inner surface of lips	Inadequate O_2 saturation of arterial blood as result of pulmonary or cardiac disorders (e.g., congenital defects)
Peripheral cyanosis	Bluish or purplish tinge in extremities or nose and ears	Reduced blood flow because of heart failure, vasoconstriction, cold environment
Splinter hemorrhages	Small red to black streaks under fingernails	Infective endocarditis (infection of endocardium, usually in area of cardiac valves)
Clubbing of nail beds	Obliteration of normal angle between base of nail and skin	Endocarditis, congenital defects, prolonged O_2 deficiency
Colour changes in extremities with postural change	Pallor, cyanosis, mottling of skin after limb elevation; glossy skin	Chronic decreased arterial perfusion
Ulcers	*Venous:* necrotic crater-like lesions usually found on lower leg at medial malleolus; characterized by slow wound healing *Arterial:* lesions with pale ischemic base and well-defined edges; usually found on toes, heels, lateral malleoli	Poor venous return, varicose veins, incompetent venous valves; arteriosclerosis, diabetes
Varicose veins	Visible dilated, tortuous vessels in lower extremities	Incompetent valves in vein
Palpation		
Pulse		
Bounding	Sharp, brisk, pounding pulse	Hyperkinetic states (anxiety, fever), anemia, hyperthyroidism
Thready	Weak, slowly rising pulse; easily obliterated by pressure	Blood loss, decreased cardiac output, aortic valve disease, peripheral arterial disease
Irregular	Regularly irregular or irregularly irregular; skipped beats	Cardiac dysrhythmias
Pulsus alternans	Regular rhythm, but strength of pulse varies with each beat	Heart failure
Absent	Lack of pulse	Atherosclerosis, thrombus, trauma, embolus
Thrill	Vibration of vessel or chest wall	Aneurysm, aortic regurgitation, arteriovenous fistula
Rigidity	Stiffness or inflexibility of vessel wall	Atherosclerosis
>100 bpm	Tachycardia	May be exercise-induced; may reflect anxiety or shock; may indicate need for increased cardiac output, hyperthyroidism
<60 bpm	Bradycardia	May be rest-induced; SA or AV node damage, athletic conditioning, adverse effect of drugs (e.g., β-adrenergic blockers), hypothyroidism
Displaced point of maximal impulse (apical pulse)	Point of maximal impulse is palpated (or auscultated) below the fifth ICS and to the left of the MCL	Left ventricular dilation
Extremities		

Finding	Description	Possible Etiology and Significance*
Unusually warm extremities	Hands and feet warmer than normal	Possible thyrotoxicosis
Cold extremities	Hands or feet, or both, cold to touch; external covering necessary for comfort	Intermittent claudication, peripheral arterial obstruction, low cardiac output, severe anemia
Pitting edema of lower extremities or sacral area	Visible finger indentation after application of firm pressure	Interruption of venous return to heart, fluid in tissues
Positive Homans sign	Presence of calf pain during sharp dorsiflexion of foot	Thrombo-phlebitis
Abnormal capillary filling time	Blanching of nail bed for >3 sec after release of pressure	Reduced arterial capillary perfusion, anemia
Asymmetry in limb circumference	Measurable swelling of involved limb	Thrombo-phlebitis, varicose veins, lymphedema
Percussion		
Abnormal cardiac borders	Left border of cardiac dullness extends beyond MCL in fifth ICS; right border of cardiac dullness extends beyond sternal border	Cardiac enlargement due to coronary heart disease, heart failure, cardiomyopathy
Auscultation		
Pulse deficit	Apical heart rate exceeds the peripheral pulse rate	Cardiac dysrhythmias
Arterial bruit	Turbulent flow sound in peripheral artery	Arterial obstruction or aneurysm
Third heart sound (S_3)	Extra heart sound, low-pitched, heard in early diastole, similar to sound of a gallop	Left ventricular failure; volume overload; mitral, aortic, or tricuspid regurgitation; hypertension (possible)
Fourth heart sound (S_4)	Extra heart sound, low-pitched, heard in late diastole, similar to sound of a gallop	Forceful atrial contraction from resistance to ventricular filling (e.g., in left ventricular hypertrophy, aortic stenosis, hypertension, coronary artery disease)
Cardiac murmurs	Turbulent sounds occurring between normal heart sounds; characterized by loudness, pitch, shape, quality, duration, timing	Cardiac valve disorder, abnormal blood flow patterns
Pericardial friction rub	High-pitched, scratchy sound heard during S_1 or S_2 or both at the apex; heard best with patient sitting and leaning forward, and at the end of expiration	Pericarditis

*Limited to common etiological factors. (Further discussion of conditions listed may be found in Chapters 35 through 40 and 68.)

AV, atrioventricular; *bpm,* beats per minute; *ICS,* intercostal space; *MCL,* midclavicular line; *SA,* sinoatrial.

Thorax

Inspection and Palpation.

An overall inspection and palpation of the bony structures of the thorax is the initial step in the examination.

Next, the areas where the cardiac valves project their sounds are inspected and palpated by identifying the intercostal spaces (ICSs). The

raised notch, the angle of Louis, where the manubrium and the body of the sternum are joined, is readily palpable in the midline of the sternum. The angle of Louis is at the level of the second rib and can therefore be used to count ICSs and locate specific auscultatory areas.

The following auscultatory areas can be located (Figure 34-7): The aortic area, in the second ICS to the right of the sternum; the pulmonic area, in the second ICS to the left of the sternum; the tricuspid area, in the fifth left ICS close to the sternum; and the mitral area, in the left midclavicular line (MCL) at the level of the fifth ICS. A fifth auscultatory area is Erb point, located at the third left ICS near the sternum. Normally, no pulsations are felt in these areas unless the patient has a thin chest wall.

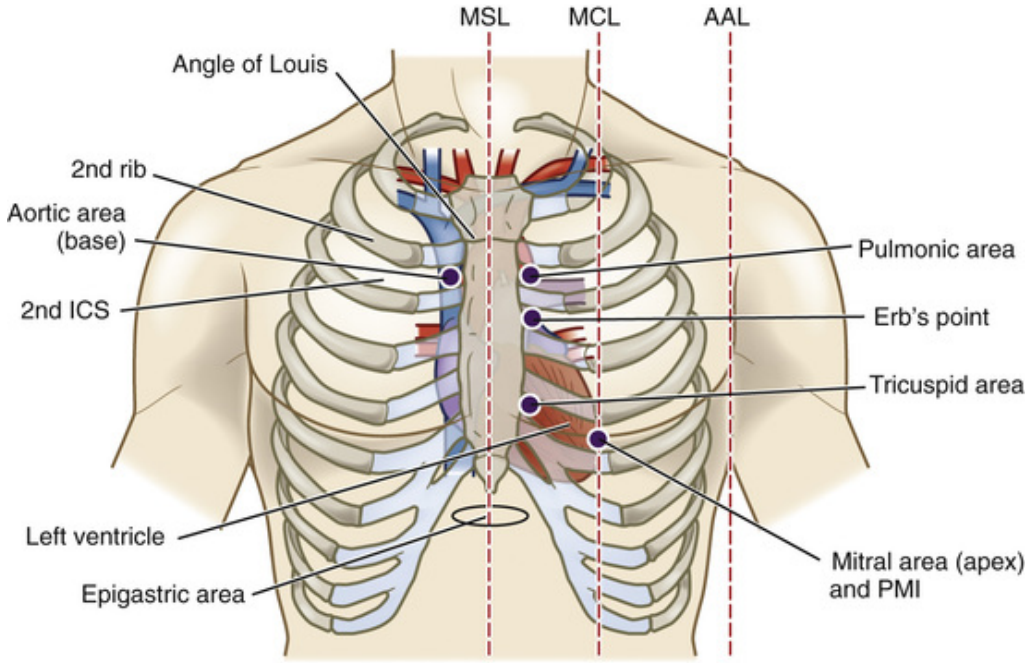

FIGURE 34-7 Orientation of the heart within the thorax and cardiac auscultatory areas. *Red lines* indicate the midsternal line (*MSL*), midclavicular line (*MCL*), and anterior axillary line (*AAL*). *ICS*, intercostal space; *PMI*, point of maximal impulse.

A valvular disorder may be suspected if abnormal pulsations or thrills are felt. Next, the epigastric area, which lies on either side of the midline just below the xiphoid process, is inspected and palpated. In a thin person, the pulsation of the abdominal aorta may be visible and can normally be palpated here. Next, the precordium, which is located between the apex and the sternum, is inspected for heaves. **Heaves** are sustained lifts of the chest wall in the precordial area that can be seen or palpated. They may be

caused by left ventricular enlargement. Normally, no pulsations are seen or felt in the precordial area.

When the patient is recumbent, the mitral valve area at the apex of the heart is inspected and palpated for the **point of maximal impulse** (PMI), the site of strongest pulsation. This pulsation or ventricular thrust lies within the MCL in the fifth ICS. If the PMI is palpable, its position is recorded in relation to the MCL and ICSs. When the PMI is to the left of the MCL, the heart may be enlarged.

Percussion.

The borders of the right and left sides of the heart can be estimated by percussion. The nurse stands to the right of the recumbent patient and percusses along the curve of the rib in the fourth and fifth ICSs, starting at the midaxillary line. The percussion note over the heart is dull in comparison with the resonance over the lung and is recorded in relation to the MCL.

Auscultation.

The movement of the cardiac valves creates some turbulence in the blood flow; the resulting heart sounds are normal (Figure 34-8). These sounds can be heard through a stethoscope placed on the chest wall. The first heart sound (S_1), which is associated with the closure of the tricuspid and mitral (atrioventricular) valves, sounds like a soft "lubb." The second heart sound (S_2), which is associated with the closure of the aortic and pulmonic (semilunar) valves, sounds like a sharp "dupp." S_1 signals the beginning of systole. S_2 signals the beginning of diastole (Figure 34-8). The nurse should listen to the auscultatory areas in sequence with both the diaphragm and the bell of the stethoscope.

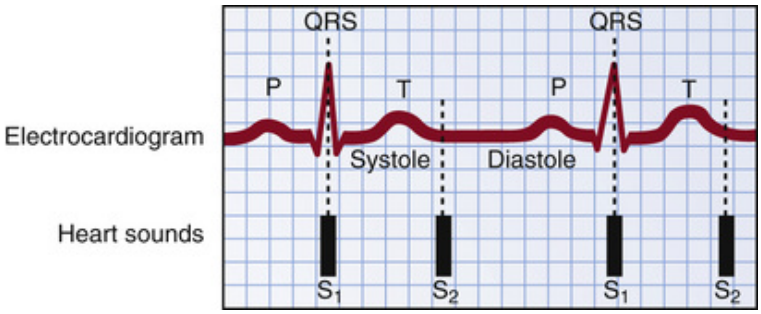

FIGURE 34-8 Relationship of electrocardiogram, cardiac cycle, and heart sounds (S_1, S_2).

S_1 and S_2 are heard best with the diaphragm of the stethoscope because they are high pitched. Extra heart sounds (S_3 or S_4), if present, are heard best with the bell of the stethoscope because they are low pitched. If the patient leans forward while sitting, sounds from the second ICSs (aortic and pulmonic areas) are accentuated, whereas in the left lateral decubitus position, sounds produced at the mitral area are accentuated.

The nurse listens at the apical area with the diaphragm of the stethoscope while simultaneously palpating the radial pulse. When fewer radial than apical pulses are counted, the difference between those numbers is called a *pulse deficit.* A judgement about the rhythm (regular or irregular) is also made when listening at the apex.

Palpating one carotid artery while auscultating it allows the examiner to distinguish between S_1 and S_2 and between systole and diastole. Because S_1 ("lubb") occurs almost simultaneously with ventricular ejection, it is heard when the carotid pulse is felt.

Normally, no sound is heard between S_1 and S_2 during the periods of systole and diastole. Sounds that are heard during these periods may represent abnormalities and should be described in the assessment. An exception to this is a normal splitting of S_2, which is best heard at the pulmonic area during inspiration. Splitting of this heart sound can be abnormal if it is heard during expiration or if it is constant (fixed) during the respiratory cycle.

S_3 is a low-intensity vibration of the ventricular walls usually associated with ventricular filling. S_3 may occur in patients with left ventricular failure or mitral valve regurgitation. It is heard closely after S_2 and is known as a *ventricular gallop.* S_4 is a low-frequency vibration caused by atrial contraction. It precedes S_1 of the next cycle and is known as an *atrial*

gallop. S_4 may occur in patients with CAD, left ventricular hypertrophy, or aortic stenosis.

Murmurs are sounds produced by turbulent blood flow through the heart or the walls of large arteries. Most murmurs are the result of cardiac abnormalities, but some occur in normal cardiac structures. Murmurs are graded on a six-point scale of loudness and recorded as a Roman numeral ratio: The numerator is the intensity of the murmur, and the denominator is always VI, which indicates that the six-point scale is being used. A grade I/VI murmur is soft and faint; a grade VI/VI murmur can be heard without a stethoscope.

If an abnormal sound is heard, it should be documented. The description should include the timing (during systole or diastole), the location (the site on the chest where it is heard the loudest), the pitch (heard best with the diaphragm or the bell of the stethoscope), the position (heard best when patient is recumbent, sitting and leaning forward, or in the left lateral decubitus position), the characteristic (harsh, musical, soft, short, long), and any other abnormal findings (irregular cardiac rhythms or palpable chest wall heaves) associated with the sound.

The most common abnormal sounds and abnormal assessment findings are described in Table 34-4. A method of recording data from the cardiovascular assessment is presented in Table 34-5.

TABLE 34-5

NORMAL FINDINGS IN THE PHYSICAL ASSESSMENT OF THE CARDIOVASCULAR SYSTEM

Inspection	Normal skin colour with capillary refill <3 sec; thorax symmetrical with no visible PMI; no JVD with patient at 45-degree angle
Palpation	PMI palpable in fifth ICS at MCL; no forceful pulsations, thrills, or heaves; slight palpable pulsations of abdominal aorta in epigastric area; carotid and extremity pulses 2+ and equal bilaterally; no evidence of impaired arterial flow or venous return in lower extremities
Percussion	Inability to distinguish right-sided heart border
Auscultation	S_1 and S_2 heard; HR, 72 and regular; no murmurs or extra heart sounds

HR, heart rate; *ICS*, intercostal space; *JVD*, jugular venous distension; *MCL*, midclavicular line; *PMI*, point of maximal impulse.

A focused assessment is used to evaluate the status of previously identified cardiovascular problems and to monitor for signs of new problems (see Table 3-6). A focused assessment of the cardiovascular system is presented in the "Focused Assessment" box afterwards.

Case Study

Objective Data: Physical Examination

Source: ESB Professional/Shutterstock.com.

Physical examination findings of Lawrence Tan are as follows:

- BP, 98/70; apical pulse rate, 164; pulse irregular; respiratory rate, 20; temperature, 36.8°C; O_2 saturation, 93% on room air
- Awake, alert, and oriented ×3
- Lungs clear on auscultation; systolic murmur present
- Cardiac monitor shows atrial fibrillation with a rapid ventricular response
- +1 pedal pulses bilaterally
- No peripheral edema, jugular venous distention, or heaves noted

Throughout this chapter, consider diagnostic studies the nurse would anticipate being ordered for Mr. Tan.

See pp. 772 and 786 for more information on Mr. Tan.

Focused Assessment

Cardiovascular System

Use this checklist to make sure the key assessment steps have been done.

Subjective

Ask the patient about any of the following, and note responses:

Chest pain or discomfort	Y	N
Shortness of breath (especially when lying down)	Y	N
Edema in legs or any part of body	Y	N
Leg pain during exercise	Y	N
Excess urination at night	Y	N
Palpitations	Y	N

Objective: Diagnostic

Check the following laboratory test results for critical values:

Hematocrit and hemoglobin	✓
Cardiac biomarkers (CK-MB, troponin)	✓
Electrocardiogram	✓

Objective: Physical Examination

Inspect and Palpate

Anterior chest wall for contour, lifts, and heaves	✓
Check pulses for symmetry, quality, and rhythm	✓

Auscultate

Blood pressure	✓
Heart for rate, rhythm, and sounds	✓

CK-MB, MB isoenzyme of creatine kinase.

Diagnostic Studies of the Cardiovascular System

Numerous diagnostic procedures add to the information obtained from the history and physical examination of the cardiovascular system. These procedures are usually classified as noninvasive or invasive. Procedures in which only a needle is inserted to withdraw blood or inject contrast media are usually considered noninvasive. Catheter insertion for angiography is considered an invasive procedure. The most common studies used to assess the cardiovascular system are presented in Table 34-6.

TABLE 34-6

DIAGNOSTIC STUDIES
Cardiovascular System

Study	Description and Purpose	Nursing Responsibility
Blood Studies*		
MB isoenzyme of creatine kinase (CK-MB)	Cardiospecific isoenzyme that is released in the presence of myocardial tissue injury. Concentrations >4%–6% of total CK are highly indicative of MI. Serum levels increase within 4–6 hr after MI.	Explain to patient the purpose of serial sampling (e.g., q6–8h tid) in conjunction with serial ECGs.
Troponin (cardiac-specific)	Contractile proteins that are released after an MI. Both troponin T and troponin I are highly specific to cardiac tissue. *Reference intervals:* **Troponin I (cTnI)** Negative: <0.5 mcg/L Indeterminate or suspicious for injury to myocardium: 0.5–2.3 mcg/L Positive for myocardial injury: >2.3 mcg/L (2.3 mcg/L) **Troponin T (cTnT)** <0.1 mcg/L	Rapid point-of-care (bedside) assays are available. Serial sampling is often done in conjunction with CK-MB measurements and ECGs.
Myoglobin	Low-molecular-weight protein that is 99%–100% sensitive for myocardial injury. Serum concentrations rise 30–60 min after MI. *Reference intervals:* Male: 15.2–91.2 mcg/L Female: 11.1–57.5 mcg/L	Myoglobin is cleared from the circulation rapidly, and the test is most diagnostic if measurements are made within first 12 hr of onset of chest pain.
C-reactive protein (CRP)	Marker of inflammation that can predict risk of cardiac disease and cardiac events, even in patients with normal lipid values. CRP assay is highly sensitive. Lowest risk: <1 mg/L Moderate risk: 1–3 mg/L High risk: >3 mg/L	CRP levels are stable and can be measured nonfasting and any time during the day. In women, CRP levels may be more predictive risk factor of cardiac disease than LDLs.
Homocysteine	Amino acid produced during protein catabolism that has been identified as a risk factor for cardiovascular disease. Homocysteine may cause damage to the endothelium or have a role in formation of thrombi. *Reference intervals:* Male: 5.2–12.9 micromoles/L Female: 3.7–10.4 micromoles/L	Hyperhomocysteinemia resulting from dietary deficiencies is treated with folic acid, vitamin B_6, and vitamin B_{12} supplements.
B-type natriuretic peptide (BNP)	Peptide that causes natriuresis. Elevation indicates presence of heart failure and may help distinguish cardiac vs. respiratory cause of dyspnea. *Reference intervals:* Levels <100 ng/L are diagnostic for heart failure	Continue to monitor for signs and symptoms of heart failure.
N-terminal–pro B-type natriuretic peptide (NT–pro-BNP)	Aids in assessing the severity of heart failure in symptomatic and asymptomatic patients. In patients with renal insufficiency, concentrations may increase and may not correlate with New York Heart Association functional classification of heart failure. *Reference intervals:* ≤74 yr: 124 pg/mL >75 yr: 449 pg/mL	
Serum Lipids		

Study	Description and Purpose	Nursing Responsibility
Cholesterol	A blood lipid. Elevated levels are considered a risk factor for atherosclerotic heart disease. *Reference interval:* <5 mmol/L (varies with age and gender)	Cholesterol levels can be measured in a nonfasting state.
Triglycerides	Mixtures of fatty acids. Elevations are associated with cardiovascular disease and diabetes. *Reference interval:* <1.7 mmol/L (varies with age and sex)	Triglyceride levels and lipoproteins must be measured in a fasting state (at least 12 hr, except for water); alcohol should be withheld for 24 hr before testing.
Lipoproteins† (HDL, LDL)	Soluble proteins that combine with and transport lipids in the plasma. Electrophoresis is performed to distinguish HDL from LDL. Serum lipid levels may fluctuate markedly from day to day. More than one determination is needed for accurate diagnosis and treatment. *Reference intervals* (vary with age): **HDL** • Recommended Male: >1.04 mmol/L Female: >1.3 mmol/L • Low risk for CAD: >1.55 mmol/L • High risk for CAD: <1.04 mmol/L **LDL** • Recommended: <2.59 mmol/L • Near optimal: 2.6–3.34 mmol/L • Moderate risk for CAD: 3.37–4.12 mmol/L • High risk for CAD: >4.14 mmol/L	After test is completed, risk for cardiac disease is assessed by dividing the total cholesterol level by the HDL level and obtaining a ratio. *Low risk:* Ratio <3 *Average risk:* Ratio 3–5 *Increased risk:* Ratio >5
Lipoprotein (a) (Lp[a])	Lipoprotein that contains one molecule of apolipoprotein B. Increased levels are associated with an increased risk of premature CAD and stroke. *Reference interval:* <0.3 g/L	Lp(a) levels can be obtained in a nonfasting state.
Lipoprotein-associated phospholipase A_2 (Lp-PLA_2)	Enzyme that catalyzes release of arachidonic acid. Elevated levels are associated with vascular inflammation and increased risk for CAD. Serum levels of Lp-PLA_2 are measured by the PLAC test. *Reference intervals:* *Low risk:* ≤151 nmol/min/mL *Moderate risk:* 152–194 nmol/min/mL *High risk:* ≥ 195 nmol/min/mL	Lp-PLA_2 levels can be obtained during a nonfasting state.
Chest Radiograph	X-ray imaging. Patient is placed in two upright positions to examine the lung fields and size of the heart. The two common positions are posteroanterior and lateral. Normal heart size and contour for the individual's age, sex, and size are noted.	The nurse should inquire about frequency of recent radiographic studies and possibility of pregnancy. Lead shielding is applied to areas not being viewed. Any jewellery or metal objects that may obstruct the view of the heart and lungs must be removed.
Electrocardiography (ECG)	Electronic graphing of cardiac activity. Electrodes are placed on the chest and extremities, allowing the ECG machine to record cardiac electrical activity from different views. This study can reveal rhythm of heart, activity of pacemaker, conduction abnormalities, position of heart, size of atria and ventricles, presence of injury, and history of MI.	The patient's skin is prepared, and electrodes and leads are applied. The nurse should inform patient that no discomfort is involved. Patient should be instructed to avoid moving, to decrease motion artifact.

Study	Description and Purpose	Nursing Responsibility
Signal-averaged electrocardiography (SAECG)	High-resolution ECG that can identify electrical activity called *late potentials* that indicate a patient is at risk for developing ventricular dysrhythmias (e.g., ventricular tachycardia).	Same as for ECG.
Ambulatory ECG Monitoring		
Holter monitoring	Recording of ECG rhythm for 24–48 hr; rhythm changes are then correlated with symptoms recorded in patient's diary. Normal patient activity is encouraged to simulate conditions that produce symptoms. Electrodes are placed on chest, and a recorder is used to store information until it is recalled, printed, and analyzed for any rhythm disturbance. It can be performed on an inpatient or outpatient basis.	The patient's skin is prepared, and electrodes and leads are applied. The nurse should explain importance of keeping an accurate diary of activities and symptoms. The patient should take no bath or shower during monitoring. Electrodes may cause skin irritation.
Event monitor or loop recorder	Recording of rhythm disturbances that are not frequent enough to be recorded in one 24-hr period. It allows more freedom than does a regular Holter monitor. Some units have electrodes that are attached to the chest and have a loop of memory that captures the onset and end of an event. Other types are placed directly on patient's wrist, chest, or fingers and have no loop of memory but record the patient's ECG in real time. Recordings may be transmitted over the phone to a receiving unit.	The patient needs instruction in the use of equipment for recording and transmitting (if appropriate) of transient events. The nurse should teach patient about skin preparation for lead placement or steady skin contact for units not requiring electrodes. This will ensure the reception of optimal ECG tracings for analysis. The nurse should instruct patient to initiate recording as soon as symptoms begin or as soon thereafter as possible.

Study	Description and Purpose	Nursing Responsibility
Exercise or stress testing	Study of the effect of exercise tolerance on cardiovascular function. Various protocols are used. A common protocol is to use 3-min stages at set speeds and with elevation of the treadmill belt. The patient can exercise to either predicted peak heart rate (calculated as the patient's age subtracted from 220) or to peak exercise tolerance, at which time the test is terminated. The test is also terminated for chest discomfort, significant increase or decrease in vital signs from baseline, or significant ECG changes indicating cardiac ischemia. Vital signs and ECG are monitored. The ECG is monitored after exercise for rhythm disturbances or, if ECG changes occurred with exercise, for return to baseline. Continual monitoring of vital signs and ECG rhythms for ischemic changes is important in the diagnosis of CAD. An exercise bike may be used if the patient is unable to walk on the treadmill.	The nurse should instruct patient (a) to wear comfortable clothes and shoes that can be used for walking and running and (b) about procedure and importance of reporting any symptoms that may occur. The nurse monitors vital signs and obtains 12-lead ECG before patient's exercise, during each stage of exercise, and after exercise until all vital signs and ECG changes have returned to normal. The nurse monitors patient's response throughout procedure. Contraindications include any reasons patient is unable to reach peak exercise. β-Adrenergic blockers may be withheld 24 hr before the test because they will blunt the heart rate and limit the patient's ability to achieve maximal heart rate. Caffeine-containing food and fluids are also withheld for 24 hr. Patients must refrain from smoking and strenuous exercise for 3 hr before test.
6-Minute walk test	Measurement of distance patient is able to walk on a flat surface in 6 min. Used to measure response to treatments and determine functional capacity for activities of daily living. Useful for patients who are unable to perform treadmill or exercise bike testing.	The nurse instructs patient to wear comfortable shoes and informs patient to carry or pull oxygen if it is used routinely. Patient should be encouraged to walk as quickly as possible.
Echocardiography • Contrast • M-mode • Two-dimensional • Colour-flow imaging (duplex) • Real-time three-dimensional	Ultrasound imaging of cardiac activity. Transducer that emits and receives ultrasound waves is placed in four positions on the chest above the heart. Transducer records sound waves that are bounced off the heart. Also records direction and flow of blood through the heart and transforms it to audio and graphic data that reflect valvular abnormalities, congenital cardiac defects, wall motion, ejection fraction, and cardiac function. IV contrast medium may be used to enhance images.	The patient is placed in a supine position on left side, facing equipment. The nurse instructs patient about procedure and expected sensations (pressure and mechanical movement from head of transducer). No contraindications to procedure exist.
Stress echocardiography	Combination of exercise testing and echocardiography. Resting images of the heart are taken with ultrasonography, and then the patient exercises. Postexercise images are taken immediately after exercise (within 1 min of stopping exercise). Differences in left ventricular wall motion and thickening before and after exercise are evaluated.	The nurse instructs and prepares patient for treadmill or exercise bicycle. The nurse also informs patient of importance of timely return to examination table for imaging after exercise. Contraindications include any reasons patient is unable to reach peak exercise.

Study	Description and Purpose	Nursing Responsibility
Pharmacological echocardiography	Echocardiography with the use of pharmacological agent. Used as a substitute for the exercise stress test for patients unable to exercise. While echocardiography is performed, dobutamine or dipyridamole is infused intravenously, and dosage is increased in 5-min intervals to detect wall motion abnormalities at each stage.	The nurse starts IV infusion. Medication is administered per protocol. The nurse monitors vital signs before, during, and after test until baseline achieved. The nurse also monitors patient for signs and symptoms of distress during procedure. The patient is observed for adverse effects (e.g., shortness of breath, dizziness, nausea). Aminophylline may be given to prevent or reverse adverse effects of dipyridamole. Contraindications include any known allergies to medications.
Transesophageal echocardiography (TEE)	Echocardiography with an internal probe. A probe with an ultrasound transducer at the tip is swallowed while the physician controls angle and depth. As the probe passes down the esophagus, it sends back clear images of heart size, wall motion, valvular abnormalities, endocarditis vegetation, and possible source of thrombi without interference from lungs or chest ribs. Contrast medium may be injected intravenously for evaluating direction of blood flow if an atrial or ventricular septal defect is suspected. Doppler ultrasonography and colour-flow imaging can also be used concurrently.	The nurse instructs patient to avoid eating for at least 6 hr before test. Removable dentures are taken out of patient's mouth, and a bite block is placed in the mouth. IV sedative is administered, and local anaesthetic is applied to throat. The nurse monitors vital signs and oxygen saturation levels and performs suctioning as needed during procedure. The nurse also assists patient to relax. Patient may not eat or drink until gag reflex returns. Sore throat is temporary. A designated driver is needed for patient if test is done in outpatient department.
Nuclear cardiology	Radiological study with radioactive isotope (technetium-99m sestamibi). Isotope is injected intravenously. Radioactive uptake is counted over the heart by scintillation camera. Study supplies information about myocardial contractility, myocardial perfusion, and acute cell injury.	The nurse explains procedure to patient. IV line is established for injection of isotopes. The nurse must explain that radioactive isotope is used in a small, diagnostic amount and will lose most of its radioactivity in a few hours. Patient is informed that he or she will be lying still on back with arms extended overhead for 20 min. Repeat scans are performed within a few minutes to hours after the injection.

Study	Description and Purpose	Nursing Responsibility
Multigated acquisition (MUGA) (cardiac blood pool) scan	Imaging with a radioactive isotope. A small amount of the patient's blood is removed, mixed with isotope (e.g., technetium-99m sestamibi with Cardiolite kit), and reinjected intravenously. The ECG is used for timing, and images are acquired during the cardiac cycle. Indicated for patients with MI, heart failure, or valvular heart disease. It also can be used to evaluate the effect of various cardiac or cardiotoxic medications on the heart.	Procedure is explained to patient. The nurse establishes IV line for removal of blood sample and reinjection of isotope and then establishes ECG monitoring. Patient is informed that procedure involves little risk.
Single-photon emission computed tomography (SPECT)	Computed tomography with radioactive isotope. Used to evaluate myocardium at risk of infarction and to determine infarction size. Small amounts of isotope (e.g., technetium-99m tetrofosmin [Myoview] or thallium-201) are injected intravenously, and recordings are made of the radioactivity emitted over a specific area of the body. Circulation of the isotope can be used to detect coronary artery blood flow, intracardiac shunts, motion of ventricles, ejection fraction, and size of the heart chambers.	The nurse explains procedure to patient, establishes IV line for injection of isotope, and establishes ECG monitoring. Patient must be informed that procedure involves little risk.
Exercise (stress) nuclear imaging	Nuclear imaging performed while patient is at rest and after exercise. The injection is given when patient reaches maximum heart rate on bicycle or treadmill. Patient is then required to continue exercise for 1 min to circulate the radioactive isotope. Scanning is done 15–60 min after exercise. A resting scan is performed 60–90 min after initial infusion or 24 hr later.	Explain procedure to patient. Instruct patient to eat only a light meal between scans. Certain medications may need to be held for 1–2 days before the scan.
Pharmacological nuclear imaging	Nuclear imaging performed with vasodilating drugs. Dipyridamole or adenosine is used to produce vasodilation when patients are unable to tolerate exercise. Vasodilation will increase blood flow to well-perfused coronary arteries. Scanning procedure is same as for exercise nuclear imaging. Aminophylline may be given to prevent or reverse adverse effects of dipyridamole (e.g., shortness of breath, dizziness, nausea). Dobutamine is used if vasodilators are contraindicated.	The nurse explains procedure to patient and instructs patient to avoid all caffeine products for 12 hr before procedure. Calcium channel blockers and β-adrenergic blockers should be avoided 24 hr before the test. The nurse observes patient for adverse effects (e.g., shortness of breath, dizziness, nausea).
Positron emission tomography (PET)	Tomographic imaging with two radionuclides. Highly sensitive in distinguishing viable and nonviable myocardial tissue. Nitrogen-13 ammonia is injected intravenously first, and scanning is performed to evaluate myocardial perfusion. A second radioactive isotope, fluorine-18 fludeoxyglucose, is then injected, and scanning is performed to show myocardial metabolic function. If the heart is normal, the two scans will match, but if the heart is ischemic or damaged, they will differ. The patient may undergo this test with or without conditions of stress. A baseline resting scan is usually obtained for comparison.	The nurse instructs patient on procedure, explaining that patient will be scanned by a machine and will need to stay still for a period of time. Patient's glucose level must be between 3.3 and 7.8 mcmol/L for accurate glucose metabolic activity. If exercise is included as part of testing, patient will need to fast and refrain from tobacco and caffeine for 24 hr before test.

Study	Description and Purpose	Nursing Responsibility
Cardiovascular magnetic resonance imaging (CMRI)	Noninvasive imaging technique that obtains information about cardiac tissue integrity, aneurysms, ejection fractions, cardiac output, and patency of proximal coronary arteries. It does not involve ionizing radiation and is an extremely safe procedure. It provides images in multiple planes with uniformly good resolution.	The nurse explains procedure to patient, informing patient that the small diameter of the cylinder, along with loud noise of the procedure, may cause panic or anxiety. Antianxiety drugs and distraction strategies (e.g., music) may be recommended. Patient must lie still during MRI. Contraindicated for patients with implanted metallic devices or other metal fragments. The nurse must discern the presence of any implants before scan.
Magnetic resonance angiography (MRA)	Imaging of vascular occlusive disease and abdominal aortic aneurysms. Same as MRI but with use of gadolinium as IV contrast medium.	Contraindications include any known allergies to contrast medium and the presence of implanted metallic devices or other metal fragments.
Cardiac computed tomography (CT)	Heart-specific CT imaging technology with or without IV contrast media. It is used to visualize heart anatomy, coronary circulation, and blood vessels.	The nurse explains procedure to patient.
Computed tomographic angiography (CTA)	Use of CT with injected IV contrast medium to obtain images of blood vessels and diagnose CAD.	The nurse explains procedure to patient. Metal objects should be removed before examination. The patient may be asked not to eat or drink for several hours before the procedure.
Calcium-scoring CT scan • Electron beam computed tomography (EBCT)	Also known as *ultrafast CT;* a scanning electron beam is used to quantify calcification in coronary arteries and heart valves (see Figure 34-12). Used primarily for risk assessment in asymptomatic patients and to assess for heart disease in patients with atypical symptoms potentially resulting from cardiac causes.	The nurse explains procedure to patient and informs patient that procedure is quick and involves little or no risk.

Study	Description and Purpose	Nursing Responsibility
Cardiac catheterization	Insertion of catheter into heart, via artery, to obtain information about O_2 levels and pressure readings within heart chambers. Contrast medium is injected to assist in examining structure and motion of heart.	The nurse checks patient for iodine sensitivity. Food and fluids are withheld for 6–18 hr before procedure. The nurse administers sedative and other drugs, if ordered, and informs patient about use of local anaesthesia, insertion of catheter, feeling of warmth when dye is injected, and possible fluttering sensation of heart as catheter is passed. Patient may be instructed to cough or take a deep breath when dye is injected and then is monitored by ECG throughout procedure. After procedure, the nurse assesses circulation to extremity used for catheter insertion. The nurse checks peripheral pulses, colour, and sensation of extremity every 15 min for 1 hr and then with decreasing frequency. The puncture site is observed for hematoma and bleeding. A compression device is placed over arterial site to achieve hemostasis, if indicated. The nurse monitors vital signs and ECG and assesses for hypotension or hypertension, abnormal heart rate, dysrhythmias, and signs of pulmonary emboli (e.g., respiratory difficulty).
Coronary angiography	Imaging during a cardiac catheterization in which contrast medium is injected directly into coronary arteries. Used to evaluate patency of coronary arteries and collateral circulation.	Same as for cardiac catheterization.
Noninvasive coronary computed tomographic angiography (CCTA)	A noninvasive imaging modality that can be used to evaluate the anatomy of the coronary arteries. Unlike coronary artery calcium scoring, in which noncontrast CT is used to assess atherosclerotic disease burden, CCTA allows direct visualization of the coronary artery wall and lumen with the administration of IV contrast medium.	Same as for cardiac catheterization.
Intracoronary ultrasonography	Ultrasound imaging in which a small ultrasound probe is introduced into coronary arteries during cardiac catheterization. Data are used to assess size and consistency of plaque, arterial walls, and effectiveness of intracoronary artery treatment.	Same as for cardiac catheterization.
Fractional flow reserve	Measurement of blood pressure and flow. During cardiac catheterization, a special wire is inserted into the coronary arteries to gather these measurements. Information is used to determine need for angioplasty or stent placement on nonsignificant blockages.	Same as for cardiac catheterization.

Study	Description and Purpose	Nursing Responsibility
Electrophysiology study (EPS)	Invasive study used to record intracardiac electrical activity. Catheters (with multiple electrodes) are inserted via the femoral and jugular veins into the right side of the heart. The catheter electrodes record the electrical activity in different cardiac structures. In addition, dysrhythmias can be induced and terminated.	Antidysrhythmic medications may be discontinued several days before study. Patient should be on NPO status 6–8 hr before test. The nurse administers premedication to promote relaxation, if ordered. IV sedative is often used during procedure. Patient must have frequent monitoring of vital signs and continuous ECG monitoring after the procedure.
Peripheral arteriography and venography‡	Radiographic study involving injection of radiopaque contrast medium into either arteries or veins. Serial radiographs are taken to detect and visualize any atherosclerotic plaques, occlusion, aneurysms, or traumatic injury.	The nurse checks for iodine allergy and administers mild sedative, if ordered. The nurse checks extremity with puncture site for pulsation, warmth, colour, and motion after procedure. Insertion site is inspected for bleeding or swelling. The nurse observes patient for allergic reactions to dye.
Hemodynamic monitoring	Hemodynamic monitoring of arterial blood pressures, pulmonary artery pressure, pulmonary artery wedge pressure, and cardiac output to evaluate cardiovascular status and response to treatment.	Patients requiring hemodynamic monitoring are critically ill and are monitored in critical care units. See Chapter 68 for complete information on hemodynamic monitoring.

*Reference ranges for the laboratory tests vary by institution because of differences in equipment and reagents used.

Noninvasive Studies

Chest Radiography.

A radiograph can depict cardiac contours, heart size and configuration, and anatomical changes in individual chambers (see Figure 34-9). The radiographic image records any displacement or enlargement of the heart, the presence of extra fluid around the heart (pericardial effusion), and pulmonary congestion.

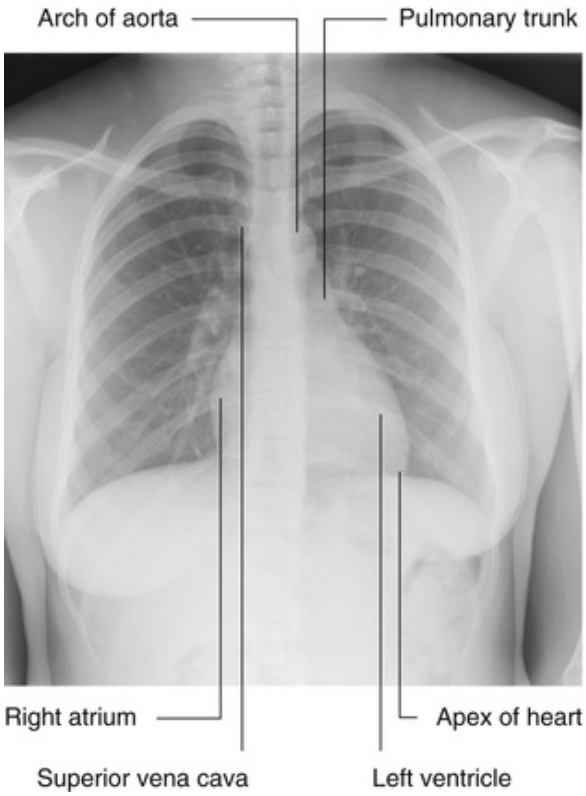

FIGURE 34-9 Chest radiograph: standard posteroanterior view.

Source: Drake, R. L., Vogl, A. W., & Mitchell, A. W. M. (2010). *Gray's anatomy for students* (2nd ed.). Philadelphia: Churchill Livingstone.

Electrocardiography.

The basic P, QRS, and T waveforms (see Figure 34-4) are used to assess cardiac function. Deviations from the normal sinus rhythm can indicate abnormalities in heart function. There are many types of electrocardiographic monitoring, including resting ECG, ambulatory ECG monitoring, and exercise or stress testing.

A resting ECG helps identify at one point in time primary conduction abnormalities, cardiac dysrhythmias, cardiac hypertrophy, pericarditis, myocardial ischemia, site and extent of myocardial infarction (MI), pacemaker performance, and effectiveness of drug therapy. It is also used to monitor recovery from an MI. (See Chapter 38 for a complete discussion of ECG monitoring.)

Ambulatory Electrocardiographic Monitoring.

Continuous ambulatory ECG (Holter monitoring) can provide diagnostic information over a longer period than can a standard resting ECG. In

Holter monitoring, a recorder is worn by the patient for 24 to 48 hours, and the resulting ECG information is then stored until it is played back for printing and evaluation. Holter monitoring gives the patient freedom to perform usual activities of daily living and those that may be associated with cardiovascular symptoms. The patient maintains a record of activities, symptoms, and sleep and this record is correlated with the ECG events recorded by the device (see Table 34-6).

Transtelephonic Event Recorders.

This type of recorder is helpful for monitoring less frequent ECG events. The monitor is a portable unit with which electrodes are used to transmit a limited ECG over the phone to a receiving device. A disadvantage of this type of monitoring is that if the event is of short duration, the symptoms may end before the patient puts on the device and calls the assigned number. Likewise, if patients are extremely symptomatic (e.g., syncopal), they may not be physically able to transmit the ECG.

Exercise or Stress Testing.

Cardiac symptoms frequently occur only with activity because of the demand on the coronary arteries to provide more oxygen. Exercise testing is used to evaluate the heart's response to physical stress. This helps to assess cardiovascular disease and set limits for exercise programs. Exercise testing is used for individuals who do not have restrictions related to walking or using a bicycle. It is also helpful for patients with normal ECGs that limit diagnostic interpretation (e.g., those with pacemakers; see Table 34-6).

Echocardiography.

In echocardiography, ultrasound waves are used to record the movement of the structures of the heart. In the normal heart, ultrasonic sound waves directed at the heart are reflected back in typical configurations. The echocardiogram provides information about abnormalities of (a) valvular structure and motion, (b) cardiac chamber size and contents, (c) ventricular muscle and septal motion and thickness, (d) the pericardial sac, and (e) the ascending aorta. The **ejection fraction,** or the percentage of end-diastolic blood volume that is ejected during systole, can also be measured. The ejection fraction provides information about the function of the left ventricle during systole.

Two commonly used types are M-mode (motion mode) and two-dimensional echocardiography. In the M-mode type, a single ultrasound

beam is directed toward the heart, and the motion of the intracardiac structures is recorded, as are wall thickness and chamber size. In two-dimensional echocardiography, the ultrasound beam sweeps through an arc, producing a cross-sectional view, and shows correct spatial relationships among the structures.

Doppler technology allows for sound evaluation of the flow or motion of the scanned object (heart valves, ventricular walls, blood flow). Colour-flow (duplex) imaging is the combination of two-dimensional echocardiography and Doppler technology (Figure 34-10). Colour changes demonstrate the velocity and direction of blood flow. Pathological conditions, such as valvular leaks and congenital defects, can be diagnosed more effectively. Stress echocardiography, a combination of treadmill test and ultrasound images, is used to evaluate segmental wall motion abnormalities (Pagana, Pagana, & Pagana, 2014). A digital computer system is used to compare images before and after exercise, and wall motion and segmental function can be clearly seen. This diagnostic test provides the information of an exercise stress test combined with that obtained from an echocardiogram. For patients unable to exercise, infusion of a pharmacological agent—usually dobutamine (Dobutrex) or dipyridamole (Persantine)—induces stress on the heart while the patient is resting. The same ultrasound technology is used.

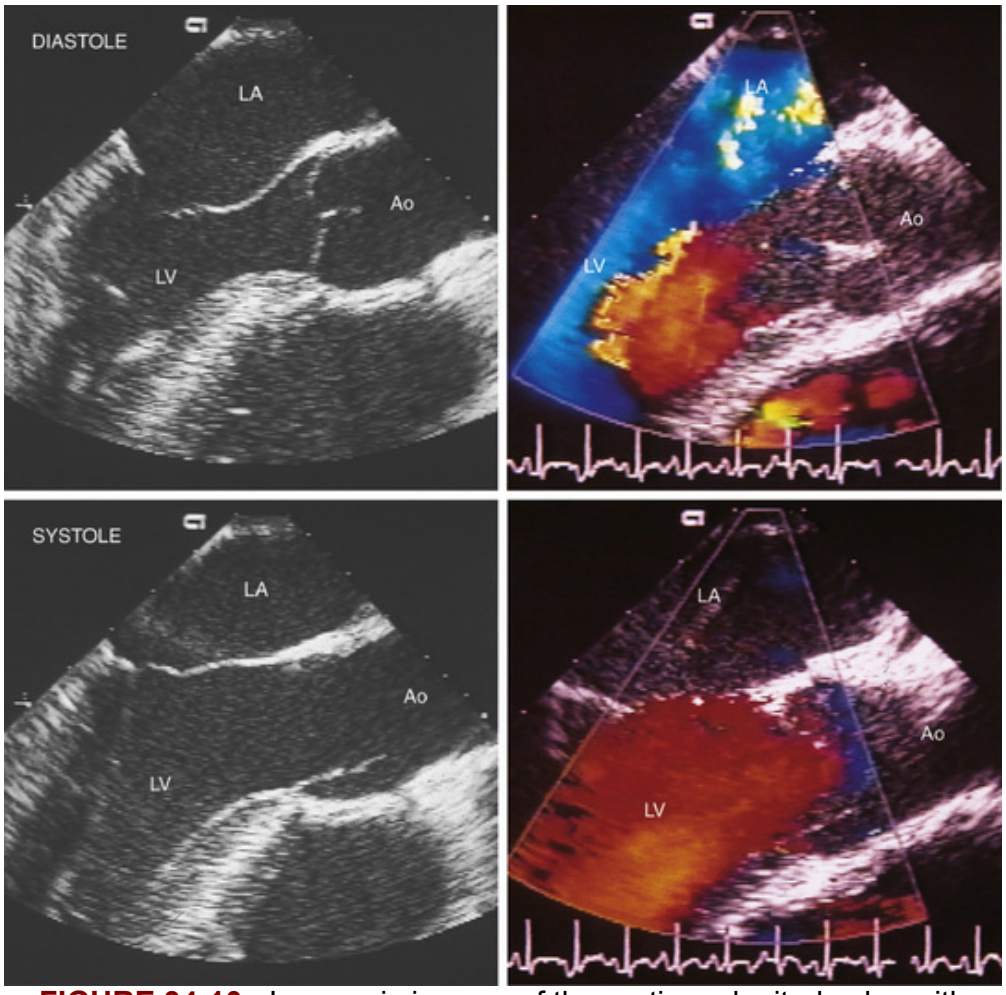

FIGURE 34-10 Long-axis images of the aortic and mitral valve with the depth adjusted to optimize evaluation of valve anatomy and motion. The two-dimensional images *(left)* in diastole *(top)* and systole *(bottom)* show normal aortic and mitral opening and closure. The colour flow images *(right)* show normal left ventricular inflow with no aortic regurgitation in diastole *(top)* and normal antegrade flow in the left ventricular outflow tract and no mitral regurgitation in systole *(bottom)*. Source: From Otto, C. (2004). *Textbook of clinical echocardiography* (3rd ed.). St. Louis: Saunders.

In comparison with surface two-dimensional echocardiography, transesophageal echocardiography (TEE) is used to provide more precise images of the heart by eliminating interference from the chest wall and the lungs. TEE involves the use of a modified, flexible endoscope probe with an ultrasound transducer in the tip for imaging of the heart and great vessels. The probe is introduced into the esophagus to the level of the heart, and M-mode, two-dimensional, pulsed Doppler, and colour-flow images can be obtained.

TEE is used frequently in an outpatient setting primarily for evaluation of mitral regurgitation, of the presence of thrombus before cardioversion is performed, or of the source of cardiac emboli. In addition, TEE has applications in the operating room to assess presurgical and postsurgical cardiac function and in the emergency department for suspicion of aortic dissection.

The risks with TEE are minimal. However, complications may include perforation of the esophagus, hemorrhage, dysrhythmias, vasovagal reactions, and transient hypoxemia. TEE is contraindicated if the patient has a history of esophageal disorders, dysphagia, or radiation therapy involving the chest wall. Patients must be sedated during TEE.

In contrast echocardiography, intravenous contrast agents (e.g., albumin microbubbles, agitated saline) are used to assist in delineation of the images, especially in cases of technical difficulties (Pagana, Pagana, & Pagana, 2014). When these agents are injected into the cardiac blood pool, they greatly enhance reflectivity for the ultrasound procedure.

Nuclear Cardiology.

One of the most common nuclear imaging tests is the multigated acquisition (MUGA), or cardiac blood pool, scanning. This test provides information on wall motion during systole and diastole, cardiac valves, and ejection fraction (see Table 34-6).

Perfusion imaging is also used with exercise testing to determine whether the coronary blood flow changes with increased activity. Stress perfusion imaging may show an abnormality even when a resting image is normal. This procedure is used to diagnose CAD, establish a prognosis for patients with existing CAD, differentiate viable myocardium from scar tissue, and determine the potential for success of various interventions, such as coronary artery bypass surgery and percutaneous coronary intervention (Zaret & Beller, 2010; see Chapter 36).

Exercise stress perfusion imaging is always preferred but, if a patient cannot exercise, intravenous dipyridamole or adenosine (Adenocard) can be administered to dilate the coronary arteries and simulate the effect of exercise. After the drug takes effect, the isotope is injected and the imaging is performed.

Cardiovascular Magnetic Resonance Imaging.

Cardiovascular magnetic resonance imaging (CMRI) can reveal areas of MI in a three-dimensional view. It is sensitive enough to find even small MIs

that are not apparent with single-photon emission computed tomography imaging. CMRI aids in the final diagnosis of MI and the assessment of ejection fraction. It also plays a role in prediction of recovery from MI and in the diagnosis of congenital heart and aortic disorders and CAD (Hundley, Bluemke, & Finn, 2010).

One major advantage of CMRI is that it does not require any irradiation of the patient. In general, the use of CMRI in patients with pacemakers and ICDs is discouraged because the magnets can alter the function of the devices. When clinical need is strong and the benefits outweigh the risks, CMRI should be performed only at experienced centres (Hundley, Bluemke, & Finn, 2010). Some newer models of these devices are approved for use with MRI.

Cardiac Computed Tomography.

Cardiac computed tomography (CT) is a heart-imaging test in which CT technology, with or without intravenous contrast medium (dye), is used to see the heart anatomy, coronary circulation, and great blood vessels (e.g., aorta, pulmonary veins, artery). This technology is often called *multidetector CT scanning.* Types of CT scans used to diagnosis heart disease include coronary CT angiography (CTA) and calcium-scoring CT scan (see Table 34-6).

Coronary CTA is a noninvasive test. It can be performed faster than cardiac catheterization with less risk and discomfort to the patient (Mark, Berman, & Budoff, 2010). Although the use of coronary CTA is increasing, cardiac catheterization (discussed in the next section) remains the gold standard for diagnosing coronary artery stenosis. Furthermore, when a cardiac catheterization is done, interventions (e.g., angioplasty, stent placement) can be performed if coronary blockages are found.

The calcium-scoring CT scan is used to find calcium deposits in plaque in the coronary arteries. The most common method used is electron beam CT (Figure 34-11). It can detect early coronary calcification before symptoms develop. The amount of coronary calcium is a predictor of future cardiac events.

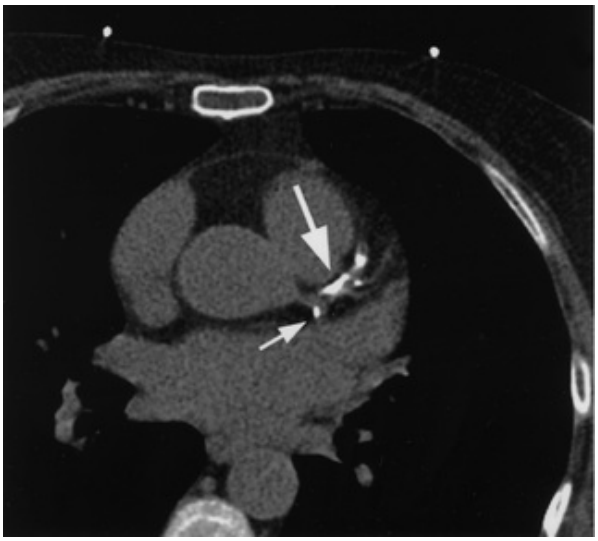

FIGURE 34-11 Examples of coronary calcification of the left anterior descending coronary artery *(large arrow)* and left circumflex artery *(small arrow)* as seen on electron beam computed tomography. Source: From Libby, P., Bonow, R., Zipes, D., et al. (Eds.). (2008). *Braunwald's heart disease: A textbook of cardiovascular medicine* (8th ed.). St. Louis: Saunders.

Blood Studies.

Many blood studies provide information about the cardiovascular system. For example, some reflect the O_2-carrying capacity (red blood cell count and hemoglobin) and coagulation properties (clotting times) of the blood. (See Chapter 32 and Tables 32-7 and 32-8 for hematology studies.) The studies most commonly used to assess the cardiovascular system are listed in Table 34-6.

Cardiac Biomarkers.

When cells are injured, they release their contents, including enzymes and other proteins, into the circulation. These *biomarkers* are useful in the diagnosis of myocardial injury and infarction.

Cardiac-specific troponin is a myocardial muscle protein released into circulation after injury or infarction. Two subtypes, cardiac-specific troponin T (cTnT) and cardiac-specific troponin I (cTnI), are specific to myocardial tissue. Normally the level in the blood is very low, and so a rise in level is diagnostic of myocardial injury. Rising levels of cTnT and cTnI are detectable within hours (on average 4 to 6 hours) of myocardial injury; these levels peak at 10 to 24 hours and can be detected for up to 10

to 14 days (see Figure 36-11). Troponin is the biomarker of choice in the diagnosis of MI. The development of high-sensitivity troponin (hs-cTnT, hs-cTnI) assays may provide even earlier detection of a cardiac event (Lee, Browne, Guest, et al., 2016).

Creatine kinase (CK) enzymes are found in a variety of organs and tissues and occur as three isozymes. These isozymes are specific to skeletal muscle (CK-MM), brain and nervous tissue (CK-BB), and the heart (CK-MB). CK-MB elevation is specific for myocardial injury or infarction. CK-MB levels begin to rise 3 to 6 hours after symptom onset, peak in 12 to 24 hours, and return to baseline within 12 to 48 hours after MI (Pagana, Pagana, & Pagana, 2014). The peak level and return to normal can be delayed in cases of large MI. Levels drop more rapidly in patients who are quickly and successfully treated for an MI. (Figure 36-11 depicts the changes in cardiac markers related to an MI.)

Myoglobin is a low-molecular-weight heme protein found in cardiac and skeletal muscle. Elevation in myoglobin levels is a sensitive indicator of very early myocardial injury but lacks specificity for MI. Its usefulness in diagnosing MI is limited (Pagana and Pagana, 2014).

To interpret diagnostic test results correctly, the time of onset of symptoms and the time of the expected presence and elevation of the biomarkers must be considered. Additional data (patient symptoms, history, and ECG changes) complete the diagnostic picture for the patient with suspected myocardial injury or MI.

C-Reactive Protein.

C-reactive protein (CRP) is a protein produced by the liver during periods of acute inflammation. CRP can be measured with a high-sensitivity test (hs-CRP). An increased level of CRP is an independent risk factor for CAD. The level of CRP may also be predictive of the risk for future cardiac events in patients with unstable angina and MI, but studies have produced conflicting results.

Homocysteine.

Homocysteine is an amino acid that is produced during protein catabolism. Elevated homocysteine levels can be either hereditary or acquired from dietary deficiencies of vitamin B_6, vitamin B_{12}, or folate. Elevated levels of homocysteine have been linked to a higher risk of CAD, peripheral vascular disease, and stroke. It is recommended that homocysteine testing be performed in patients with a familial predisposition for early cardiovascular disease or a history of

cardiovascular disease in the absence of other common risk factors (American Heart Association, 2012).

Cardiac Natriuretic Peptide Markers.

There are three natriuretic peptides: (a) atrial natriuretic peptide (ANP) from the atrium, (b) b-type natriuretic peptide (BNP) from the ventricles, and (c) c-type natriuretic peptide from endothelial and renal epithelial cells. BNP is the marker of choice for distinguishing a cardiac or respiratory cause of dyspnea. N-terminal pro–b-type natriuretic peptide (NT–pro-BNP) is also secreted in the ventricles and is more sensitive but less specific than BNP as a diagnostic marker of heart failure (Pagana, Pagana, & Pagana, 2014). When diastolic blood pressure increases (e.g., heart failure), BNP and NT–pro-BNP are released and increase natriuresis (excretion of sodium in the urine). (ANP and BNP are also discussed in Chapter 37.)

Serum Lipids.

Serum lipids consist of triglycerides, cholesterol, and phospholipids. They circulate in the blood bound to protein. Thus they are often referred to as *lipoproteins*.

Triglycerides are the main storage form of lipids and make up about 95% of fatty tissue. Cholesterol, a structural component of cell membranes and plasma lipoproteins, is a precursor of corticosteroids, sex hormones, and bile salts. In addition to being absorbed from food in the gastrointestinal tract, cholesterol can also be synthesized in the liver. Phospholipids contain glycerol, fatty acids, phosphates, and a nitrogenous compound. Although formed in most cells, phospholipids usually enter the circulation as lipoproteins synthesized by the liver. Apoproteins are water-soluble proteins that combine with most lipids to form lipoproteins.

Different classes of lipoproteins contain varying amounts of the naturally occurring lipids. These include the following:

1. *Chylomicrons:* primarily exogenous triglycerides from dietary fat
2. *Low-density lipoproteins (LDLs):* mostly cholesterol with moderate amounts of phospholipids
3. *High-density lipoproteins (HDLs):* approximately 50% protein and 50% phospholipids and cholesterol
4. *Very-low-density lipoproteins (VLDLs):* primarily endogenous triglycerides with moderate amounts of phospholipids and cholesterol

A lipid panel usually includes measurements of cholesterol, triglyceride, LDL, and HDL. Elevations in triglyceride and LDL levels are strongly associated with CAD. An increased HDL level is associated with a decreased risk of CAD (Huether & McCance, 2012). High levels of HDLs serve a protective role by mobilizing cholesterol from tissues.

Although an association exists between elevated serum cholesterol levels and CAD, a measure of total cholesterol alone is not sufficient for an assessment of CAD. To calculate a risk assessment, the ratios of total cholesterol to HDL ratio are compared over time. An increase in the ratio indicates increased risk. This provides more information than either value alone. The patient must fast before blood is drawn for a lipid panel so that food intake does not affect the results.

Plasma levels of apolipoprotein A-I (the major HDL protein) and the ratio of apolipoprotein A-I to apolipoprotein B (the major LDL protein) are stronger predictors of CAD than is the HDL cholesterol level alone. Measurements of these lipoproteins can be useful in identifying patients at risk for CAD (Pagana, Pagana, & Pagana, 2014).

Lipoprotein (a) has been studied for its role as a risk factor for CAD. Increased levels of lipoprotein (a), especially with increased levels of lactate dehydrogenase, have been linked with the progression of atherosclerosis, especially in women (Huether & McCance, 2012).

Lipoprotein-Associated Phospholipase A_2.

Lipoprotein-associated phospholipase A_2 (Lp-PLA_2) is an inflammatory enzyme expressed in atherosclerotic plaques. Elevated levels of Lp-PLA_2 are related to an increased risk of CAD (Lp-PLA_2 Studies Collaboration, 2010).

Invasive Studies

Invasive studies are performed if definitive information is required. These studies include cardiac catheterization, coronary angiography, electrophysiology (see Table 34-6), intracoronary ultrasonography, and hemodynamic monitoring.

Cardiac Catheterization and Coronary Angiography.

Cardiac catheterization is a common outpatient procedure. It provides information about CAD, coronary spasm, congenital and valvular heart disease, and ventricular function. Cardiac catheterization is also used to

measure intracardiac pressures and O_2 levels, as well as CO and ejection fraction. With injection of contrast media and fluoroscopy, the coronary arteries can be seen, chambers of the heart can be outlined, and wall motion can be observed.

In cardiac catheterization, a radiopaque catheter is inserted into the right or left side of the heart, or both sides. For the right side of the heart, a catheter is inserted through an arm vein (basilic or cephalic) or a leg vein (femoral). Pressures are recorded as the catheter is moved into the vena cava, the right atrium, the right ventricle, and the pulmonary artery. The catheter is then moved until it is wedged or lodged in position. This blocks the blood flow and pressure from the right side of the heart and looks ahead through the pulmonary capillary bed to the pressure in the left side of the heart *(pulmonary artery wedge pressure).* This pressure is used to assess the function of the left side of the heart.

In left-sided cardiac catheterization, a catheter is inserted into a femoral, brachial, or radial artery. The catheter is passed in a retrograde manner up to the aorta, across the aortic valve, and into the left ventricle.

Coronary angiography is performed with a left-sided heart catheterization. The catheter is positioned at the origin of the coronary arteries (see Figure 34-3), and contrast medium is injected into the arteries. Patients often feel a temporary flushed sensation with dye injection. The images identify the location and severity of any coronary blockages (Figure 34-12; see also Figure 36-7). Complications of cardiac catheterization include bleeding or hematoma at the puncture site; allergic reactions to the contrast media; looping or kinking of the catheter; infection; thrombus formation; aortic dissection; dysrhythmias; MI; stroke; and puncture of the ventricles, cardiac septum, or lung tissue.

FIGURE 34-12 Normal left coronary artery angiogram. Source: From Drake, R. L., Vogl, A. W., & Mitchell, A. W. M. (2010) *Gray's anatomy for students* (2nd ed.). Philadelphia: Churchill Livingstone.

Intracoronary Ultrasonography.

Intracoronary ultrasonography (ICUS), also known as *intravascular ultrasonography* (IVUS), is an invasive procedure performed in the catheterization laboratory with coronary angiography. The two- or three-dimensional ultrasound images provide a cross-sectional view of the arterial walls of the coronary arteries. In this procedure, a miniature transducer attached to a small catheter is moved to the artery to be studied. Once it is in the artery, ultrasound images are obtained. The health of the arterial layers is assessed, including the composition, location, and thickness of any plaque. ICUS can help evaluate vessel response to treatments such as stent placement and atherectomy, as well as any complications that may have occurred during the procedure. Patients most often undergo ICUS in addition to angiography or a coronary intervention. Thus nursing care is similar to that after cardiac catheterization (see Table 34-6).

Fractional Flow Reserve.

Fractional flow reserve is a procedure that is performed during a cardiac catheterization. It involves using a special wire that can measure pressure and flow in the coronary artery. Fractional flow reserve helps to determine

the need to perform angioplasty or stent placement on nonsignificant blockages.

Hemodynamic Monitoring.

Bedside hemodynamic monitoring of pressures of the cardiovascular system is frequently used to assess cardiovascular status. Invasive hemodynamic monitoring with the use of intra-arterial and pulmonary artery catheters can be performed to monitor arterial blood pressure, intracardiac pressures, and CO (see Chapter 68). The central venous pressure (CVP) is a measurement of preload and can be used to monitor the pressure in the right atrium and right ventricle. The CVP reading is influenced by the function of the left side of the heart, pressures in the pulmonary vessels, venous return to the heart, and the position of the patient when the reading is taken. The last factor must be kept in mind to obtain an accurate reading. The CVP can be used as a guide in fluid volume management of overhydration or dehydration.

CVP can be measured with a pulmonary artery catheter (see Chapter 68) or a central venous line threaded through the jugular or the subclavian vein into the superior vena cava. The normal CVP is 2 to 9 mm Hg.

Case Study

Objective Data: Diagnostic Studies

Source: ESB Professional/Shutterstock.com.

The health care provider orders the following initial diagnostic studies for Lawrence Tan:

- 12-lead ECG
- Complete blood cell count, basic metabolic panel (glucose, electrolytes, blood urea nitrogen, creatinine)
- Partial thromboplastin time, prothrombin time, international normalized ratio
- Pro-BNP measurement
- Troponin, CK-MB measurement
- Thyroid-stimulating hormone, free thyroxine
- Chest radiograph

Mr. Tan's initial troponin and CK-MB levels are within normal limits. The ECG demonstrates atrial fibrillation with a rapid ventricular response. Results of the chest radiograph, complete blood cell count, basic metabolic panel, pro-BNP measurement, and coagulation studies are all within normal limits. The health care provider orders intravenous diltiazem (Cardizem) and heparin to be started in the emergency department. Mr. Tan will be admitted to the progressive care unit and will have a consult with a cardiologist.

See pp. 772 and 777 for more information on Mr. Tan.

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. A patient has a tricuspid valve disorder. Between which of the following will the blood flow be impaired?
   a. Vena cava and right atrium
   b. Left atrium and left ventricle
   c. Right atrium and right ventricle
   d. Right ventricle and pulmonary artery
2. A patient has a severe blockage in his right coronary artery. Which cardiac structures are most likely to be affected by this blockage? *(Select all that apply)*
   a. Atrioventricular node
   b. Left ventricle
   c. Coronary sinus
   d. Right ventricle
   e. Pulmonic valve
3. Where is the conduction impairment when the Purkinje system is damaged?
   a. Atria
   b. Atrioventricular node
   c. Ventricles
   d. Bundle of His
4. Why does prolonged pressure on the skin cause areas at the point of contact to redden?
   a. Arterial vasodilation from smooth muscle relaxation
   b. Compression of veins, which results in venous engorgement
   c. Occlusion of major arteries causing infarction of the tissue
   d. Tissue damage and inflammation resulting from impaired capillary blood flow
5. When a person's blood pressure rises, which compensatory homeostatic mechanism is stimulated?

a. Chemoreceptors that inhibit the sympathetic nervous system, causing vasodilation
b. Baroreceptors that inhibit the parasympathetic nervous system, causing vasodilation
c. Baroreceptors that inhibit the sympathetic nervous system, causing a decrease in heart rate
d. Chemoreceptors that stimulate the sympathetic nervous system, causing an increase in heart rate

6. If a patient's capillary refill assessment shows that the colour returns in 10 seconds, what does this indicate?
a. A normal response
b. Thrombus formation in the veins
c. Lymphatic obstruction of venous return
d. Impaired arterial flow to the extremities

7. Which auscultatory area is found at the left midclavicular line at the level of the fifth intercostal space?
a. Aortic area
b. Mitral area
c. Tricuspid area
d. Pulmonic area

8. When a palpable precordial thrill is found upon assessment, what could this indicate?
a. Heart murmurs
b. Gallop rhythms
c. Pulmonary edema
d. Right ventricular hypertrophy

9. Which of the following may be found on assessment of a 79-year-old patient?
a. A narrowed pulse pressure
b. Diminished carotid artery pulses
c. Difficulty in isolating the apical pulse
d. An increased heart rate in response to stress

10. Which of the following is an important nursing responsibility for a patient undergoing an invasive cardiovascular diagnostic study?

a. Checking the peripheral pulses and percutaneous insertion site
b. Instructing the patient about radioactive isotope injection
c. Informing the patient that general anaesthesia will be given
d. Assisting the patient to do a surgical scrub of the insertion site

11. Which of the following statements best describe the P-wave impulse?
a. Arising at the sinoatrial node and repolarizing the atria
b. Arising at the sinoatrial node and depolarizing the atria
c. Arising at the atrioventricular node and depolarizing the atria
d. Arising at the atrioventricular node and spreading to the bundle of His

1. c; 2. a, b, d; 3. c; 4. d; 5. c; 6. d; 7. b; 8. a; 9. c; 10. a; 11. b.

CHAPTER 35

Nursing Management

Hypertension

Written by, Melissa L. Hutchinson

Adapted by, Kara Sealock

LEARNING OBJECTIVES

1. Relate the pathophysiological mechanisms associated with primary hypertension to the clinical manifestations and complications.
2. Select appropriate strategies for the prevention of primary hypertension.
3. Describe the collaborative care for primary hypertension, including drug therapy and lifestyle modifications.
4. Explain the collaborative care of the older adult with primary hypertension.
5. Prioritize the nursing management of the patient with primary hypertension.
6. Describe the collaborative care of a patient with hypertensive crisis.

KEY TERMS

baroreceptors, p. 790
blood pressure (BP), p. 789
cardiac output (CO), p. 789
hypertension, p. 791
hypertensive crisis, p. 809
isolated systolic hypertension (ISH), p. 792

orthostatic hypotension, p. 806

primary (essential) hypertension, p. 793

secondary hypertension, p. 793

systemic vascular resistance (SVR), p. 789

Hypertension, or high blood pressure (BP), is one of the most important modifiable risk factors that can lead to the development of cardiovascular disease (CVD). As BP increases, so does the risk for myocardial infarction (MI), heart failure, stroke, and renal disease. This chapter discusses the nursing and interprofessional care of patients who are at risk for or who have hypertension.

Normal Regulation of Blood Pressure

Blood pressure (BP) is the force exerted by the blood against the walls of the blood vessel and must be adequate for tissue perfusion to be maintained during activity and rest. The maintenance of normal BP and tissue perfusion requires the integration of both systemic factors and local peripheral vascular effects. Arterial BP is primarily a function of cardiac output (CO) and systemic vascular resistance (SVR). The relationship between the two is summarized by the following equation: Arterial blood pressure = cardiac output multiplied by systemic vascular resistance (arterial BP = CO × SVR).

Cardiac output (CO) is the volume of blood ejected from the heart per minute. CO can be described as the stroke volume (SV, or the amount of blood pumped out of the left ventricle per beat [~70 mL]) multiplied by the heart rate (HR) for 1 minute. **Systemic vascular resistance (SVR)** is the force opposing the movement of blood within the blood vessels. The radius of the small arteries and arterioles is the principal factor determining vascular resistance. A small change in the radius of the arterioles creates a major change in the SVR. If SVR is increased and CO remains constant or increases, arterial BP will increase.

The mechanisms that regulate BP can affect either CO or SVR, or both. Regulation of BP is a complex process involving nervous, cardiovascular, renal, and endocrine functions (Figure 35-1). BP is regulated by both short-term (over seconds to hours) and long-term (over days to weeks) mechanisms. Short-term mechanisms, including the effects exerted by the sympathetic nervous system (SNS) and the vascular endothelium, are active within a few seconds. Long-term mechanisms include renal and hormonal processes that regulate arteriolar resistance and blood volume.

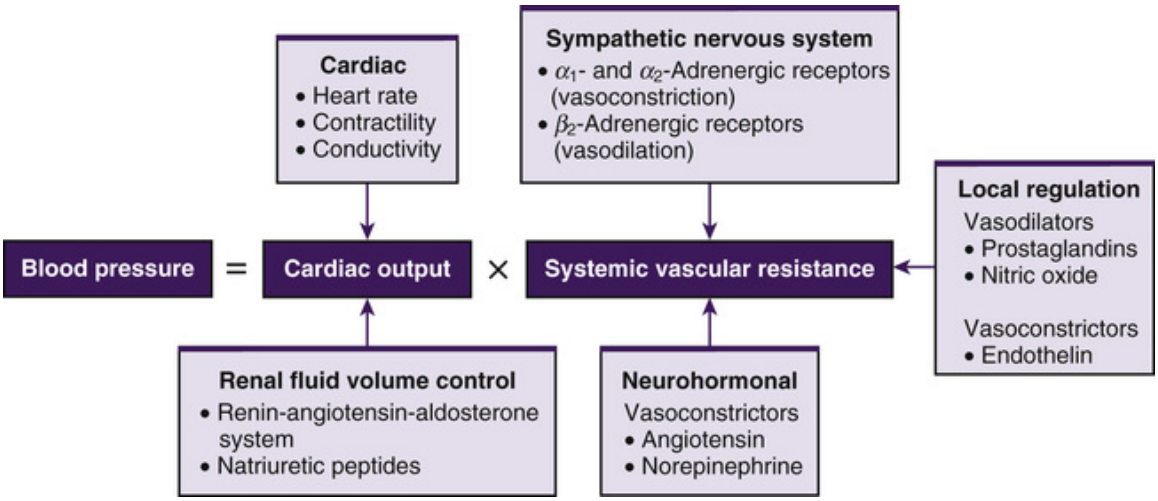

FIGURE 35-1 Factors influencing blood pressure (BP). Hypertension develops when one or more of the BP-regulating mechanisms are defective.

Sympathetic Nervous System

The nervous system, which reacts within seconds after a decrease in arterial pressure, increases BP primarily by activation of the SNS. Increased SNS activity increases HR and cardiac contractility, produces widespread vasoconstriction in the peripheral arterioles, and promotes the release of renin from the kidneys. The net effect of SNS activation is to increase arterial pressure by increasing both CO and SVR.

Changes in BP are sensed by specialized nerve cells called *baroreceptors* and transmitted to the vasomotor centres in the brain stem. Information received in the brain stem is relayed throughout the brain by complex networks of interneurons that excite or inhibit efferent nerves, thereby influencing cardiovascular function. Sympathetic efferent nerves innervate cardiac and vascular smooth muscle cells. Under normal conditions, a low level of continuous sympathetic activity maintains tonic vasoconstriction. BP may be reduced by withdrawal of SNS activity or by stimulation of the parasympathetic nervous system, which decreases the HR (via the vagus nerve) and thereby decreases CO.

The neurotransmitter norepinephrine (NE) is released from sympathetic nerve endings. NE activates receptors located in the sinoatrial node, the myocardium, and vascular smooth muscle. The response to NE depends on the type and the density of receptors present. SNS receptors are classified as α_1, α_2, β_1, and β_2 (Table 35-1). α-Adrenergic receptors located in peripheral vasculature cause vasoconstriction when stimulated by NE.

β_1-Adrenergic receptors in the heart respond to NE with increased HR (chronotropic effect), increased force of contraction (inotropic effect), and increased speed of conduction (dromotropic effect). Diminished responsiveness of cardiovascular cells to sympathetic stimulation is one of the most significant cardiovascular effects of aging. The smooth muscle of the blood vessels has β_1-adrenergic and β_2-adrenergic receptors. β_2-Adrenergic receptors are activated primarily by epinephrine released from the adrenal medulla and cause vasodilation.

TABLE 35-1

SYMPATHETIC NERVOUS SYSTEM RECEPTORS INFLUENCING BLOOD PRESSURE

Adrenergic Receptor	Location	Response When Activated
α_1	Vascular smooth muscle	Vasoconstriction
	Heart	Increased contractility
α_2	Presynaptic membrane	Inhibition of norepinephrine release
	Vascular smooth muscle	Vasoconstriction
β_1	Heart	Increased contractility (positive inotropic effect) Increased heart rate (positive chronotropic effect) Increased conduction (positive dromotropic effect)
	Juxtaglomerular cells	Increased renin secretion
β_2	Smooth muscle of peripheral blood vessels in skeletal muscle, coronary arteries, lungs, kidneys, liver, islet cells, bladder, liver	Vasodilation Relaxation Gluconeogenesis Increase in secretion
Dopaminergic receptors	Primarily kidney and mesenteric blood vessels	Vasodilation

The sympathetic vasomotor centre, located in the medulla, interacts with many areas of the brain to maintain normal BP under various conditions. During exercise, the motor area of the cortex is stimulated, activating the vasomotor centre and the SNS through neuronal connections. This causes an appropriate increase in BP to accommodate the increased oxygen demand of the exercising muscles. During postural change from lying to standing, there is a transient decrease in BP. The vasomotor centre is stimulated and activates the SNS, causing peripheral vasoconstriction and increased venous return to the heart. If this response did not occur, there would be inadequate blood flow to the brain, resulting

in dizziness. Cerebral cortical perceptions such as pain and stress activate the vasomotor centres through the neuronal connections.

Baroreceptors.

Baroreceptors (pressoreceptors) are specialized nerve cells located in the carotid sinus at the bifurcation of the external and internal carotid arteries and the arch of the aorta. They are sensitive to stretching and, when stimulated by an increase in BP, send inhibitory impulses to the sympathetic vasomotor centre in the brain stem. Inhibition of sympathetic activity results in decreased HR, decreased force of contraction, and vasodilation in peripheral arterioles. Increased parasympathetic activity (vagus nerve) also reduces HR.

A fall in BP, sensed by the baroreceptors, leads to activation of the SNS. The result is constriction of the peripheral arterioles, increased HR, and increased contractility of the heart. The baroreceptors have an important role in the maintenance of BP stability during normal activities. In the presence of longstanding hypertension, the baroreceptors become adjusted to elevated levels of BP and recognize this level as "normal." Consequently, the long-term regulation of arterial pressure requires activation of other mechanisms (primarily hormonal and renal) to maintain normal BP. The baroreceptor reflex is less responsive in some older adults.

Vascular Endothelium

The vascular endothelium is a single cell layer that lines the blood vessels. Previously considered inert, it is now known to have the ability to produce vasoactive substances and growth factors. Nitric oxide, an endothelium-derived relaxing factor (EDRF), helps maintain low arterial tone at rest, inhibits growth of the smooth muscle layer, and inhibits platelet aggregation. Other substances released by the vascular endothelium with local vasodilator effects include prostacyclin and endothelium-derived hyperpolarizing factor.

Endothelin (ET), produced by the endothelial cells, is an extremely potent vasoconstrictor. There are three subclasses of ETs: ET-1, ET-2, and ET-3. ET-1 is the most potent ET in producing vasoconstriction. ET-1 also causes adhesion and aggregation of neutrophils and stimulates smooth muscle growth. Endothelial function and dysfunction is an area of ongoing investigation. There is some evidence that vascular endothelial dysfunction may contribute to atherosclerosis and primary hypertension.

The prevention or reversal of endothelial dysfunction may become important for therapeutic interventions in the future.

Renal System

The kidneys contribute to BP regulation by controlling sodium excretion and extracellular fluid (ECF) volume (see Chapter 47). Sodium retention results in water retention, which causes an increased ECF volume. This increases the venous return to the heart, increasing the stroke volume, which elevates the BP through an increase in CO.

The renin–angiotensin–aldosterone system (RAAS) also plays an important role in BP regulation. In response to sympathetic stimulation, decreased blood flow through the kidneys, or decreased serum sodium concentration, renin is secreted from the juxtaglomerular apparatus in the kidney. Renin is an enzyme that converts angiotensinogen to angiotensin I. Angiotensin-converting enzyme (ACE) converts angiotensin I into angiotensin II (A-II), which can increase BP by two different mechanisms (see Chapter 47, Figure 47-6). First, A-II is a potent vasoconstrictor and increases vascular resistance, resulting in an immediate increase in BP. Second, over a period of hours or days, A-II increases BP indirectly by stimulating the adrenal cortex to secrete aldosterone, which causes sodium and water retention by the kidneys, resulting in increased blood volume and increased CO.

A-II also functions at a local level within the heart and the blood vessels. The local vasoactive effects of A-II (vasoconstriction and growth promotion) may contribute to atherosclerosis and primary hypertension.

Prostaglandins (PGs) E_2 (PGE_2) and I_2 (PGI_2), secreted by the renal medulla, have a vasodilator effect on the systemic circulation. This results in decreased SVR and lowering of BP. (PGs are discussed in Chapter 14.)

Endocrine System

Stimulation of the SNS results in release of epinephrine along with a small fraction of NE by the adrenal medulla. Epinephrine increases CO by increasing HR and myocardial contractility. Epinephrine activates β_2-adrenergic receptors in peripheral arterioles of skeletal muscle, causing vasodilation. In peripheral arterioles with only α_1-adrenergic receptors (skin and kidneys), epinephrine causes vasoconstriction.

The adrenal cortex is stimulated by A-II to release aldosterone. (Release of aldosterone is also regulated by other factors, such as low sodium levels

[see Chapters 50 and 51].) Aldosterone stimulates the kidneys to retain sodium and, therefore, water. This increases BP by increasing CO.

An increased blood sodium osmolarity level stimulates the release of antidiuretic hormone (ADH) from the posterior pituitary gland. ADH increases the ECF volume by promoting the reabsorption of water in the distal and the collecting tubules of the kidneys. The resulting increase in blood volume can cause an elevation in BP.

In the healthy person, these regulatory mechanisms function in response to the demands of the body. When hypertension develops, one or more of the BP-regulating mechanisms are defective.

Hypertension

Hypertension is sustained elevation of systemic arterial BP and is the leading cause for visits to primary care physicians (Hypertension Canada, 2014). High BP is the most significant modifiable risk factor for cardiovascular disease and mortality in Canada (McAlister, Wilkins, Joffres, et al., 2011). High blood pressure remains a significant cardiovascular risk factor affecting 40% of the global adult population ≥25 years (World Health Organization, 2013) and is predicted to become the leading cause of death and disability worldwide by 2020 (Sliwa, Stewart, & Gersh, 2011). As indicated by Padwal, Bienek, McAlister, et al. (2015), even small incremental changes in systolic and diastolic pressures have a direct effect on mortality—for every 20-mm Hg increase in systolic BP to >115 mm Hg (or a 10-mm Hg increase in diastolic BP to >75 mm Hg), the risk for cardiovascular mortality doubles. The prevalence of diagnosed high BP has steadily increased among the Canadian population, from 12.9% in 1998–1999 (Dai, Robitaille, Bancej, et al., 2010) to 22.6% in 2012–2013 (Padwal et al., 2015). Consequently, new recommendations have appeared in the 2017 Hypertension Canada guidelines (formerly the Canadian Hypertension Education Program [CHEP] guidelines). CHEP is Hypertension Canada's "knowledge translation program that targets various healthcare professionals in clinical and community settings, provides regularly updated standardized recommendations and clinical practice guidelines to detect, treat and control hypertension" (Hypertension Canada, 2017).

Hypertension is defined as a systolic blood pressure (SBP) equal to or greater than 140 mm Hg or a diastolic blood pressure (DBP) equal to or greater than 90 mm Hg. According to the Canadian Diabetes Association (CDA) and Hypertension Canada target blood pressures for persons diagnosed with hypertension and diabetes mellitus, SBP should be less than or equal to 130 mm Hg and DBP should be less than or equal to 80 mm Hg (Gilbert, Rabi, LaRochelle, et al., 2013). This is the established level at which antihypertensive therapy is effective at decreasing cardiovascular morbidity and mortality. Canadian targets for blood pressure are shown in Table 35-2. The American Joint National Committee 7 (JNC-7) defines normal BP as an SBP less than 120 mm Hg and a DBP less than 80 mm Hg. Based on JNC-7, patients with sustained hypertension are further divided into stage 1 hypertension (SBP 140–159 or DBP 90–99 mm Hg), and stage 2 hypertension (SBP =160 or DBP =100 mm Hg).

TABLE 35-2
TARGET VALUES FOR BLOOD PRESSURE*

Setting	Target (mm Hg)
Out-of-Office Assessments (Home or Pharmacy)	
Home blood pressure and daytime ambulatory blood pressure measurement (ABPM)*	≤135/85
24-hour ambulatory blood pressure measurement	<130/80
Office	
Diastolic and/or systolic hypertension	<140/90
Isolated systolic hypertension	<140/90 (age <80) <150/90 (age >80)
Diabetes (with microalbuminuria, renal disease, cardiovascular disease, or additional cardiovascular risk factors)	<130/80
Non-diabetic chronic kidney disease	<140/90
Automated office oscillometric device	<130/80
Awake	<135/85
24-hr	<130/80

*Automated blood pressure method (preferred)

Source: Adapted from Canadian Hypertension Education Program (CHEP). (2015). *2015 Canadian Recommendations for the Management of Hypertension. What's new?* (Summary document.) Markham, ON: Hypertension Canada. Retrieved from https://drive.google.com/file/d/0B_aFVG-E49pmc1BwTFFHbHczaWlRYTR4aHNzOVQwZV9WQTd3/view.

According to the Canadian Health Measures Survey (CHMS), approximately 19% of adults ages 20 to 79 years have hypertension, with the rates increasing with age. Older women have higher rates of hypertension than older men. Women with high BP have three and one-half times greater risk of developing cardiovascular disease than women with normal BP do (Heart and Stroke Foundation, 2015). See the Determinants of Health box for statistics on hypertension in selected ethnic groups.

Determinants of Health

Hypertension

Ethnicity: Education and Literacy

- 50% of all Canadians are not aware of the impact of hypertension on kidneys, of the need to adhere to antihypertensive medication, and that hypertension is a chronic condition.
- Chinese Canadians are less aware than other Canadians of the relationship between hypertension and heart attacks; Indian Canadians are less knowledgeable than other Canadians of the association between hypertension and weight.
- Hypertension education needs to be promoted in populations of people from all ethnic backgrounds and should target individuals of lower socioeconomic status.
- Educational materials need to be available in multiple languages and use multi-modal delivery (e.g., television, radio, brochures).

Source: Cunningham, C. T., Sykes, L. L., Metcalfe, A., et al. (2014). Ethnicity and health literacy: A survey on hypertension knowledge among Canadian ethnic populations. *Ethnicity & disease*, *24*(3), 276–282.

Canada has increased awareness and treatment of hypertension compared to other developed countries (Campbell & Chen, 2010). The World Health Organization (WHO) (2013) identified hypertension as a silent killer requiring increased global public awareness necessary for early detection (WHO, 2013). According to McAlister and colleagues (2011), the status of hypertension control improved considerably between 1992 and 2009; however, the prevalence of hypertension still increased by 3% between 2012 and 2013 (Padwal et al., 2015). Large-scale education programs, such as the CHEP and Heart and Stroke Foundation, have increased people's awareness of hypertension. McAlister and colleagues (2011) found that 83% of those with hypertension are aware of their condition and 17% remain unaware. Padwal et al. (2015) found no changes in this statistical data between the years of 2012 and 2013. Despite these statistics, hypertension remains on the rise in Canada (Padwal et al., 2015) and globally (Campbell & Niebylski, 2014). In addition, the mortality rate for individuals aged 20 to 49 years is two to four times higher for people with hypertension than those without it (Robitaille, Dai, Waters, et al., 2012).

One in five adult Canadians is affected by hypertension, which is also a major risk factor for cardiovascular disease, chronic kidney disease, and death (Daskalopoulou, Rabi, Zarnke, et al., 2015). Adults with high-normal BP (also called *prehypertension*) require annual BP assessment. Health care providers who have been specifically trained to measure BP accurately

should assess BP in all adult patients, at all appropriate visits, to determine cardiovascular risk and monitor antihypertensive treatment. Home measurement of BP has been recommended since the 2008 CHEP guidelines to encourage patient self-efficacy and is consistent with the 2017 Hypertension Canada guidelines (Leung, Daskalopoulou, Dasgupta, et al., 2017). Out-of-office BP readings, including ambulatory and home readings, are recommended by Hypertension Canada to identify higher BP readings, prompting patients to seek treatment and earlier diagnosis (Leung, Daskalopoulou, Dasgupta, et al., 2017). Patient instructions for purchasing and using home BP measurement devices are available at both the Hypertension Canada and the Heart and Stroke Foundation of Canada websites. A comprehensive instructional video on home measurement of BP was developed in 2009 and can be viewed at the Hypertension Canada website (see the Resources at the end of this chapter).

The recommendations for diagnosis of hypertension and follow-up are shown in Figure 35-2. It should be emphasized that, when using BPs recorded during office visits to diagnose hypertension, the thresholds given refer to readings averaged over a specified range of visits and are not one-time measurements from the last visit.

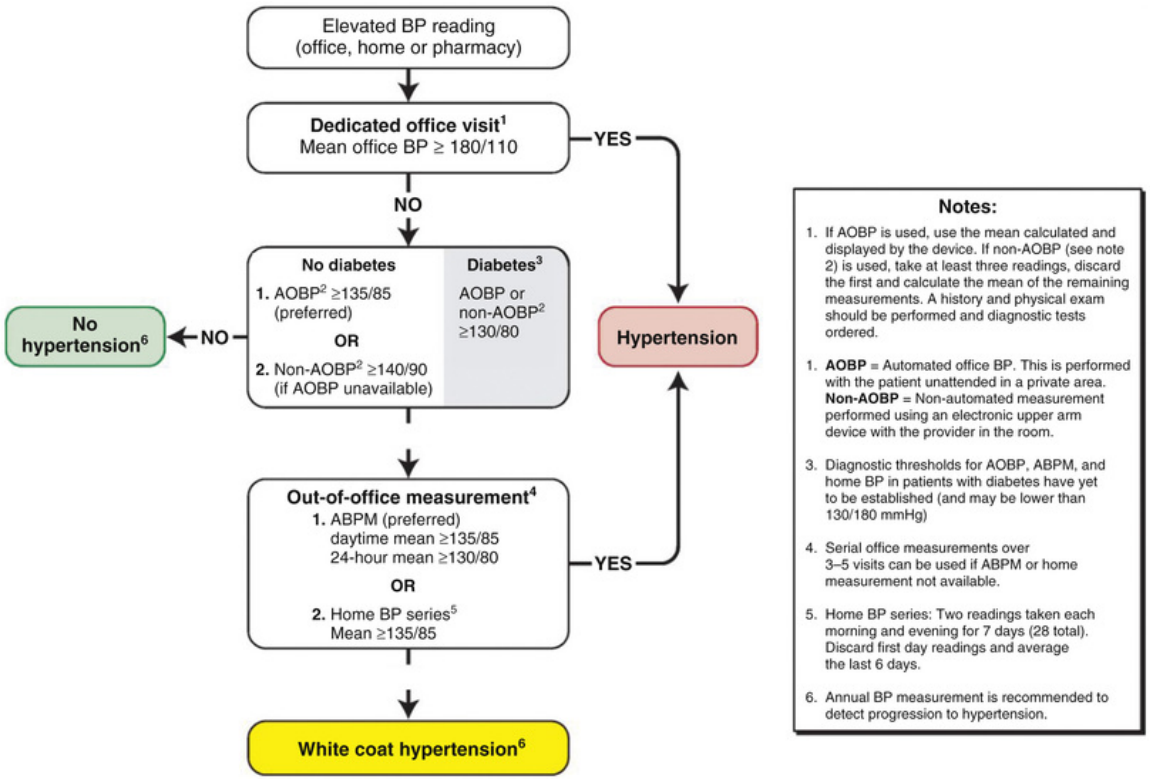

FIGURE 35-2 Criteria for the diagnosis of hypertension and recommendations for follow-up. The thresholds shown here are blood pressure *(BP)* values that are averaged across the corresponding number of visits and are not one-time measurements taken at the most recent office visit. All BP measurements are in millimetres of mercury. *ABPM,* ambulatory blood pressure monitoring; *BPM,* blood pressure monitoring; *DBP,* diastolic blood pressure; *HBPM,* home blood pressure monitoring; *SBP,* systolic blood pressure. Source: Leung, A. A., Daskalopoulou, S. S., Dasgupta, K., et al. (2017). Hypertension Canada's 2017 guidelines for diagnosis, risk assessment, prevention, and treatment of hypertension in adults. *Canadian Journal of Cardiology, 33*(5), 557-576. doi: http://dx.doi.org/10.1016/j.cjca.2017.03.005

Subtypes of Hypertension

Isolated systolic hypertension (ISH) is defined as a sustained elevation in SBP equal to or greater than 140 mm Hg with a DBP less than 90 mm Hg. (A one-time isolated reading of increased SBP is not classified as ISH.) Arterial BP increases with advancing age.

An increase of the SBP without an increase of the DBP, as occurs in ISH, increases the pulse pressure. The *pulse pressure* is the difference between the SBP and the DBP. Loss of elasticity of the large arteries contributes to

this widening of the pulse pressure. Once considered to be harmless, a high pulse pressure is now considered an independent risk factor for cardiovascular disease and end-organ damage. ISH is associated with a two- to four-fold increased future risk for cardiomegaly, MI, or stroke. There is compelling evidence that treatment of ISH with a reduction in the SBP of 20 to 30 mm Hg results in significant cardiovascular benefits. Figure 35-3 presents the treatment algorithm for ISH.

Etiology

Hypertension can be classified etiologically as either primary or secondary.

Primary Hypertension.

Primary (essential) hypertension is elevated BP and accounts for 90% to 95% of all cases of hypertension (Riaz, Dreisbach, Madhur, et al., 2012). Although the exact cause of primary hypertension has not been identified,

it is considered to be a complex interaction between genes and the environment (Geller, 2015). Several contributing factors, including increased SNS activity, overproduction of sodium-retaining hormones and vasoconstrictors, increased sodium intake, greater-than-ideal body weight, diabetes mellitus, and excessive alcohol intake, have been identified. Primary hypertension is the focus of this chapter because of its prevalence in clinical practice.

Secondary Hypertension.

Secondary hypertension is elevated BP with a specific cause that often can be identified and corrected. This type of hypertension accounts for 5% to 10% of hypertension in adults and more than 80% of hypertension in children. If a person younger than age 20 or older than age 50 suddenly develops hypertension, especially if it is severe, a secondary cause should be suspected. Clinical findings that suggest secondary hypertension include unprovoked hypokalemia; abdominal bruit; variable pressures with history of tachycardia, sweating, and tremor; or a family history of renal disease.

Causes of secondary hypertension include the following: (1) coarctation or congenital narrowing of the aorta; (2) renal disease such as renal artery stenosis and parenchymal disease (see Chapter 48); (3) endocrine disorders such as pheochromocytoma, Cushing's syndrome, and hyperaldosteronism (see Chapter 51); (4) neurological disorders such as brain tumours, quadriplegia, and head injury; (5) sleep apnea; (6) medications such as sympathetic stimulants (including cocaine), monoamine oxidase inhibitors taken with tyramine-containing foods, estrogen replacement therapy, oral contraceptive pills, and nonsteroidal anti-inflammatory drugs (NSAIDs); and (7) pregnancy-induced hypertension. Treatment of secondary hypertension is directed at eliminating the underlying cause. Secondary hypertension is a contributing factor to hypertensive urgency (see section at end of this chapter).

Pathophysiology of Primary Hypertension

For arterial pressure to rise, there must be an increase in either CO or SVR. Increased CO is sometimes found in people with early and borderline hypertension. Later in the course of hypertension, SVR rises and the CO returns to normal. The hemodynamic hallmark of hypertension is persistently increased SVR. This persistent elevation in SVR may come

about in various ways. Factors that are known to be related to the development of primary hypertension or contribute to its consequences are presented in Table 35-3.

TABLE 35-3
RISK FACTORS FOR PRIMARY HYPERTENSION

Advancing age	• BP rises progressively with increasing age. • Elevated BP is present in approximately 50% of people >65 yr, with 90% of the remainder developing hypertension during their lifespan.
Heavy alcohol consumption	• Excessive alcohol intake is strongly linked to hypertension. • Canadians with hypertension should limit their daily intake to 30 mL of alcohol.
Cigarette smoking	• The incidence of hypertension is increased among those who smoke ≥15 cigarettes/day. • Canadians with hypertension and who smoke have a greater risk for secondary cardiovascular disease.
Glucose intolerance (diabetes mellitus)	• Hypertension is diagnosed three times more often in individuals diagnosed with diabetes. • When hypertension and diabetes coexist, hypertension augments the already raised risk for cardiovascular diseases and worsens outcomes.
Elevated serum lipids	• Elevated levels of cholesterol and triglycerides are primary risk factors in atherosclerosis. • Hyperlipidemia is more common in Canadians with hypertension.
High dietary sodium intake	• High sodium intake can contribute to hypertension in some patients and can decrease the efficacy of certain antihypertensive medications. • For prevention of hypertension, the daily recommended dietary sodium intake is 1 500 mg for adults ages 14–50 yr of age; 1 300 mg for adults ages 50–70 yr; and 1 200 mg for adults >70 yr.
Gender	• In young adulthood and early middle age, hypertension is more prevalent in men. • After age 55, hypertension is more prevalent in women.
Family history	• Level of BP is strongly familial. • Risk for hypertension increases for those with a close relative having hypertension.
Obesity	• Weight gain is associated with increased risk for hypertension. • According to Statistics Canada, 59% of Canadian adults are at a weight that increases their risk for hypertension. • Risk is greatest with central abdominal obesity. Waist circumference recommendations are <102 cm for men and <88 cm for women.* • Maintenance of a healthy weight and BMI of 18.5–24.9 kg/m^2 is recommended.*
Ethnicity	• Black people or people of South Asian descent are three times more likely to have hypertension than the general population. • Almost 50% of Black people have already developed hypertension in their 40s and 50s.
Sedentary lifestyle	• Physical activity may decrease BP. • Regular physical activity can help control weight and reduce cardiovascular risk. • Daily accumulation of 30–60 min of moderate-intensity dynamic exercise (walking, jogging, cycling, or noncompetitive swimming), 4–7 days/wk is recommended. • Higher intensities of exercise are no more effective.
Socioeconomic status	• Canadians living in low-income neighbourhoods have higher rates of hypertension.
Psychosocial stress	• Canadians exposed to repeated stress may develop hypertension more frequently than others. • Canadians who develop hypertension may respond differently to stress from those who do not.

*Leung, A. A., Daskalopoulou, S. S., Dasgupta, K., et al. (2017). Hypertension Canada's 2017 Guidelines for diagnosis, risk assessment, prevention, and treatment of hypertension in adults. *Canadian Journal of Cardiology, 33*(5), 557-576. doi: http://dx.doi.org/10.1016/j.cjca.2017.03.005.

BP, blood pressure; *BMI,* body mass index.

Genes.

Genetic observations to date suggest that primary hypertension is polygenic and also involves numerous environmental influences. Genetic factors are thought to account for a 30% to 60% variability in BP in individuals (Singh, Mensah, & Bakris, 2010) and vary depending on the study population, from 15% to 20% or from 65% to 70%. Familial heritability is a significant factor. A child with both parents and a sibling with hypertension has a 40% to 60% chance of developing hypertension. This risk increases to 80% if the child is a monozygotic twin. It is unlikely that this risk is from a single genetic locus but, rather, from multiple genes. Similarities across populations have not been established; ongoing research is needed in the area of genetic susceptibility to hypertension.

Sodium and Water Retention.

Excessive dietary intake of sodium is the most studied environmental factor and is strongly linked to the initiation of hypertension in some people. Studies of populations with a low sodium intake (usually primitive hunter–gatherer societies) show little or no hypertension and no progressive increase in BP with age as is found in industrialized societies. In addition, the prevalence of hypertension increases when people from these societies adopt industrialized lifestyles. In many people with hypertension, when sodium is restricted, their BP falls. A high sodium intake may alter the pressure–natriuresis relationship and cause water retention. Although almost everyone in Western countries consumes a high-sodium diet, only about 20% develop hypertension. This indicates that some degree of sodium sensitivity must be present for high sodium intake to trigger the development of hypertension.

Altered Renin–Angiotensin–Aldosterone Mechanism.

The RAAS is a significant mechanism in the regulation of blood volume and pressure. Its role in hypertension is complex. High plasma renin activity (PRA) results in the increased conversion of angiotensinogen to angiotensin I (see Chapter 47, Figure 47-6). A-II causes direct arteriolar constriction, promotes vascular hypertrophy, and induces aldosterone secretion. Thus, altered renin–angiotensin mechanisms may contribute to the development and maintenance of hypertension. However, only about 20% of patients with primary hypertension have high PRA.

Stress and Increased Sympathetic Nervous System Activity.

The SNS also has a critical role in BP control. It has long been recognized that arterial pressure is influenced by factors such as anger, fear, and pain. Physiological responses to stress, which are normally protective, may persist to a pathological degree, resulting in prolonged increase in SNS activity. Increased sympathetic stimulation produces increased vasoconstriction, increased HR, and increased renin release. Increased renin activates the angiotensin mechanism and increases aldosterone secretion, both leading to elevated BP. People exposed to high levels of repeated psychological stress develop hypertension to a greater extent than those who do not experience as much stress.

Insulin Resistance and Hyperinsulinemia.

Abnormalities of glucose, insulin, and lipoprotein metabolism are common in primary hypertension. Insulin resistance is present in 50% of patients with primary hypertension; a strong genetic component is associated with hyperinsulinemia-associated hypertension. Insulin resistance is associated with endothelial dysfunction. High insulin concentration in the blood stimulates SNS and RAAS activity and impairs nitric oxide–mediated vasodilation. Additional pressor effects of insulin include vascular hypertrophy and increased renal sodium reabsorption.

Endothelial Cell Dysfunction.

Vascular endothelial cells are known to be a source of multiple vasoactive substances such as nitric oxide and ET. Some people with hypertension have a reduced vasodilator response to nitric oxide. ET produces pronounced and prolonged vasoconstriction. The role of endothelial dysfunction in the pathogenesis and treatment of hypertension is an area of ongoing investigation.

Obesity.

Obesity is a well-known risk factor for hypertension. Hypertension and central (visceral) obesity are major components of cardiometabolic syndrome. The relationship between hypertension and obesity is multifaceted; the etiology is complex, and it is not well elucidated. Several hormone abnormalities that are associated with obesity are linked to the

development of hypertension. Enlarged adipocytes or fat cells secrete leptin, proinflammatory cytokines, and reactive oxygen species. This dysfunctional adipose tissue may induce activation of the SNS and RAAS.

Clinical Manifestations

Hypertension is a lanthanic, or silent, disease because it is frequently asymptomatic until it becomes severe and target-organ disease has occurred. A patient with severe hypertension may experience a variety of symptoms secondary to effects on blood vessels in the various organs and tissues or to the increased workload of the heart. These secondary symptoms include fatigue, reduced activity tolerance, dizziness, palpitations, angina, and dyspnea. In the past, symptoms of hypertension were thought to include headache, nosebleeds, and dizziness. However, unless BP is extremely high or low, these symptoms are not more frequent in people with hypertension than in the general population.

Complications

The most common complications of hypertension are *target-organ diseases* (Table 35-4) occurring in the heart (hypertensive heart disease), the brain (cerebro-vascular disease), the peripheral vasculature (peripheral arterial disease), the kidneys (nephrosclerosis), and the eyes (retinal damage).

TABLE 35-4

PATHOLOGICAL EFFECTS OF SUSTAINED, COMPLICATED PRIMARY HYPERTENSION

Site of Injury	Mechanism of Injury	Potential Pathological Effect
Heart		
• Myocardium	Increased workload combined with diminished blood flow through coronary arteries	Left ventricular hypertrophy, myocardial ischemia, left heart failure
• Coronary arteries	Accelerated atherosclerosis (coronary artery disease)	Myocardial ischemia, myocardial infarction, sudden death
Aorta	Weakened vessel wall	Aneurysms, acute aortic syndromes
Kidneys	Renin and aldosterone secretion stimulated by reduced blood flow	Retention of sodium and water, leading to increased blood volume and perpetuation of hypertension
	Inflammation and ischemia	Tissue damage that compromises filtration
	High pressures in renal arterioles	Nephrosclerosis leading to renal failure
Brain	Reduced blood flow and oxygen supply; weakened vessel walls, accelerated atherosclerosis	Transient ischemic attack, cerebral thrombosis, aneurysm, hemorrhage, acute brain infarction
Eyes (retinas)	Reduced blood flow	Retinal vascular sclerosis
	High arteriolar pressure	Exudation, hemorrhage
Arterial vessels of lower extremities	Reduced blood flow and high pressures in arterioles, accelerated atherosclerosis	Intermittent claudication, arterial thrombosis, gangrene

Hypertensive Heart Disease

Coronary Artery Disease.

Hypertension is an established major risk factor for coronary artery disease, almost doubling the risk. The mechanisms by which hypertension contributes to the development of atherosclerosis are multifactorial. The shear stress (response-to-injury hypothesis of atherogenesis) results in endothelial dysfunction, causing impairment in the synthesis and release of the potent vasodilator, nitric oxide. A decreased nitric oxide level promotes the development and acceleration of atherosclerosis and plaque formation.

The intimal layer is exposed to activated white blood cells and platelets. Growth factors released by the vascular endothelium and platelets may induce smooth muscle proliferation within the lesion. These arteriolar changes may account for a high incidence of coronary artery disease and the resulting problems of angina and MI.

Left Ventricular Hypertrophy.

Sustained high BP increases the cardiac workload and produces left ventricular hypertrophy (LVH) (Figure 35-4). The risk for LVH doubles with associated obesity. Initially, LVH is an adaptive or compensatory mechanism that strengthens cardiac contraction and increases CO. However, increased contractility increases myocardial work and oxygen consumption. When the heart can no longer meet the demands for myocardial oxygen, heart failure develops. Progressive LVH, especially in association with coronary artery disease, is associated with the development of heart failure.

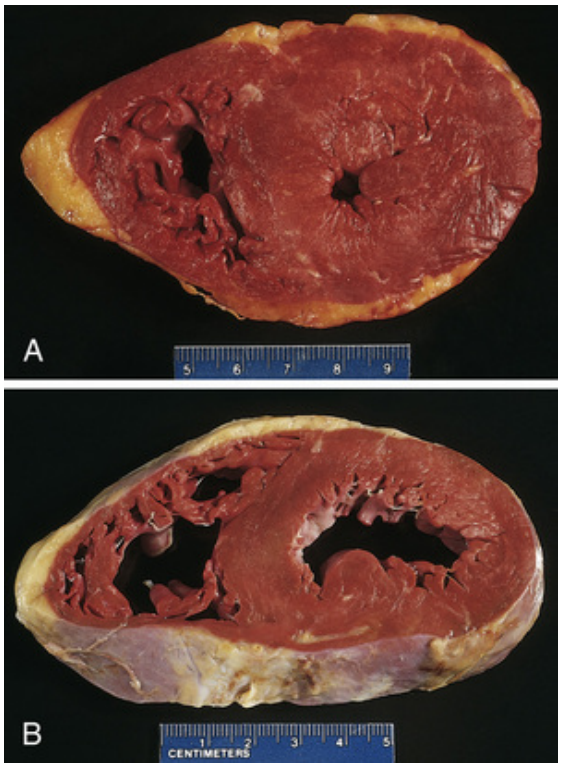

FIGURE 35-4 **A,** Massively enlarged heart caused by hypertrophy of the muscle in the left ventricle. **B,** Compare with the thickness of the normal left ventricle. The patient suffered from severe hypertension. Source: Kumar, V., Cotran, R. S., & Robbins, S.L. (2007). *Robbins basic pathology*, 8th ed. Philadelphia: Saunders.

Heart Failure.

Heart failure is a common complication of a chronically elevated BP and occurs when the heart's compensatory adaptations are overwhelmed and

the heart can no longer pump enough blood to meet the metabolic needs of the body (see Chapter 37). Contractility is depressed, and SV and CO are decreased. The patient may complain of shortness of breath on exertion, paroxysmal nocturnal dyspnea, and fatigue. Signs of an enlarged heart may be present on radiograph, and an electrocardiogram (ECG) may show electrical changes indicative of LVH.

Cerebro-vascular Disease.

Atherosclerosis is the most common cause of cerebro-vascular disease. Hypertension is a major risk factor for cerebral atherosclerosis and stroke. Even in people with mild hypertension, the risk for stroke is four times higher than in people with normal BP. Adequate control of BP effectively diminishes the risk for stroke.

Atherosclerotic plaques are commonly distributed at the bifurcation of the common carotid artery into the internal and external carotid arteries. Portions of the atherosclerotic plaque, or the blood clot that forms on the plaque, may break off and travel to intracerebral vessels, producing a thrombo-embolism. The patient may experience transient ischemic attacks or a stroke. (These conditions are discussed in Chapter 60.)

Hypertensive encephalopathy may occur after a marked rise in BP if the cerebral blood flow is not decreased by autoregulation. *Autoregulation* is a physiological process that maintains constant cerebral blood flow despite fluctuations in arterial BP. Normally, as pressure in the cerebral blood vessels rises, the vessels constrict to maintain constant flow. When arterial BP exceeds the body's ability to autoregulate, the cerebral vessels suddenly dilate and cerebral edema develops, producing a rise in intracranial pressure. If left untreated, patients die quickly from brain damage. (Cerebral blood flow and autoregulation are discussed in Chapter 59.)

Peripheral Arterial Disease.

As it does with other vessels, hypertension speeds up the process of atherosclerosis in the peripheral arterial blood vessels, leading to the development of aortic aneurysm, aortic dissection, and peripheral arterial disease (see Chapter 40). *Intermittent claudication* (ischemic muscle pain precipitated by activity and relieved with rest) is a classical symptom of peripheral arterial disease.

Nephrosclerosis.

Hypertension is one of the leading causes of end-stage renal disease (ESRD). Some degree of kidney dysfunction is usually present in the patient with hypertension, even one with a minimally elevated BP. One of the earliest markers of nephropathy is microalbuminuria, the presence of protein in the urine. Kidney dysfunction is the direct result of ischemia caused by the narrowed lumen of the intrarenal blood vessels. Gradual narrowing of the arteries and arterioles leads to atrophy of the tubules, destruction of the glomeruli, and eventual death of nephrons. Initially intact nephrons can compensate, but these changes may eventually lead to renal failure. Common laboratory indications of kidney dysfunction are microalbuminuria, macroalbuminuria, elevated blood urea nitrogen (BUN), serum creatinine levels, and microscopic hematuria.

Retinal Damage.

The appearance of the retina provides important information about how severe and longstanding the hypertensive process has been. The retina is the only place in the body where the blood vessels can be directly visualized. Damage seen to have occurred to retinal vessels thus provides an indication of vessel damage in the heart, the brain, and the kidneys. An ophthalmoscope is used to visualize the blood vessels of the eye. Manifestations of severe retinal damage include blurring of vision, retinal hemorrhage, and loss of vision.

Diagnostic Studies

The diagnosis of hypertension is not based on a single elevated reading (if <80/110 mm Hg) but requires several elevated readings over several weeks (see Figure 35-1). (Measurement of BP is discussed in Chapter 34.)

Table 35-5 is a list of basic laboratory studies that are performed in a person with sustained hypertension. Routine urinalysis and serum creatinine levels are used to screen for kidney involvement and to provide baseline information about kidney function. (Serum creatinine is discussed in Chapters 47 and 49.)

TABLE 35-5

COLLABORATIVE CARE
Hypertension

Diagnosis

• History and physical examination
• Routine laboratory tests should be performed for the investigation of all patients with hypertension, including the following:
  • Urinalysis
  • Blood chemistry (potassium, sodium, creatinine, blood urea and nitrogen)
  • Fasting blood glucose
  • Fasting total cholesterol and high-density lipoprotein cholesterol, low-density lipoprotein cholesterol, and triglycerides
  • Standard 12-lead electrocardiography
• Assess urinary albumin excretion in patients with diabetes
• All patients with treated hypertension need to be monitored for the appearance of diabetes, according to the Canadian Diabetes Association (CDA) guidelines (available at http://www.canadianjournalofdiabetes.com/article/S1499-2671%2813%2900034-8/pdf).

Collaborative Therapy

• Periodic monitoring of BP
  • Home BP monitoring
  • Ambulatory BP monitoring
  • Every 3–6 mo once BP is stabilized
• Nutritional therapy (see Tables 35-7 and 35-8)
  • Restricted sodium intake (reduce to 2 000 mg per day)*
  • Restricted intake of cholesterol and saturated fats
  • Maintenance of adequate intake of potassium
  • Maintenance of adequate intake of calcium and magnesium
• Weight management
• Regular, moderate physical activity
• Tobacco cessation
• Moderation in alcohol consumption
• Antihypertensive drugs (see Table 35-8)
• Patient and caregiver teaching

*Leung, A. A., Daskalopoulou, S. S., Dasgupta, K., et al. (2017). Hypertension Canada's 2017 Guidelines for diagnosis, risk assessment, prevention, and treatment of hypertension in adults. *Canadian Journal of Cardiology, 33*(5), 557-576. doi: http://dx.doi.org/10.1016/j.cjca.2017.03.005.

NOTE: During the maintenance phase of hypertension management, tests (including those for electrolytes, creatinine, and fasting lipids) should be repeated with a frequency reflecting the clinical situation.

BP, blood pressure.

Measurement of serum electrolytes, especially potassium levels, is important to detect hyperaldosteronism, a cause of secondary hypertension. Blood glucose levels should be assessed to assist in the diagnosis of diabetes mellitus. Serum cholesterol and triglyceride levels provide information about additional risk factors that predispose to atherosclerosis. An ECG provides baseline information about the cardiac status. It is helpful in identifying the presence of LVH and myocardial ischemia. If the patient's age, history, physical examination findings, or

severity of hypertension points to a secondary cause, further diagnostic tests may be indicated.

Ambulatory Blood Pressure Monitoring.

Twenty-four–hour ambulatory BP readings are useful in the diagnosis of uncomplicated mild-to-moderate hypertension and are more accurate in predicting cardiovascular risk than office BP. This method of measuring BP is incorporated into the Hypertension Canada diagnostic algorithm to facilitate more rapid diagnosis of hypertension and reduce the risk of patients being left untreated for long periods of time while a diagnosis is being made over numerous office visits.

A fully automated system that measures BP at preset intervals over a 24-hour period is used. The equipment includes a BP cuff and a small microprocessing unit that fits into a pouch worn on a shoulder strap or belt. Patients are asked to maintain a diary of activities that may affect BP. This procedure may be helpful in patients with suspected white coat hypertension, masked hypertension, apparent drug resistance, hypotensive symptoms with hypertensive medications, episodic hypertension, or autonomic nervous system dysfunction.

Some patients have elevated BP readings in a clinical setting and normal readings when BP is measured elsewhere. This phenomenon is referred to as *white coat hypertension.* Other patients have normal BP in the office and elevated BP at home. This condition is called *masked hypertension.*

As with most physiological phenomena, BP demonstrates diurnal variability, expressed as sleep–wakefulness difference. For day-active people, BP is highest in the early morning, decreases during the day, and is lowest at night. Some patients with hypertension do not show a normal, nocturnal fall in BP—they are called "nondippers." A decrease in nocturnal BP of less than 10% is associated with increased risk for cardiovascular events. The presence or absence of diurnal variability can be determined by continuous ambulatory BP monitoring.

Canadians with hypertension should be encouraged to use an approved BP-measuring device and use proper technique to assess BP at home. BP measured at home is a stronger predictor of cardiovascular events than office-based readings. Home measurement can help to confirm the diagnosis of hypertension, improve BP control, reduce the need for medications, help to identify white coat and masked hypertension, and improve medication adherence in nonadherent patients. An Internet-based toolbox to assist patient self-management for home BP measurement and

lifestyle change can be found at the Heart and Stroke Foundation of Canada's website.

Canadian adults with high-normal BP require annual BP assessment. All Canadian adults need to have BP assessed at all appropriate clinical visits. One in five adult Canadians has hypertension, and for those age 55 with normal BP, 90% will develop hypertension if they live to an average age. All adults require ongoing assessment of BP throughout their lives.

Collaborative Care

Since the establishment of CHEP in 1999, evidence-informed recommendations for the management of hypertension have been updated annually. In 2011, CHEP joined with Hypertension Canada and Blood Pressure Canada with the goal of providing a stronger, united approach to the prevention and control of hypertension. Each year, new evidence is reviewed and integrated into previous evidence-informed guidelines to develop new guidelines (now known as Hypertension Canada guidelines), where appropriate. In order for health care providers to remain informed of updates, the guidelines and other hypertension resources are available at the Hypertension Canada website.

Risk Stratification.

The risk for cardiovascular disease in people with hypertension is determined by the level of BP; the presence of target-organ damage; risk factors such as diabetes, dyslipidemia, smoking, and obesity; and other exogenous, potentially modifiable factors that can induce or aggravate hypertension (Table 35-6). Over 90% of Canadians with hypertension have other cardiovascular risks. Hypertension Canada guidelines recommend that global cardiovascular risk should be assessed in all patients. Simply counting risk factors may lead to underestimating risk.

TABLE 35-6
ASSESSMENT OF THE OVERALL CARDIOVASCULAR RISK

Search for Target-Organ Damage

- Cerebrovascular disease

Hypertension Canada's 2017 Guidelines for diagnosis, risk assessment, prevention, and treatment of hypertension in adults. *Canadian Journal of Cardiology, 33*(5), 557-576. (Supplemental tables.) doi: http://dx.doi.org/10.1016/j.cjca.2017.03.005. Reprinted with permission.

Follow-up monitoring of BP is important. The frequency of monitoring varies initially with the level of BP. After the BP has stabilized, follow-up visits should be scheduled every 3 to 6 months to ensure continued control of BP, provide support for lifestyle changes, assess for target-organ damage, and detect adverse effects of medications.

Lifestyle Modifications.

All patients with hypertension should use lifestyle modifications as either definitive or adjunctive therapy. Lifestyle modifications are directed toward reducing BP and overall cardiovascular risk factors. Modifications include (1) dietary changes, including reduced sodium intake, (2) limitation of alcohol intake, (3) regular physical activity, (4) avoidance of tobacco use (smoking and chewing), (5) stress management, and (6) weight reduction (see Figure 35-3).

Nutritional Therapy.

Hypertension Canada and the Heart and Stroke Foundation of Canada recommend consumption of the Dietary Approaches to Stop Hypertension (DASH) diet, which emphasizes fruits, vegetables, and low-fat dairy products; dietary and soluble fibre; whole grains; and protein from plant sources and that is reduced in saturated fat and cholesterol. The DASH diet is recommended for both patients with hypertension and individuals with normal BP who are at increased risk of developing hypertension. Dietary management of hypertension consists of restriction of sodium; maintenance of dietary potassium, calcium, and magnesium intake; and calorie restriction if the patient is overweight (Table 35-7). (See the Government of Canada's recommended intake for sodium, and the DASH diet to lower high blood pressure, in the Resources at the end of this chapter.)

TABLE 35-7

NUTRITIONAL THERAPY
Hypertension

Food Group	Daily Servings	Examples	Significance to DASH Eating Pattern
Whole grains	7–8	Whole wheat breads, cereals; oatmeal; brown rice; pasta; quinoa; barley; low-fat, low-sodium crackers	Major sources of energy and fibre
Vegetables	4–5	Dark green and orange fresh or frozen vegetables, tomatoes, leafy greens, carrots, peas, squash, spinach, peppers, broccoli, sweet potatoes	Rich sources of potassium, magnesium, and fibre
Fruits	4–5	Have fruit more often than juice: apples, apricots, bananas, dates, grapes, oranges, grapefruit, melons, peaches, berries, pineapple	Important sources of potassium, magnesium, and fibre
Low-fat or fat-free dairy foods or alternatives	2–3	Skim milk, 1% milk, fortified soy beverage or yogourt, 6%–18% modified-fat cheese	Major sources of calcium and protein
Lean meats, poultry, and fish	≤170 g	Lean meats; choose fish such as char, herring, mackerel, salmon, sardines, and trout; trim fat; broil, roast, or boil; no frying; remove skin from poultry; low-sodium, low-fat deli meats	Rich sources of protein and magnesium
Nuts, seeds, and dry beans	4–5/wk	—	Rich sources of energy, magnesium, potassium, protein, and fibre
Fats and oils*	2–3 tsp	Soft margarine, mayonnaise, vegetable oil (olive, corn, canola, or safflower), salad dressing	Added fat and high-fat sources should be minimal. DASH has 27% of calories as fat, including fat in or added to foods.
Sweets	≤5/wk	Sugar, jelly, jam, hard candy, syrups, sorbet, chocolate	Sweets should be low in fat.

*Fat content changes serving counts for fats and oils: For example, 1 tablespoon of regular salad dressing equals 1 serving, 1 tablespoon of low-fat salad dressing equals ½ serving, and 1 tablespoon of fat-free salad dressing equals 0 servings.

DASH, Dietary Approaches to Stop Hypertension. The DASH eating plan is based on approximately 2 000 calories/day. The number of daily servings in a food group may vary from those listed, depending on specific caloric needs.

Source: National Heart, Lung, and Blood Institute. (2006). *The DASH diet.* NIH Publication No. 06-4082. Washington, DC: National Institutes of Health. Retrieved from http://www.nhlbi.nih.gov/files/docs/public/heart/hbp_low.pdf.

The Hypertension Canada 2017 recommendations included the reduction in salt intake for the prevention and treatment of hypertension in accordance with the recommendations of Health Canada. According to the World Health Organization (WHO), reducing salt intake is the most cost-effective measure to improve population health outcomes for all individuals, with or without hypertension (2014).

"High dietary salt causes an estimated 30% of hypertension and increases blood pressure in people with or without hypertension"

(Campbell, Lackland, & Niebylski, 2014, p. 7). The daily adequate intake (AI) for sodium is 1 200 mg (52 mmol) to 1 500 mg (65 mmol) for healthy adults, decreasing with age. The upper tolerable intake level (UL) for sodium is 2 300 mg/day. There is a large discrepancy between recommended levels of sodium intake and actual sodium intake levels by Canadians. The average sodium consumption in Canada is 3 500 mg/day. Eighty percent of sodium intake comes from processed and restaurant foods, whereas only 10% is added at the table or in cooking. See "Sodium 101" and Government of Canada's "Recommended intake of sodium" in the Resources at the end of this chapter for more educational resources about salt. (See also Chapter 37, Tables 37-6 through 37-9.)

The patient and caregivers, especially those who prepare the meals, should be taught about sodium-restricted diets. Instruction should include reading labels of over-the-counter drugs, packaged foods, and health products (e.g., baking soda–containing toothpaste) to identify hidden sources of sodium. It is helpful to review the patient's normal diet and to identify foods high in sodium. Analysis of a 3-day diet history will help identify foods high in sodium in the patient's usual diet.

Sodium restriction may be enough to control BP in some patients with stage 1 hypertension. If drug therapy is needed, a lower dose may be effective if the patient also restricts sodium intake. Furthermore, moderate sodium restriction lessens the risk for hypokalemia associated with diuretic therapy. However, people with hypertension respond differently to salt restriction. This heterogeneity of response has led to attempts to define subgroups of people with hypertension as "salt sensitive" or "salt resistant." Patients with low renin activity are more likely to respond to salt restriction with a reduction in BP.

The significance of other dietary elements for the control of hypertension is not certain. There is evidence that greater levels of dietary potassium, calcium, magnesium, and vitamin D are associated with lower BP in the general population and in those with hypertension. Based on available evidence, the Hypertension Canada 2017 guidelines advise the maintenance of adequate potassium, magnesium, and calcium intake from food sources (Leung, Daskalopoulou, Dasgupta, et al., 2017). Supplementation of potassium, calcium, and magnesium is not recommended for the prevention or treatment of hypertension. Caffeine may raise BP acutely, but there is no long-term relationship between caffeine intake and elevated BP.

Weight Reduction.

Overweight individuals have an increased incidence of hypertension and increased cardiovascular disease risk. Height, weight, and waist circumference should be measured and body mass index (BMI) calculated for all adults. Maintenance of a healthy body weight (BMI 18.5–24.9 kg/m^2 and waist circumference <102 cm for men and <88 cm for women) is recommended for individuals who are normotensive to prevent hypertension and for Canadians with hypertension to reduce BP. All individuals with hypertension who are overweight should be advised to lose weight. Weight reduction has a significant effect on lowering BP, and the effect is seen with even moderate weight loss. When a person decreases caloric intake, sodium and fat intake may also be reduced. Although reducing the fat content of the diet has not been shown to produce sustained benefits in BP control, it may slow the progress of atherosclerosis and reduce overall cardiovascular disease risk (see Chapter 36). Weight-loss strategies should employ a multidisciplinary approach that includes dietary education, increased physical activity, and behavioural intervention.

Modification in Alcohol Consumption.

Excessive alcohol consumption is strongly associated with hypertension. To reduce BP, alcohol consumption should be in accordance with Canadian low-risk drinking guidelines for both adults with hypertension and those with normal BP. Healthy adults should limit alcohol consumption to 2 drinks or fewer per day, and consumption should not exceed 14 standard drinks per week for men and 9 standard drinks per week for women. (One standard drink is considered 13.6 g or 17.2 mL of ethanol, or approximately 44 mL of 80-proof [40%] spirits, 148 mL of 12% wine, or 355 mL of 5% beer [Leung, Daskalopoulou, Dasgupta, et al., 2017].)

Physical Activity.

Recommendations for individuals with normal BP (to reduce the possibility of developing hypertension) and for patients with hypertension (to reduce their BP) include the accumulation of 30 to 60 minutes of moderate-intensity dynamic exercise (such as walking, jogging, cycling, or swimming), 4 to 7 days per week, in addition to the routine activities of daily living (Leung, Daskalopoulou, Dasgupta, et al., 2017). Higher intensities of exercise are no more effective.

Moderately intense activity can lower BP, promote relaxation, and decrease or control body weight. Regular activity of this type can reduce

SBP in the patient with hypertension by approximately 10 mm Hg. Sedentary people should be advised to increase activity levels gradually. People with heart disease or other serious health problems need a thorough examination, possibly including a stress test, before beginning an exercise program.

Avoidance of Tobacco Products.

Nicotine contained in tobacco causes vasoconstriction and increases BP in people with hypertension. In addition, smoking tobacco is a major risk factor for cardiovascular disease. The cardiovascular benefits of discontinuing tobacco use can be seen within 1 year in all age groups. Everyone, especially people with hypertension, should be strongly advised to avoid tobacco use. The lower amounts of nicotine contained in smoking cessation aids usually will not raise BP and may be used as indicated. People who continue to use tobacco products should be advised to monitor their BP during use. (See Chapter 11 and the Resources at the end of this chapter for links to smoking cessation materials.)

Stress Management.

In patients with hypertension in whom stress may be contributing to BP elevation, stress management should be considered as an intervention. Individualized cognitive–behavioural interventions are more likely to be effective when relaxation techniques are used.

Drug Therapy.

The implementation of the CHEP and Hypertension Canada recommendations has resulted in an increased use of antihypertensive medications, increased use of multiple antihypertensive medications, and improved persistence with medication use. The general goal of drug therapy is to achieve a BP of less than 140/90 mm Hg. For patients with chronic kidney disease or diabetes, target BP is less than 130/80 mm Hg. The drugs currently available for treating hypertension have two main actions: (1) to reduce SVR and (2) to decrease the volume of circulating blood (Table 35-8). The drugs used in the treatment of hypertension include diuretics, adrenergic (sympathetic) inhibitors, direct vasodilators, angiotensin inhibitors, and calcium channel blockers. The sites where the drugs exert their action and the methods of action are shown in Figure 35-5.

TABLE 35-8
DRUG THERAPY
Hypertension

Drug	Mechanism of Action	Adverse Effects	Nursing Considerations
Diuretics			
Thiazide and Related Diuretics			
Indapamide (Lozide) Metolazone (Zaroxolyn)	Inhibit NaCl reabsorption in the distal convoluted tubule; increase excretion of Na^+ and Cl^-. Initial decrease in ECF; sustained decrease in SVR. Lower BP moderately in 2–4 wk.	Fluid and electrolyte imbalances (volume depletion, hypokalemia, hyponatremia, hypochloremia, hypomagnesemia, hypercalcemia, hyperuricemia, metabolic alkalosis); CNS effects (vertigo, headache, weakness); GI effects (anorexia, nausea, vomiting, diarrhea, constipation, pancreatitis); sexual problems (impotence and decreased libido); blood dyscrasias; dermatological effects (photosensitivity, skin rash); decreased glucose tolerance	Monitor for orthostatic hypotension, hypokalemia, and alkalosis. Thiazides may potentiate cardiotoxicity of digoxin by producing hypokalemia. Dietary sodium restriction reduces the risk for hypokalemia. NSAIDs can decrease diuretic and antihypertensive effect of thiazide diuretics. Advise patient to supplement with potassium-rich foods. Current doses are lower than previously recommended. Indapamide should be administered with caution to patients with renal failure.
Loop Diuretics			
Bumetanide (Burinex) Ethacrynic acid (Edecrin) Furosemide (Lasix)	Inhibit NaCl reabsorption in the thick ascending limb of the loop of Henle. Increase excretion of Na^+ and Cl^-. More potent diuretic effect than thiazides, but shorter duration of action; less effective for hypertension.	Fluid electrolyte imbalance as with thiazides, except no hypercalcemia; ototoxicity (hearing impairment, deafness, vertigo) that is usually reversible; metabolic effects, including hyperuricemia, hyperglycemia, increased LDL cholesterol and triglycerides with decreased HDL cholesterol	Monitor for orthostatic hypotension and electrolyte abnormalities. Loop diuretics remain effective despite renal insufficiency. Diuretic effect of drug increases at higher doses.
Potassium-Sparing Diuretics			
Amiloride hydrochloride (Midamor, Novamilor)	Reduce K^+ and Na^+ exchange in the distal and collecting tubules. Reduce excretion of K^+, H^+, Ca^{2+}, and Mg^{2+}.	Hyperkalemia, nausea, vomiting, diarrhea, headache, leg cramps, and dizziness	Monitor for orthostatic hypotension and hyperkalemia. Potassium-sparing diuretics are contraindicated for use in patients with renal failure and used with caution in patients on ACE inhibitors or angiotensin II blockers. Avoid potassium supplements.
Spironolactone (Aldactone)	Inhibit the Na^+-retaining and K^+-excreting effects of aldosterone in the distal and collecting tubules.	Same as amiloride; may cause gynecomastia, impotence, decreased libido, and menstrual irregularities	
Adrenergic Inhibitors			

Drug	Mechanism of Action	Adverse Effects	Nursing Considerations
Central-Acting Adrenergic Antagonists			
Clonidine hydrochloride (Catapres)	Reduce sympathetic outflow from CNS. Reduce peripheral sympathetic tone, produces vasodilation; decrease SVR and BP.	Dry mouth, sedation, impotence, nausea, dizziness, sleep disturbance, nightmares, restlessness, and depression; symptomatic bradycardia in patients with conduction disorder	Sudden discontinuation may cause withdrawal syndrome, including rebound hypertension, tachycardia, headache, tremors, apprehension, and sweating. Chewing gum or hard candy may relieve dry mouth. Alcohol and sedatives increase sedation. May be given transdermally with fewer adverse effects and better patient adherence.
Methyldopa	Same as clonidine.	Sedation, fatigue, orthostatic hypotension, decreased libido, impotence, dry mouth, hemolytic anemia, hepatotoxicity, sodium and water retention, psychological depression	Instruct patient about daytime sedation and avoidance of hazardous activities. Administration of a single daily dose at bedtime minimizes sedative effect.
α_1-Adrenergic Blockers			
Doxazosin mesylate (Cardura) Prazosin hydrochloride (Minipress) Terazosin hydrochloride (Hytrin)	Block α_1-adrenergic effects, producing peripheral vasodilation (decrease SVR and BP).	Variable amount of orthostatic hypotension, depending on the plasma volume; may see profound orthostatic hypotension with syncope within 90 min after initial dose; retention of salt and water	Reduced resistance to the outflow of urine in benign prostatic hyperplasia. Taking drug at bedtime reduces risks associated with orthostatic hypotension. Has beneficial effects on lipid profile.
Phentolamine mesylate (Rogitine)	Block α_1-adrenergic receptors, resulting in peripheral vasodilation (decrease SVR and BP).	Acute, prolonged hypotension, cardiac dysrhythmias, tachycardia, weakness, flushing; abdominal pain, nausea, and exacerbation of peptic ulcer	Used in short-term management of pheochromocytoma. Also used locally to prevent necrosis of skin and subcutaneous tissue after extravasation of an α-adrenergic drug. No oral formulation.
β-Adrenergic Blockers			
Acebutolol hydrochloride (Sectral) Atenolol (Tenormin) Betaxolol hydrochloride Bisoprolol fumarate Carvedilol Metoprolol tartrate Nadolol Propranolol hydrochloride Timolol maleate	Reduce BP by antagonizing β_1-adrenergic effects. Decrease CO and reduce sympathetic vasoconstrictor tone. Decrease renin secretion by kidney.	Bronchospasm, atrioventricular conduction block, impaired peripheral circulation; nightmares, depression, weakness, reduced exercise capacity; may induce or exacerbate heart failure in susceptible patients; sudden withdrawal of β-adrenergic blockers may cause rebound hypertension and exacerbate symptoms of ischemic heart disease	β-Adrenergic blockers vary in lipid solubility, selectivity, and presence of partial sympathomimetic effect, which explains different therapeutic and adverse effect profiles of specific agents. Monitor pulse regularly. Use with caution in patients with diabetes mellitus because drug may mask signs of hypoglycemia.
Esmolol hydrochloride (Brevibloc)	Reduce BP by antagonizing β_1-adrenergic effects.	—	IV administration; has rapid onset and brief duration of action.
Combined α- and β-adrenergic blocker			

Drug	Mechanism of Action	Adverse Effects	Nursing Considerations
Labetalol hydrochloride (Trandate)	α_1-, β_1-, and β_2-Adrenergic blocking properties, producing peripheral vasodilation and decreased heart rate. Reduce CO, SVR, and BP.	Dizziness, fatigue, nausea, vomiting, dyspepsia, paresthesia, nasal stuffiness, impotence, edema; hepatic toxicity	Same as β-adrenergic blockers. IV form available for hypertensive crisis in hospitalized patients. Patients must be kept supine during IV administration. Assess patient tolerance of upright position (severe orthostatic hypotension) before allowing upright activities (e.g., use of commode).
Direct Vasodilators			
Diazoxide (Proglycem)	Reduce SVR and BP by direct arterial vasodilation.	Reflex sympathetic activation, producing increased HR, CO, and salt and water retention; hyperglycemia, especially in patients with type 2 diabetes	IV use only for hypertensive crisis in hospitalized patients. Administer only into peripheral vein.
Hydralazine hydrochloride (Apresoline)	Reduce SVR and BP by direct arterial vasodilation.	Headache, nausea, flushing, palpitation, tachycardia, dizziness, and angina; hemolytic anemia, vasculitis, and rapidly progressive glomerulonephritis	IV use for hypertensive crisis in hospitalized patients. Twice-daily oral dosage. Not used as monotherapy because of adverse effects. Contraindicated for use in patients with coronary artery disease; used with caution in patients >40 yr of age.
Minoxidil (Loniten)	Reduce SVR and BP by direct arterial vasodilation.	Reflex tachycardia, marked sodium and fluid retention (may require loop diuretics for control), and hirsutism; may cause ECG changes (flattened and inverted T waves) not related to ischemia	Reserved for treatment of severe hypertension associated with renal failure and resistant to other therapy. Once- or twice-daily dosage.
Nitroglycerin	Relax arterial and venous smooth muscle reducing preload and SVR. At low dose, venous dilation predominates; at higher dose, arterial dilation is present.	Hypotension, headache, vomiting, flushing IV use for hypertensive crisis in hospitalized patients with myocardial ischemia	Administered by continuous IV infusion with pump or control device.
Sodium nitroprusside (Nipride)	Direct arterial vasodilation reduce SVR and BP.	Acute hypotension, nausea, vomiting, muscle twitching; signs of thiocyanate toxicity include anorexia, nausea, fatigue, disorientation	IV use for hypertensive crisis in hospitalized patients. Administered by continuous IV infusion with pump or control device. Use intra-arterial monitoring of BP. Light-resistant bags, bottles, and administration sets must be used; stable for 24 hr. Monitor thiocyanate levels with prolonged (>24–48 hr) use.
Angiotensin Inhibitors			
Angiotensin-Converting Enzyme (ACE) Inhibitors			

Drug	Mechanism of Action	Adverse Effects	Nursing Considerations
Benazepril hydrochloride (Lotensin) Captopril Enalapril sodium (Vasotec) Fosinopril sodium Lisinopril (Prinivil, Zestril) Perindopril erbumine (Coversyl) Quinapril hydrochloride (Accupril) Ramipril (Altace) Trandolapril (Mavik, Tarka) Enalaprilat injection (Vasotec IV)	Inhibit ACE; reduce conversion of angiotensin I to angiotensin II (A-II); prevent A-II–mediated vasoconstriction. Inhibit ACE when oral drugs not appropriate.	Hypotension, loss of taste, cough, hyperkalemia, acute kidney injury, skin rash, angioneurotic edema; same as oral forms	ASA and NSAIDs may reduce drug effectiveness. Addition of diuretic enhances drug effect. Should not be used with potassium-sparing diuretics. Can cause fetal morbidity or mortality. Captopril may be given orally for hypertensive crisis. Given by IV route over 5 min; may be given every 6 hr.
Angiotensin II Receptor Blockers			
Candesartan cilexetil (Atacand) Eprosartan mesylate (Teveten) Irbesartan (Avapro) Losartan potassium (Cozaar) Telmisartan (Micardis) Valsartan (Diovan)	Prevent action of angiotensin II and produce vasodilation and increased salt and water excretion.	Hyperkalemia, decreased kidney function	Full effect on BP may not be seen for 3–6 wk.
Calcium Channel Blockers			
Amlodipine besylate (Caduet, Norvasc) Diltiazem hydrochloride (Tiazac) Felodipine (Plendil) Nifedipine (Adalat) Verapamil hydrochloride (Isoptin)	Block movement of extracellular calcium into cells, causing vasodilation and decreased SVR.	Nausea, headache, dizziness, peripheral edema; reflex tachycardia (with dihydropyridines); reflex decrease HR (with diltiazem); constipation (with verapamil)	Use with caution in patients with heart failure. Contraindicated for use in patients with second- or third-degree heart block. Sustained-release formulations for some drugs. Avoid grapefruit consumption when on nifedipine.

(2003). *The seventh report of the Joint National Committee on Detection, Evaluation, and Treatment of High Blood Pressure (JNC-7).* Washington, DC: National Institutes of Health.

Although the precise action of diuretics in the reduction of BP is unclear, it is known that they promote sodium and water excretion, reduce plasma volume, decrease sodium in the arteriolar walls, and reduce the vascular

response to catecholamines. Adrenergic-inhibiting drugs act by diminishing the sympathetic effects that increase BP. Adrenergic inhibitors include drugs that act centrally on the vasomotor centre and peripherally to inhibit NE release or to block the adrenergic receptors on blood vessels. Direct vasodilators decrease the BP by relaxing vascular smooth muscle and reducing SVR. Calcium channel blockers increase sodium excretion and cause arteriolar vasodilation by preventing the movement of extracellular calcium into cells.

There are two types of angiotensin inhibitors. The first type is angiotensin-converting enzyme (ACE) inhibitors, which prevent the conversion of angiotensin I to A-II and thus reduce A-II–mediated vasoconstriction and sodium and water retention. The second type is A-II receptor blockers (ARBs), which prevent A-II from binding to its receptors in the walls of the blood vessels.

Drug therapy is recommended for all patients at low risk with stage 1 hypertension (140–159/90–99 mm Hg), although lifestyle management may be the sole therapy. For patients with diabetes or chronic kidney disease, target blood pressure is <130/80 mm Hg. Many younger Canadians with hypertension have multiple cardiovascular risks and are not treated with antihypertensive drugs. Currently, this is a gap in treatment. See the treatment algorithm of systolic–diastolic hypertension without other compelling indications, in Figure 35-3 and Tables 35-9 and 35-10.

TABLE 35-9

CONSIDERATIONS REGARDING THE CHOICE OF FIRST-LINE THERAPY

• Low-dose single pill combinations are preferred as first line therapy to reduce BP and prevent cardiovascular events and reduce the risk of adverse events.
• Use caution in initiating therapy with two drugs in patients in whom adverse events are more likely (e.g., frail older adult, patients with orthostatic hypotension or who are dehydrated).
• ACE inhibitors, renin inhibitors, and ARBs are contraindicated in pregnancy, and caution is required in prescribing to women of child-bearing potential.
• β-Adrenergic blockers are not recommended for patients ≥60 yr without another compelling comorbid condition (such as diabetes mellitus or heart disease).
• Diuretic-induced hypokalemia should be avoided through the use of potassium-sparing agents, if required.
• ACE inhibitors are not recommended (as monotherapy) for patients who are Black, without another compelling comorbid condition.

ACE, angiotensin-converting enzyme; *ARB,* angiotensin II receptor blocker.

TABLE 35-10

DRUG COMBINATIONS

To achieve optimal blood pressure targets:
• Multiple drugs are often required to reach target levels, especially in patients with type 2 diabetes.
• Replace multiple antihypertensive agents with single pill combination therapy.
• Low doses of multiple drugs may be more effective and better tolerated than higher doses of fewer drugs.
• Reassess patients with uncontrolled blood pressure at least every 2 months.
• A combination of two first-line agents may also be considered as initial treatment of hypertension.
• The combination of ACE inhibitors and ARBs should not be used.

ACEIs, angiotensin-converting enzyme inhibitors; *ARBs,* angiotensin II receptor blockers; *CCB,* calcium channel blocker.

Source: Hypertension Canada. (2017). *What's new? 2017 Hypertension Canada guidelines for the management of hypertension.* Retrieved from https://www.hypertension.ca/images/CHEP_2017/HTN_Whats_New_2017_EN.pdf.

The initial drug may be started at a low dosage for several weeks. The full effects of antihypertensive medication may not be apparent for up to 6 weeks. If the BP is not controlled, the dosage of the first-line drug can be increased. A second drug from a different class can be substituted or added if the initial drug was ineffective or there were adverse effects to the initial drug. For most patients, at least two medications (probably taken in

a single tablet) will be necessary in addition to lifestyle changes. Before proceeding with the addition or substitution of medication, consideration should be given to possible reasons for the lack of response to drug therapy.

A new drug therapy has been marketed recently in Canada. Although long-term mortality and morbidity studies have yet to be published, it has been authorized for use in Canada. Aliskiren fumarate (Rasilez) is an oral direct renin inhibitor (DRI). Renin inhibition acts on the conversion of angiotensinogen to angiotensin I. This is the rate-limiting step in the production of A-II, which is a key mediator of BP, body fluid volume, and vascular remodelling. DRIs may be more effective in inhibiting RAAS when compared with ACE inhibitors or ARBs.

The addition of a third or fourth drug may be necessary, but only after the maximum doses of the first and second drugs have been achieved.

After 1 year of optimum BP control, step-down therapy may be tried. The number of medications and their dosages are gradually decreased to the lowest amount that controls the BP. Regular follow-up is needed to detect any elevation of BP.

Adverse effects of antihypertensive drugs may be so severe or undesirable that the patient does not adhere to therapy. Table 35-8 describes the major adverse effects of antihypertensive drugs. Hyperuricemia, hyperglycemia, and hypokalemia are common adverse effects with both thiazide and loop diuretics. ACE inhibitors can lead to high levels of bradykinin, which can cause coughing. An individual who develops a cough with the use of ACE inhibitors may be switched to an A-II receptor blocker. Hyperkalemia can be a serious adverse effect of the potassium-sparing diuretics and ACE inhibitors. Impotence may occur with some of the diuretics. Orthostatic hypotension and sexual dysfunction are two undesirable effects of adrenergic-inhibiting agents. Tachycardia and orthostatic hypotension are potential adverse effects of both vasodilators and angiotensin inhibitors.

Patient Teaching Related to Drug Therapy.

Patient and caregiver teaching related to drug therapy is needed to identify and minimize adverse effects and to cope with therapeutic effects. Adverse effects of antihypertensive drug therapy are common. Adverse effects may be an initial response to a drug and may decrease with continued use of the drug. Informing the patient that adverse effects may lessen with time may enable the individual to continue taking the drug. The number or severity of adverse effects may be related to the dosage,

and it may be necessary to change the drug or decrease the dosage. In this case, the patient should be advised to report the adverse effects to the health care provider who prescribed the medication.

A common adverse effect of several of these drugs is orthostatic hypotension. This condition is caused by an alteration of the autonomic nervous system's mechanisms for regulating BP, which are required for position changes. Consequently, the patient may feel dizzy, weak, and faint when assuming an upright position after sitting or lying down. (Specific measures to control or decrease orthostatic hypotension are presented later on in Table 35-15.)

Sexual dysfunction may occur with many of the antihypertensive drugs (see Table 35-8) and can be a major reason for nonadherence to the treatment plan. Often, the nurse must approach the patient on this sensitive subject and encourage discussion of any sexual dysfunction the patient may experience. It may be easier for the patient to discuss sexual problems once it has been explained that the drug may be the source of the problem and that the adverse effects can be decreased or eliminated by changing to another antihypertensive drug. The patient should be encouraged to discuss adverse effects with the health care provider who prescribed the medication. If the patient is reluctant to do so, the nurse may offer to alert the health care provider to the sexual adverse effect that the patient is experiencing. There are many options for treating hypertension; a plan that is acceptable to the patient should be achievable.

Some unpleasant effects of drugs result from their therapeutic effect, but the impact can be minimized. For example, dry mouth and frequent voiding are unpleasant effects of diuretics. Sugarless gum or candy may relieve the dry mouth. The nurse can assist the patient to develop a medication schedule to minimize unpleasant effects. When frequent urination interrupts sleep, taking the diuretic earlier in the day may be beneficial. Adverse effects of vasodilators and adrenergic inhibitors decrease if the drugs are taken in the evening. BP is lowest during the night and highest shortly after awakening; therefore, drugs with 24-hour duration of action should be taken as early in the morning as possible (e.g., 0400 or 0500 hours, if the patient awakens to void).

Resistant Hypertension.

Resistant hypertension is the failure to reach goal BP in patients who are taking full doses of an appropriate three-drug therapy regimen that includes a diuretic. The nurse should carefully explore reasons why the patient is not at goal BP (Table 35-11). Studies have shown that the use of

renal denervation (destruction of overactive renal nerves) reduces BP and muscle sympathetic nerve activity in patients with resistant hypertension. The exact mechanisms underlying sympathetic neural inhibition are not clear (Hering, Lambert, Marusic, et al., 2013).

TABLE 35-11
CAUSES OF RESISTANT HYPERTENSION

Improper BP measurement
• Volume overload
• Excess salt intake
• Volume retention from kidney disease
• Inadequate diuretic therapy
Drug-induced or other causes
• Nonadherence
• Illegal drugs (e.g., cocaine, amphetamines)
• Inadequate drug dosages
• Inappropriate combinations of drug therapy
• Nonsteroidal anti-inflammatory drugs
• Sympathomimetics (e.g., decongestants, diet pills)
• Oral contraceptives
• Corticosteroids
• Cyclosporin and tacrolimus (Prograf)
• Erythropoietin
• Licorice (including some chewing tobacco)
• Selected over-the-counter dietary or herbal supplements and medicines (e.g., ma huang, bitter orange)
Associated conditions
• Increasing obesity
• Excess alcohol consumption
Identifiable causes of secondary hypertension

Source: National Heart, Lung, and Blood Institute. (2004). *Seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC-7).* NIH Publication No. 04-5230. Bethesda, MD: The Institute. Nursing Management Primary Hypertension

Nursing Assessment

Subjective and objective data that should be obtained from a patient with hypertension are presented in Table 35-12.

TABLE 35-12

NURSING ASSESSMENT
Hypertension Data

Subjective Data
Important Health Information
Current health history: Family history of hypertension or cardiovascular disease; smoking or other tobacco use, alcohol use; sedentary lifestyle; usual salt and fat intake; weight gain or loss *Past health history:* Known duration and past workup of high BP; cardiovascular, cerebro-vascular, renal, or thyroid disease; diabetes; pituitary disorders; obesity; dyslipidemia; menopause or hormone replacement status *Medications:* Use of any prescription or over-the-counter, illicit, or natural health products; previous use of antihypertensive drug therapy
Symptoms
• Dyspnea on exertion, palpitations on exertion, anginal chest pain • Fatigue • Intermittent claudication, muscle cramps • Nocturia • Dizziness; blurred vision, paresthesias • Erectile dysfunction, decreased libido
Objective Data
Cardiovascular
BP consistently >140 mm Hg systolic or 90 mm Hg diastolic, orthostatic change in BP and pulse; abnormal heart sounds; laterally displaced, sustained, forceful, apical pulse; diminished or absent peripheral pulses; carotid, kidney, ischial, or femoral bruits; presence of edema
Musculo-skeletal
Truncal obesity
Neurological
Mental status changes
Possible Findings
Abnormal serum electrolytes (especially potassium); increased creatinine, glucose, cholesterol, and triglyceride levels; proteinuria, microalbuminuria; evidence of ischemic heart disease and left ventricular hypertrophy on ECG

BP, blood pressure; *ECG*, electrocardiogram.

Nursing Diagnoses

Nursing diagnoses and collaborative problems for the patient with hypertension include, but are not limited to, those presented in Table 35-13.

TABLE 35-13
NURSING ASSESSMENT
Hypertension

Nursing Diagnoses

• *Ineffective health maintenance* related to *insufficient resources* (lack of knowledge)
• *Anxiety* related to *stressors, threat to current status* (lifestyle changes associated with hypertension)
• *Sexual dysfunction* related to *vulnerability* (effects of antihypertensive medications)
• *Ineffective health management* related to:
  • *Insufficient knowledge of therapeutic regimen*
  • *Difficulty managing complex treatment regimen*
  • *Perceived barrier* (cost of medications)
  • *Insufficient social support*
  • *Difficulty navigating complex health care systems*
  • *Powerlessness*
• *Disturbed body image* related to *alteration in self-perception*
• *Ineffective peripheral tissue perfusion* related to *insufficient knowledge of disease process* (hypertension)

Collaborative Problems
• Potential complication: adverse effects from antihypertensive therapy • Potential complication: hypertensive crisis • Potential complication: stroke

Planning

The overall goals for the patient with hypertension are that the patient will (1) achieve and maintain the individually determined target BP; (2) understand, accept, and implement the therapeutic plan; (3) experience minimal or no unpleasant adverse effects of therapy; and (4) be confident about the ability to manage and cope with this condition.

Nursing Implementation

Health Promotion.

Primary prevention of hypertension provides an attractive alternative to the costly cycle of managing hypertension and its complications. Current recommendations for primary prevention are based on lifestyle modifications that have been shown to prevent or delay the expected rise in BP in susceptible people. A diet rich in fruits, vegetables, and low-fat dairy foods, with reduced saturated and total fats, significantly lowers BP (see Table 35-7). This diet has been recommended for primary prevention in the general population. Dietary modifications that do not require active participation of the individual, such as a reduction in the amount of salt added to processed foods, may be even more effective.

Individual Patient Evaluation.

The majority of cases of hypertension are identified through routine screening procedures such as insurance and pre-employment or premilitary physical examinations. The nurse in these settings, as well as in most other practice settings, is in an ideal position to assess for the presence of hypertension, identify the risk factors for hypertension and coronary artery disease, and teach the patient about these conditions. In addition to BP determination, a complete health assessment should include such factors as age, sex, and race; diet history (including sodium and alcohol intake); weight patterns; and family history of heart disease, stroke, renal disease, and diabetes mellitus. Medications taken, both prescribed and over-the-counter, should be noted. The patient should be asked about a previous history of high BP and the results of treatment (if any) (see Table 35-12).

Initially, the BP is taken two or three times, at least 2 minutes apart, with the average pressure recorded as the value for that visit. Waiting for at least 2 minutes between readings allows the venous blood to drain from the arm and prevents inaccurate readings. Size and placement of the BP cuff are important considerations for accurate measurement. The width of the inflatable bladder should be 40% of the upper arm circumference, and the length should be 80%. Use of a cuff that is too small or too large will result in readings that are falsely high or low, respectively. Ensure that the cuff is placed 2.5 cm above the antecubital fossa.

BP measurements of both arms should be performed initially to detect any differences between arms. Atherosclerotic narrowing of the subclavian artery can cause a falsely low reading on the side where the narrowing occurs. Therefore, the arm with the higher reading should be used for all subsequent BP measurements. The patient's arm is uncovered and placed at the level of the heart. The cuff should be inflated until no pulse is felt in the brachial artery located in the antecubital fossa of the arm being used. The cuff is then inflated an additional 10 to 20 mm Hg to ensure vascular occlusion. The pressure is released at 2 mm Hg per second. Releasing the pressure any more slowly or quickly may create inaccurate readings. Both SBP and DBP should be recorded, with the DBP recorded as the disappearance of sound (Table 35-14).

TABLE 35-14
APPROPRIATE TECHNIQUE FOR MEASURING BLOOD PRESSURE

1. The use of electronic (oscillometric) measurement methods is preferred to manual measurement. The patient should be seated with the arm bared, supported, and positioned at heart level. The patient should have neither smoked nor ingested caffeine within 30 min before measurement. The patient should also not have used substances containing adrenergic stimulants, such as phenylephrine or pseudoephedrine, which may be found in decongestants or ophthalmic drops.
2. The patient's bowel and bladder should be comfortable. A quiet environment at a comfortable room temperature should be provided.
3. The patient should stay quiet before and during the procedure.
4. For initial readings, the nurse should take the blood pressure in both arms, and subsequently measure in the arm with the highest reading. Thereafter, two measurements should be taken on the side where the BP is highest. Out-of-office measurement should be performed to confirm the initial diagnosis of hypertension.
5. The appropriate cuff size must be used to ensure an accurate measurement. The rubber bladder should reach nearly around (at least 80% of the circumference) or completely encircle the arm. Cuff width should be at least 40% of the arm circumference. Several sizes of cuffs (e.g., child, adult, and large adult) should be available.
6. Measurements should be taken with a mercury sphygmomanometer, a recently calibrated anaeroid manometer, or a calibrated electronic device. Electronic measurement methods are preferred.
7. Both systolic and diastolic pressures should be recorded. The disappearance of sound should be used for the diastolic reading.
8. Two or more readings (taken at least 2 min apart) should be averaged. If the first two readings differ by >5 mm Hg, additional readings should be obtained.
9. The patient should be informed of the reading and advised of the need for periodic remeasurement.

BP, blood pressure.

Source: Adapted from Leung, A. A., Daskalopoulou, S. S., Dasgupta, K., et al. (2017). Hypertension Canada's 2017 Guidelines for diagnosis, risk assessment, prevention, and treatment of hypertension in adults. *Canadian Journal of Cardiology*, 33(5), 557-576. doi: http://dx.doi.org/10.1016/j.cjca.2017.03.005.

The BP and the pulse are initially measured with the patient in either the supine or the sitting position after at least 5 minutes of rest. BP and pulse should be measured again after 2 minutes, in the standing position. Usually, the SBP decreases on standing, whereas the DBP and the pulse increase. A decrease of more than 10 mm Hg in SBP, or any decrease in DBP when standing, is abnormal and should prompt further investigation. Common causes of abnormal postural BP values include intravascular volume loss (e.g., with diuretic therapy or dehydration) and inadequate vasoconstrictor mechanisms related to disease or medications. Postural changes in BP and pulse should be measured in older adults, people taking antihypertensive drugs, and when orthostatic hypotension is suspected. The common definition for **orthostatic hypotension** is a decrease of 20 mm Hg (or more) in SBP or a decrease of 10 mm Hg (or more) in DBP that occurs when an individual assumes a standing position.

Screening Programs.

Screening programs in the community are widely used to assess BP. At the time of the BP measurement, each person should be informed in writing of the numerical value of the reading and, if necessary, why further evaluation is important. Effort and resources should be focused on controlling BP in the person already identified as having hypertension; identifying and controlling BP in high-risk groups such as people who are Black or Southeast Asian, people who are obese, and blood relatives of people with hypertension; and screening those with limited access to the health care system.

Cardiovascular Risk Factor Modification.

Education regarding cardiovascular risk factors is appropriate for individual and targeted screening programs. Modifiable cardiovascular risk factors include hypertension, obesity, diabetes mellitus, elevated serum lipids, tobacco use, and physical inactivity. Risk factors can easily be identified and modification discussed with the patient. (Health-promoting behaviours for cardiovascular risk factors are presented in Chapter 36, Table 36-4 and Figure 36-5.)

Ambulatory and Home Care.

The primary nursing responsibilities for long-term management of hypertension are to assist the patient in reducing BP and adhering to the treatment plan. Nursing actions include patient and family teaching, detection and reporting of adverse treatment effects, adherence assessment and enhancement, and evaluation of therapeutic effectiveness (Table 35-15). Patient and caregiver teaching includes the following: (1) nutritional therapy, (2) drug therapy, (3) physical activity, (4) home monitoring of BP (if appropriate), (5) tobacco cessation (if applicable), and (6) stress management.

TABLE 35-15

PATIENT & CAREGIVER TEACHING GUIDE
Hypertension

When presenting information to the patient or caregiver, the nurse should do the following:
1. Provide the numerical value of the patient's BP and explain what it means.
2. Inform the patient that hypertension is usually asymptomatic and symptoms do not reliably indicate BP levels.
3. Explain that hypertension means elevated BP and does not relate to a "hyper" personality.
4. Explain that long-term follow-up and therapy are necessary to treat hypertension.
5. Explain that therapy will not cure, but should control, hypertension.
6. Tell the patient that controlled hypertension is usually compatible with an excellent prognosis and a normal lifestyle.
7. Explain the potential dangers of uncontrolled hypertension.
8. Be specific about the names, the actions, the dosages, and the adverse effects of prescribed medications.
9. Tell the patient to plan regular and convenient times for taking medications.
10. Tell the patient not to discontinue drugs abruptly because withdrawal may cause a severe hypertensive reaction.
11. Tell the patient not to double up on doses when a dose is missed.
12. Inform the patient that, if BP increases, the patient should not take an increased medication dosage before consulting with the health care provider.
13. Tell the patient not to take a medication belonging to someone else.
14. Inform the patient that adverse effects of medication often diminish with time.
15. Tell the patient to consult with the health care provider about changing drugs or dosages if impotence or other sexual problems develop.
16. Tell the patient to supplement the diet with foods high in potassium (e.g., citrus fruits and green leafy vegetables) if taking potassium-losing diuretics.
17. Tell the patient to avoid hot baths, excessive amounts of alcohol, and strenuous exercise within 3 hr of taking medications that promote vasodilation.
18. Explain that, to decrease orthostatic hypotension, the patient should arise slowly from bed, sit on the side of the bed for a few minutes, stand slowly, not stand still for prolonged periods, do leg exercises to increase venous return, sleep with the head of the bed raised or on pillows, and lie or sit down when dizziness occurs.
19. Caution about potentially high-risk over-the-counter medications, such as high-sodium antacids, appetite suppressants, and cold and sinus medications. Advise the patient to read warning labels and to consult with a pharmacist.

BP, blood pressure.

Evidence-Informed Practice

Translating Research Into Practice

The nurse is caring for Thao Nguyen, a 46-year-old man with a history of poorly controlled hypertension and chronic kidney disease. The nurse notes that he is taking three antihypertensive medications. He tells the nurse that he can no longer live with the adverse effects of these drugs (e.g., fatigue, dry mouth, erectile dysfunction). He states that he wants to stop taking the medications. He believes that if he changes his lifestyle by reducing salt from his diet, losing weight, and beginning exercise, he can control his hypertension.

Best Available Evidence	Clinician Expertise	Patient Preferences and Values
Uncontrolled BP places persons with concurrent risk for cardiovascular disease (e.g., diabetes, kidney disease) at highest risk for a cardiovascular event (e.g., stroke). Most patients with hypertension will need two or more medications to achieve their goal BP in addition to lifestyle changes.	The nurse knows that lifestyle changes can help reduce and control BP in many patients. However, patients with poorly controlled hypertension and target-organ disease require medications to control BP and prevent further complications.	Mr. Nguyen wishes to eliminate antihypertensive medications because of unpleasant and unacceptable adverse effects that are interfering with his quality of life.

Decision and Actions

The nurse discusses the role of lifestyle changes and medications in the treatment of hypertension and prevention of (further) target-organ disease with Mr. Nguyen. The nurse supports his intention to make lifestyle changes and validates his concerns regarding the adverse effects of the medications. They discuss these adverse effects, and the nurse explains that it may be possible to change some of his medications to eliminate or reduce the unpleasant adverse effects. However, given the severity of his hypertension and the chronic kidney disease, he will need to be on medications on a long-term basis. Any of his plans to discontinue medications need to be discussed with his health care provider.

Reference for Evidence

Daskalopoulou SS, Rabi DM, Zarnke KB, et al. The 2015 Canadian hypertension education program recommendations for blood pressure measurement, diagnosis, assessment of risk, prevention, and treatment of hypertension. *Journal of Cardiology*. 2015;31:549–568; 10.1016/j.cjca.2015.02.016.

Informatics in Practice

Monitoring Blood Pressure

- Patients with hypertension who have a smartphone or computer access should be encouraged to use applications aimed at helping them manage their care, including BP self-monitoring and appointment tracking.
- Patients enter their SBP and DBP, heart rate, and other information, including the arm measured. They also indicate whether they were standing, sitting, or lying down as well as the time the BP was taken.
- At appointment time, the nurse can review the reports generated from the application to assist in determining how well the patient's BP has been controlled.

DBP, diastolic BP; *SBP*, systolic BP.

Physical Activity.

Physical activity is bodily movement produced by skeletal muscles that requires energy expenditure. Health benefits from physical activity can be achieved with moderate-intensity activities. The goal for all adults is to accumulate 30 minutes of moderate-intensity activity daily. Generally, physical activity is more likely to be sustained if it is safe and enjoyable, fits easily into the daily schedule, and does not generate financial or social costs.

Shopping malls in many communities are open early in the morning (before shopping hours) and provide a warm, safe, flat area for walking. In some communities, health clubs offer special “off-peak” rates to encourage

physical activity among older adults. Cardiac rehabilitation programs offer supervised exercise with education about reduction of cardiovascular risk factors. Nurses can assist people with hypertension to increase their physical activity by identifying and communicating the need for increased activity, explaining the difference between physical activity and exercise, assisting in initiating activity, and following up appropriately.

Home Blood Pressure Monitoring.

Some patients benefit from regularly monitoring their BP at home. Home BP measurement may give a more valid indication of the BP because the patient is more relaxed. It is important to emphasize to the patient that a single reading is not as important as a series of readings over time. The patient should be instructed to take BP readings weekly (unless otherwise instructed), once the BP has stabilized. A log of the BP measurements should be maintained by the patient and brought to office visits.

Home BP readings may help achieve patient adherence by reinforcing the need to continue therapy. A patient may become excessively concerned with the BP readings when using home monitoring. Generally, however, this practice should reassure the patient that the treatment is effective.

Patient Adherence.

A major challenge in the long-term management of the patient with hypertension is poor adherence with the prescribed treatment plan. The reasons are many and include inadequate patient teaching, unpleasant adverse effects of drugs, return of BP to normal range while on medication, lack of motivation, high cost of drugs, and lack of a trusting relationship between the patient and the health care provider. In addition to using BP determinations as an indicator of adherence, the nurse should also assess the patient's diet, activity level, and lifestyle.

Individual assessment to determine the reasons the patient does not adhere to the treatment plan as well as the development of an individualized plan with the patient's assistance are essential. The plan should be compatible with the patient's personality, habits, and lifestyle. Active patient participation increases the likelihood of adherence to the treatment plan. Measures such as involving the patient in scheduling medication convenient to a daily routine, helping the patient link pill-taking with another daily activity, and involving family members (if necessary) help increase patient adherence. Substituting combination tablets for multiple drugs once the BP is stabilized may also facilitate adherence because the patient has to take fewer pills each day and the cost

may be less. It is important to help the patient and the family understand that hypertension is a chronic condition that cannot be cured but can be controlled with drug therapy, diet therapy, physical activity, periodic evaluation, and other relevant lifestyle changes (Table 35-16).

TABLE 35-16

RECOMMENDATIONS TO IMPROVE ADHERENCE TO ANTIHYPERTENSIVE PRESCRIPTIONS

Adherence can be improved by a multipronged approach. The nurse should:
• Assess adherence to pharmacological and nonpharmacological therapy at every physician visit. • Simplify medication regimens to once-daily administration and utilize electronic medication adherence aids. Use fixed-dose combinations where available and appropriate. • Tailor pill-taking to fit patient's daily habits. • Encourage greater patient responsibility and autonomy in monitoring blood pressure and adjusting prescriptions. • Coordinate with work-site health care providers to improve monitoring of adherence to pharmacological and lifestyle modification prescriptions. • Educate patients and families about disease or treatment regimens.

Evaluation

The overall expected outcomes are that the patient with hypertension will (1) achieve and maintain desired BP as defined for the individual; (2) understand, accept, and implement the therapeutic plan; and (3) experience minimal or no unpleasant adverse effects of therapy.

Age-Related Considerations

Hypertension

Hypertension is common in people 60 years of age and older in industrialized countries. The SBP rises throughout the lifespan and DBP rises until age 55 or 60 years and then levels off. The following age-related physical changes play a role in the pathophysiology of hypertension in the older adult: (1) loss of tissue elasticity; (2) increased collagen content and stiffness of the myocardium; (3) increased peripheral vascular resistance; (4) decreased β-adrenergic receptor sensitivity; (5) blunting of baroreceptor reflexes; (6) decreased kidney function; and (7) decreased renin response to sodium and water depletion (Acelajado & Oparil, 2009).

In older adults taking antihypertensive medication, absorption of some drugs may be altered as a result of decreased splanchnic blood flow. Metabolism and excretion of drugs may also be prolonged.

Careful technique is important in assessing BP in older adults. In some older people, there is a wide gap between the first Korotkoff sound and subsequent beats. This is called the *auscultatory gap.* Failure to inflate the cuff enough may result in seriously underestimating the SBP. This problem can be avoided by palpating the brachial or radial artery while inflating the cuff to a level above the disappearance of the pulse.

Older adults are sensitive to BP changes; therefore, reducing SBP to less than 120 mm Hg in a person with longstanding hypertension could lead to inadequate cerebral blood flow. Medical therapy should be considered for adults when DBP is ≥100 mm Hg or SBP is ≥160 mm Hg regardless of age but excluding those with macrovascular tent organ damage or other cardiovascular risks (Leung, Daskalopoulou, Dasgupta, et al., 2017).

Because of varying degrees of impaired baroreceptor reflex mechanisms, orthostatic hypotension occurs often in older adults, especially in those with ISH. Orthostatic hypotension in this age group is often associated with volume depletion or chronic disease states, such as decreased renal and hepatic function or electrolyte imbalance. To reduce the likelihood of orthostatic hypotension, antihypertensive drugs should be started at low doses and increased cautiously. BP and pulse should be measured in the sitting and standing positions at every visit.

Hypertensive Crisis

Hypertensive crisis is a severe and abrupt elevation in BP, arbitrarily defined as a DBP above 120 to 130 mm Hg. The rate of the rise of BP is more important than the absolute value in determining the need for emergency treatment. Prompt recognition and management of hypertensive crisis is essential to decrease the threat to organ function and life.

Hypertensive crisis occurs most commonly in patients with a history of hypertension who have failed to adhere to their prescribed medication regimen or who have been undermedicated. In this setting, rising BP is thought to trigger endothelial damage and the release of vasoconstrictor substances. A vicious cycle of BP elevation ensues, leading to life-threatening damage to target organs. Hypertensive crisis related to cocaine or crack use is becoming a more frequent problem. Other drugs, such as amphetamines, phencyclidine (PCP), and lysergic acid diethylamide (LSD), may also precipitate hypertensive crisis that may be complicated by drug-induced seizures, stroke, MI, or encephalopathy. Hypertensive crisis is classified by the degree of organ damage and the rapidity with which the BP must be lowered. *Hypertensive emergency,* which develops over hours to days, is a situation in which a patient's BP is severely elevated, with evidence of acute target-organ damage, especially damage to the central nervous system. Hypertensive emergencies include hypertensive encephalopathy, intracranial or subarachnoid hemorrhage, acute left ventricular failure with pulmonary edema, MI, renal failure, and dissecting aortic aneurysm. *Hypertensive urgency,* which develops over days to weeks, is a situation in which a patient's BP is severely elevated but there is no clinical evidence of target-organ damage.

Clinical Manifestations

A hypertensive emergency may be manifested as *hypertensive encephalopathy,* a syndrome in which a sudden rise in BP is associated with headache, nausea, vomiting, seizures, confusion, stupor, and coma. Other common manifestations are blurred vision and transient blindness. The manifestations of encephalopathy are probably the results of cerebral edema and spasms of cerebral vessels.

Renal insufficiency ranging from minor impairment to complete renal shutdown may occur. Rapid cardiac decompensation, ranging from

unstable angina to infarction and pulmonary edema, is also possible with associated chest pain and dyspnea. Aortic dissection causes excruciating chest and back pain, often accompanied by diaphoresis and the loss of pulses in an extremity.

Patient assessment is extremely important, especially monitoring for signs of neurological dysfunction, retinal damage, heart failure, pulmonary edema, and renal failure. The neurological manifestations are often similar to the presentation of a stroke. However, a hypertensive crisis does not show the focal or lateralizing signs often seen with a stroke.

Nursing and Collaborative Management Hypertensive Crisis

BP level alone is a poor indicator of the seriousness of the patient's condition and is not the major factor in deciding the treatment for a hypertensive crisis. The association between elevated BP and signs of new or progressive end-organ damage (e.g., cerebro-vascular, cardiac, retinal, or renal involvement) determines the seriousness of the situation.

Hypertensive emergencies necessitate hospitalization, parenteral administration of antihypertensive drugs, and intensive care monitoring. Generally, the initial treatment goal is to decrease mean arterial pressure (MAP) 10% to 20% in the first 1 to 2 hours, with further gradual reduction over the next 24 hours. Lowering the BP too far or too fast may decrease cerebral perfusion and could precipitate a stroke. A patient who has aortic dissection, unstable angina, or signs of MI must have the SBP lowered to 100 to 120 mm Hg as quickly as possible.

The intravenous (IV) drugs used for hypertensive emergencies include vasodilators (e.g., sodium nitroprusside, nitroglycerin, diazoxide [Proglycem], hydralazine hydrochloride [Apresoline]), adrenergic inhibitors (e.g., phentolamine mesylate [Rogitine], labetalol [Trandate], esmolol hydrochloride [Brevibloc]), and the ACE inhibitor enalapril (Vasotec). Sodium nitroprusside is the most effective parenteral drug for the treatment of hypertensive emergencies. Oral agents may be administered in addition to the parenteral drugs to help make an earlier transition to long-term therapy. The mechanisms of action and the adverse effects of these drugs are shown in Table 35-8.

Administered intravenously, the drugs have a rapid (within seconds to minutes) onset of action. The patient's BP and pulse should be taken every 2 to 3 minutes during the initial administration of these drugs. The use of an arterial line (see Chapter 68) or an automated BP monitoring machine (e.g., Dynamap) to monitor the BP is ideal. The rate of drug administration is titrated according to the level of BP. It is important to prevent hypotension and its effects in a person whose body has adjusted to hypertension. An excessive reduction in BP may cause stroke, MI, or visual changes. Frequently, continual ECG monitoring is done to observe for cardiac dysrhythmias. Extreme caution is needed in treating the patient with coronary artery disease or cerebro-vascular insufficiency. Hourly urinary output should be measured to assess renal perfusion. Careful

monitoring of vital signs and urinary output provides information regarding the effectiveness of these drugs and the patient's response to therapy. Patients receiving IV antihypertensive drugs may be restricted to bed; getting up (e.g., to use the commode) may cause severe cerebral ischemia and fainting.

Regular, ongoing assessment is essential to evaluate the patient with severe hypertension. Frequent neurological checks, including level of consciousness, pupillary size and reaction, movement of extremities, and reactions to stimuli help detect any changes in the patient's condition. Cardiac, pulmonary, and renal systems should be monitored for decompensation caused by the severe elevation in BP (e.g., pulmonary edema, heart failure, angina, renal failure).

Hypertensive urgencies usually do not necessitate IV administration of medications but can be managed with oral agents. The patient with a hypertensive urgency may not need hospitalization, but requires frequent follow-up. The oral drugs most frequently used for hypertensive urgencies are captopril and clonidine (Catapres) (see Table 35-8). The disadvantage of oral medications is the inability to regulate the dosage from moment to moment, as can be done with IV medications. If a patient with hypertensive urgency is not hospitalized, outpatient follow-up should be arranged within 24 hours.

A patient with severe elevation of BP but without target-organ damage may not require emergent drug therapy or hospitalization. Allowing the patient to sit for 20 or 30 minutes in a quiet environment may significantly reduce BP. Oral drugs may then be instituted or adjusted. Additional nursing interventions include encouraging the patient to verbalize fears, answering questions concerning the hypertension, and eliminating excess noise in the patient's environment.

Once the hypertensive crisis is resolved, it is important to determine the cause. The patient will need appropriate management and extensive education to avoid future crises.

Case Study

Primary Hypertension

Source: Mona Makela/Shutterstock.com.

Patient Profile

Frank Windsong is a 45-year-old man who has no previous history of hypertension. At a screening clinic, his BP was found to be 180/120 mm Hg.

Subjective Data

- Father died of stroke at age 60
- Mother is alive but has type 2 diabetes
- States that he feels fine and is not a "hyper" person
- Smokes one pack of cigarettes daily
- Drinks a six-pack of beer on Friday and Saturday nights
- Does not enjoy physical activity
- Has had type 2 diabetes for 5 years and is nonadherent to his diabetic treatment plan
- Has been told that some medications interfere with sexual relationships

Objective Data

Physical Examination

- Moderately obese male
- Sustained apical impulse palpable in the fourth intercostal space, just lateral to the midclavicular line

Diagnostic Studies

- ECG: left ventricular hypertrophy
- Urinalysis: protein 0.3 g/L

- Serum creatinine level: 141 mmol/L

Collaborative Care

- Low-sodium diet
- Hydrochlorothiazide (HCTZ) 12.5 mg daily PO
- Enalapril sodium (Vasotec) 5 mg daily PO

Discussion Questions

1. What risk factors for hypertension does Mr. Windsong have?
2. What evidence of target-organ damage is present?
3. What misconceptions about hypertension should be corrected?
4. What are the nursing priorities for Mr. Windsong? What resources are available to assist in promoting health for Mr. Windsong?
5. ***Priority decision:*** Based on the assessment data presented, what are the priority nursing diagnoses? Are there any collaborative problems? How will they affect Mr. Windsong's treatment?
6. ***Evidence-informed practice:*** Mr. Windsong wants to know the most effective nonpharmacological strategies to lower his BP. What should the nurse tell him?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. Which BP-regulating mechanism(s) can result in the development of hypertension if defective? *(Select all that apply)*
   a. Release of norepinephrine
   b. Secretion of prostaglandins PGE_2 and PGI_2
   c. Stimulation of the sympathetic nervous system
   d. Stimulation of the parasympathetic nervous system
   e. Activation of the renin–angiotensin–aldosterone system
2. While obtaining subjective assessment data from a client with hypertension, the nurse recognizes which of the following as a modifiable risk factor for the development of hypertension?
   a. Hyperlipidemia
   b. Excessive alcohol intake
   c. A family history of hypertension
   d. Consumption of a high-carbohydrate, high-calcium diet
3. The nurse includes which of the following ideas in teaching a client with hypertension about controlling the condition?
   a. All clients with elevated BP require medication.
   b. It is not necessary to limit salt in the diet if taking a diuretic.
   c. Obese people must achieve a normal weight in order to lower BP.
   d. Lifestyle modifications are indicated for all people with elevated BP.
4. What is a major consideration in the management of an older adult with hypertension?
   a. Prevent pseudohypertension from converting to true hypertension.
   b. Recognize that older adults are less likely to adhere to the drug therapy than younger adults.
   c. Ensure that the client receives larger initial doses of antihypertensive drugs because of impaired absorption.
   d. Use careful technique in assessing the BP of the client because of the possible presence of an auscultatory gap.

5. A client with newly diagnosed hypertension has a blood pressure of 158/98 mm Hg after 12 months of exercise and diet modifications. How does the nurse advise the client?
   a. Medication may be required because the BP is still not within the normal range.
   b. Continued monitoring of the BP every 3 to 6 months is all that will be necessary for treatment.
   c. Because lifestyle modifications were not effective, they do not need to be continued and drugs will be used.
   d. The client will have to make more vigorous changes in lifestyle if the client wants to stay off medication for hypertension.
6. A patient is admitted to the hospital in hypertensive emergency (BP 244/142 mm Hg). Sodium nitroprusside is started to treat the elevated BP. Which management strategy(ies) would be appropriate for this patient? *(Select all that apply)*
   a. Measuring hourly urine output.
   b. Decreasing the MAP by 50% within the first hour.
   c. Continuous BP monitoring with an intraarterial line.
   d. Maintaining bed rest and providing sedation to lower the BP.
   e. Assessing the patient for signs and symptoms of heart failure and changes in mental status.

1. a, c, e; 2. b; 3. d; 4. d; 5. a; 6. a, c, e.

CHAPTER 36

Nursing Management

Coronary Artery Disease and Acute Coronary Syndrome

Written by, Rose Shaffer, Linda Bucher

Adapted by, Sandra Goldsworthy

LEARNING OBJECTIVES

1. Describe the prevalence of heart disease in Canada.
2. Explain the etiology and the pathophysiology of coronary artery disease (CAD), angina, and acute coronary syndrome (ACS).
3. Identify risk factors for CAD and the nursing role in the promotion of therapeutic lifestyle changes for patients at risk.
4. Differentiate the precipitating factors, the clinical manifestations, and the collaborative care and nursing management of patients with CAD and ACS.
5. Explain the clinical manifestations, complications, diagnostic study results, and collaborative care of patients with ACS.
6. Describe the pathophysiology of myocardial infarction from the onset of injury through the healing process.
7. Evaluate drug therapy commonly used in treating patients with CAD and ACS.
8. Prioritize key components to include in the rehabilitation of patients recovering from ACS and coronary revascularization procedures.
9. Describe the precipitating factors, the clinical presentation, and the collaborative care of patients who are at risk for or have experienced

sudden cardiac death.

KEY TERMS

acute coronary syndrome (ACS), p. 827
angina, p. 820
atherosclerosis, p. 814
chronic stable angina, p. 821
collateral circulation, p. 815
coronary artery disease (CAD), p. 813
coronary revascularization, p. 833
myocardial infarction (MI), p. 828
percutaneous coronary intervention (PCI), p. 829
Prinzmetal's angina, p. 824
silent ischemia, p. 837
sudden cardiac death (SCD), p. 841
unstable angina (UA), p. 827

Heart disease is the second major cause of death in Canada, accounting for 19.8% (49 891) of all deaths in 2013 (Statistics Canada, 2017). In Canada, 70 000 people per year will have a myocardial infarction (MI), and, of those, 14 000 will not survive (Heart and Stroke Foundation of Canada, 2016a).

Patients with coronary artery disease (CAD) can be asymptomatic or can develop chronic stable angina. Unstable angina (UA) and MI, more serious manifestations of CAD, are termed *acute coronary syndrome* (ACS). Cardiovascular disease is the most common reason for hospitalization in Canada (Heart and Stroke Foundation of Canada, 2016a). Circulatory diseases are the leading cause of death among Indigenous peoples in Canada (Heart and Stroke Foundation of Canada, 2016a). The "Determinants of Health" box discusses culture and social status as determinants of CAD in Canada.

Determinants of Health

Coronary Artery Disease in Canada

Culture

- Immigrants to Canada tend to have better cardiovascular health than do native-born Canadians.
- Immigrants from South Asia have a higher risk for cardiovascular disease. Cardiovascular risk increases proportionally with length of stay in Canada.*

Income and Social Status

- Members of minority and low-income populations experience a disproportionate burden of death and disability from cardiovascular disease.†

Coronary Artery Disease

Coronary artery disease (CAD) is a type of blood vessel disorder that is included in the general category of atherosclerosis; it may affect the heart's arteries and produce various pathological effects, especially the reduced flow of oxygen and nutrients to the myocardium. The term *atherosclerosis* is derived from two Greek words: *athere*, meaning "fatty mush," and *skleros*, meaning "hard." This word combination indicates that atherosclerosis begins as soft deposits of fat that harden with age. Atherosclerosis is often referred to as "hardening of the arteries." Although this condition can occur in any artery in the body, the atheromas have a preference for the coronary arteries. *Arteriosclerotic heart disease (ASHD), cardiovascular heart disease (CVHD), ischemic heart disease,* and *coronary heart disease* are synonymous terms used to describe CAD.

Etiology and Pathophysiology

Atherosclerosis is the major cause of CAD. It is characterized by deposits of lipids within the intima of the artery. Endothelial injury and inflammation play a central role in the development of atherosclerosis.

The endothelium (the inner lining of the vessel wall) is normally nonreactive to platelets and leukocytes, as well as to coagulation, fibrinolytic, and complement factors. However, the endothelial lining can be injured as a result of tobacco use, hyperlipidemia, hypertension, toxins, diabetes, hyperhomocysteinemia, and infection causing a local inflammatory response (Huether & McCance, 2012) (Figure 36-1, *A*).

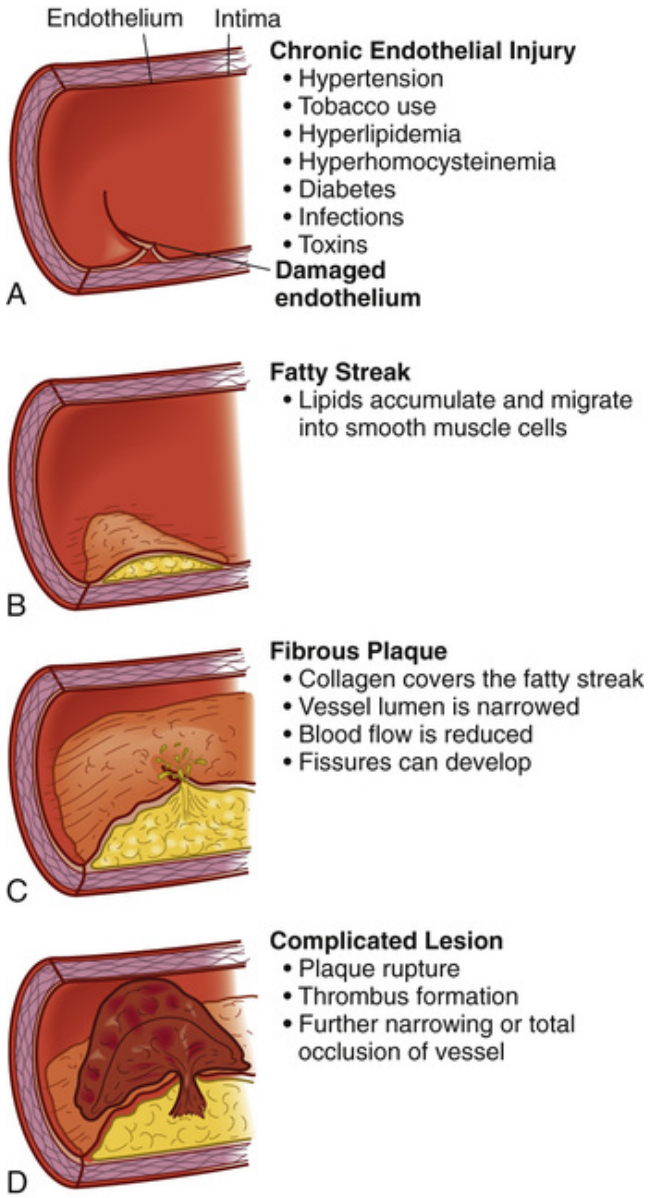

FIGURE 36-1 Pathogenesis of atherosclerosis. **A,** Damaged endothelium. **B,** Fatty streak and lipid core formation. **C,** Fibrous plaque. Raised plaques are visible: some are yellow; others are white. **D,** Complicated lesion: thrombus is red; collagen is blue. Plaque is complicated by red thrombus deposition.

C-reactive protein (CRP), a protein produced by the liver, is a nonspecific marker of inflammation. It is increased in many patients with CAD (Strang & Schunkert, 2014) (see Chapter 34, Table 34-6). The level of CRP rises when there is systemic inflammation. Chronic elevations of CRP are associated with unstable plaques and the oxidation of low-density lipoprotein (LDL) cholesterol.

Developmental Stages

CAD is a progressive disease that develops over many years. By the time it becomes symptomatic, the disease process is usually well advanced. The stages of development in atherosclerosis are (a) fatty streak, (b) fibrous plaque, and (c) complicated lesion.

Fatty Streak.

Fatty streaks, the earliest lesions of atherosclerosis, are characterized by lipid-filled smooth muscle cells. As streaks of fat develop within the smooth muscle cells, a yellow tinge appears (Huether & McCance, 2012). Fatty streaks can be seen in the coronary arteries by age 15 and involve an increasing amount of surface area as one ages. Treatment that lowers LDL cholesterol may reverse this process (Figure 36-1, *B*).

Fibrous Plaque.

The *fibrous plaque* stage is the beginning of progressive changes in the endothelium of the arterial wall. These changes can appear in the coronary arteries by age 30 and increase with age.

Normally, the endothelium repairs itself immediately. However, this does not happen in people with CAD. LDLs and growth factors from platelets stimulate smooth muscle proliferation and thickening of the arterial wall. Once endothelial injury has taken place, lipoproteins (carrier proteins within the bloodstream) transport cholesterol and other lipids into the arterial intima. Collagen covers the fatty streak and forms a fibrous plaque that has a greyish or whitish appearance. These plaques can form on one portion of the artery or in a circular fashion involving the entire lumen. The borders can be smooth or irregular with rough, jagged edges. The result is a narrowing of the vessel lumen and a reduction in blood flow to the distal tissues (Figure 36-1, *C*).

Complicated Lesion.

The final stage in the development of the atherosclerotic lesion is the most dangerous. As the fibrous plaque grows, continued inflammation can result in plaque instability, ulceration, and rupture. Once the integrity of the artery's inner wall is compromised, platelets accumulate in large numbers, leading to a thrombus. The thrombus may adhere to the wall of the artery, leading to further narrowing or total occlusion of the artery. Activation of the exposed platelets causes expression of the glycoprotein IIb/IIIa receptors that bind fibrinogen. This, in turn, leads to further

platelet aggregation and adhesion, further enlarging the thrombus. At this stage, the plaque is referred to as a *complicated lesion* (Figure 36-1, *D*).

Collateral Circulation

Normally, some arterial anastomoses or connections, termed **collateral circulation,** exist within the coronary circulation. Two factors contribute to the growth and extent of collateral circulation: (a) the inherited predisposition to develop new blood vessels *(angiogenesis)* and (b) the presence of chronic ischemia. When an atherosclerotic plaque occludes the normal flow of blood through a coronary artery and the resulting ischemia is chronic, increased collateral circulation develops (Figure 36-2). When occlusion of the coronary arteries occurs slowly over a long period, there is a greater chance that adequate collateral circulation will gradually develop, and the myocardium may continue receiving an adequate amount of blood and oxygen.

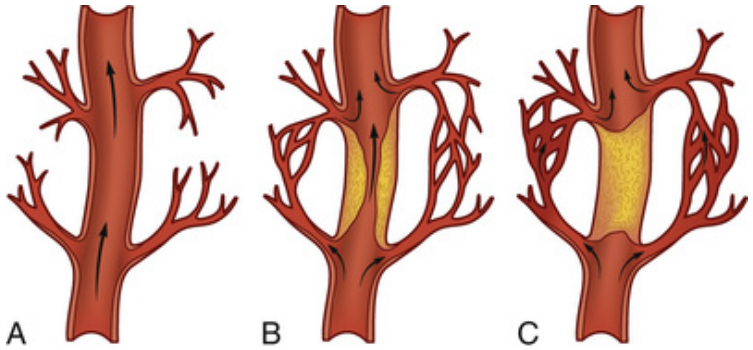

FIGURE 36-2 Vessel occlusion with collateral circulation. **A,** Open, functioning coronary artery. **B,** Partial coronary artery closure with collateral circulation being established. **C,** Total coronary artery occlusion with collateral circulation bypassing the occlusion to supply the myocardium.

However, when CAD has a rapid onset (as in familial hypercholesterolemia) or coronary spasm occurs, there is not enough time for collateral circulation development, and the diminished arterial blood flow results in more severe ischemia or infarction.

CAD usually develops over many years, and clinical manifestations are not apparent in the early stages of the disease. Therefore, it is extremely important to identify people at risk and initiate therapeutic lifestyle changes and treatment strategies early.

Risk Factors for Coronary Artery Disease

Many risk factors—characteristics or conditions that are statistically associated with a high incidence of a disease—have been associated with CAD. Cardiac risk factors are categorized as either *nonmodifiable* or *modifiable* (Table 36-1).

TABLE 36-1
RISK FACTORS FOR CORONARY ARTERY DISEASE

Nonmodifiable Risk Factors	Modifiable Risk Factors
Increasing age Sex (men > women until 65 yr of age) Ethnicity (White people > Black people) Genetic predisposition and family history of heart disease	**Major**
	Serum lipid alterations: elevated triglyceride and LDL cholesterol levels, decreased HDL levels Blood pressure ≥140/90 mm Hg Diabetes mellitus Tobacco use Physical inactivity Obesity: waist circumference ≥102 cm (40 inches) in men and ≥88 cm (35 inches) in women
	Contributing
	Fasting blood glucose level >10 mmol/L Psychosocial risk factors (e.g., depression, hostility and anger, stress) Elevated homocysteine levels

HDL, High-density lipoprotein; *LDL,* low-density lipoprotein.

Nonmodifiable Risk Factors

Age, Sex, and Ethnicity.

Genetic predisposition is an important factor in the occurrence of CAD, although the exact mechanism of inheritance is not fully understood. Some congenital defects in coronary artery walls predispose some people to the formation of plaques. Familial hypercholesterolemia, an autosomal dominant disorder, has been strongly associated with CAD at early ages (see the "Genetics in Clinical Practice" box). In most cases, patients with angina or MI can identify a parent or sibling who has died of CAD.

Genetics in Clinical Practice

Familial Hypercholesterolemia

Genetic Basis

- Autosomal dominant disorder
- Mutation in gene coding for the LDL receptor
- Multiple mutant alleles

Incidence

- Heterozygotes: 1 per 500
- Homozygotes: rare

Genetic Testing

- Disorder characterized by elevated serum LDL level
- Serum lipid profile can be used to measure total cholesterol, triglyceride, LDL, and HDL levels
- DNA testing available

Clinical Implications

- Common genetic disease
- Leading cause of coronary artery disease
- High cholesterol levels are a result of defective function of the LDL receptors
- Plasma levels of LDL remain elevated throughout life
- Those affected develop severe atherosclerosis in early to middle years

DNA, deoxyribonucleic acid; *HDL,* high-density lipoprotein; *LDL,* low-density lipoprotein.

Major Modifiable Risk Factors

Elevated Serum Lipid Levels.

An elevated serum lipid level is one of the four most firmly established risk factors for CAD (Anderson, Grégoire, Hegele, et al., 2013). The various types of serum lipids are presented in Figure 36-3. Approximately 40% of

Canadians have high blood cholesterol (>5.2 mmol/L) (Heart and Stroke Foundation of Canada, 2016a). In Canada, clinical practice guidelines for the diagnosis, treatment, and prevention of dyslipidemia are available (Anderson, Grégoire, Hegele, et al., 2013). These guidelines incorporate (a) a description of patients whose lipid profile should be screened and (b) a classification of metabolic syndrome to evaluate central obesity (waist circumference plus two of the following: plasma triglyceride levels, high-density lipoprotein [HDL] cholesterol level, blood pressure [BP], and fasting plasma glucose level).

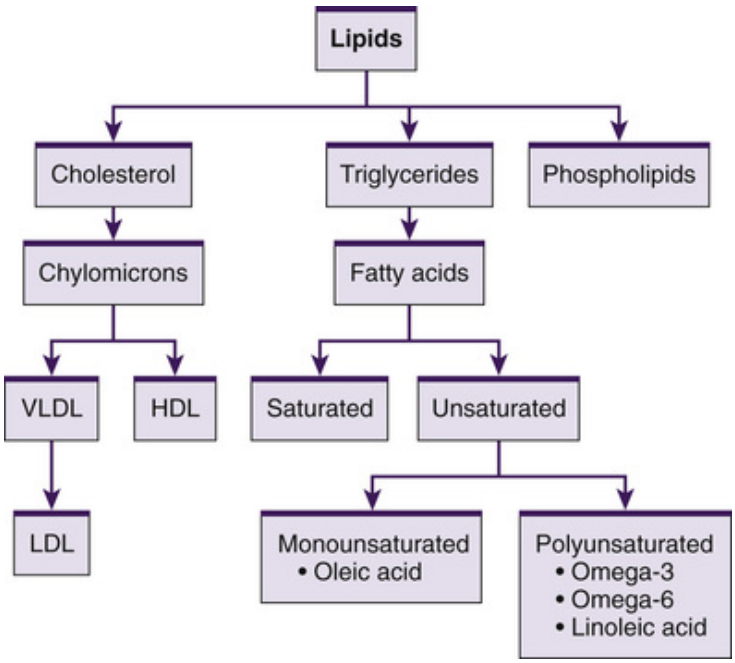

FIGURE 36-3 Types of serum lipids. *HDL*, high-density lipoprotein; *LDL*, low-density lipoprotein; *VLDL*, very-low-density lipoprotein.

The current Canadian guidelines for treating dyslipidemia include a description of patients whose plasma lipid profile should be screened (Figure 36-4) and target lipid levels associated with risk level (Anderson, Grégoire, Hegele, et al., 2013). In the summary of these 2012 guidelines, recommended treatment includes smoking cessation, diet modification (reduced consumption of both saturated fats and refined sugars), weight reduction and maintenance, daily exercise, stress management, and (in patients at high risk) pharmacological therapy.

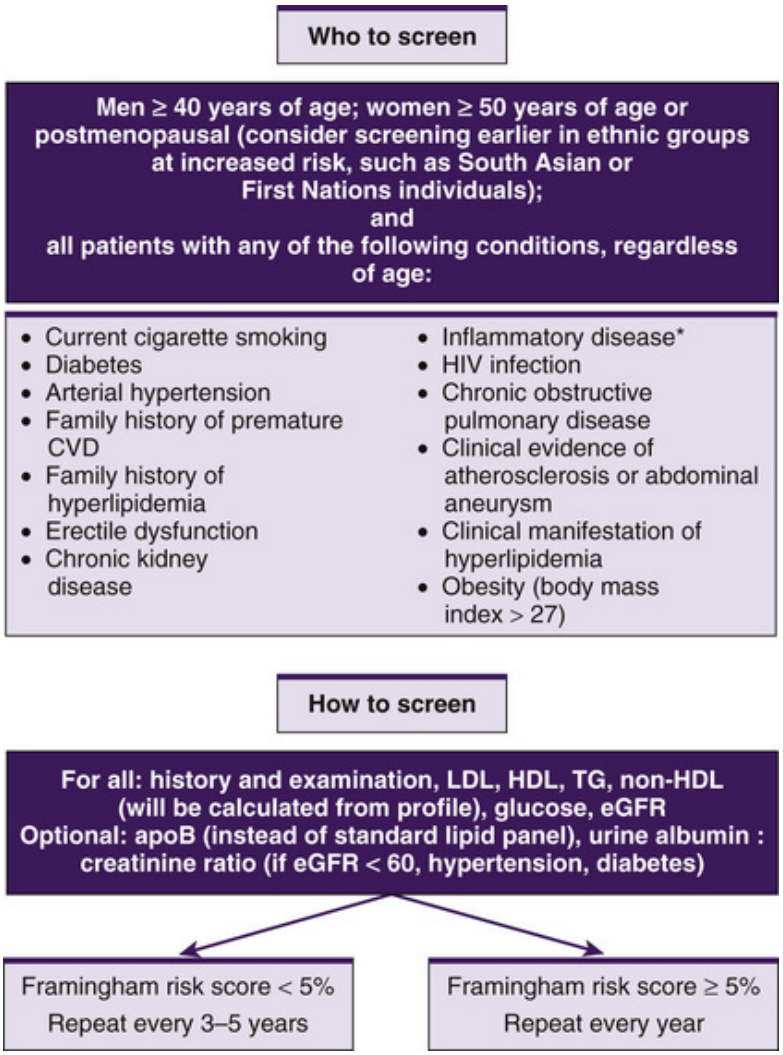

FIGURE 36-4 Patients whose plasma lipid profile should be screened. Source: Reprinted from *Journal of Cardiology,* 29(2), Anderson, T., Grégoire, J., Hegele, R., et al., Society Guidelines 2012 Update of the Canadian Cardiovascular Society Guidelines for the Diagnosis and Treatment of Dyslipidemia for the Prevention of Cardiovascular Disease in the Adult, pp. 151–167, Copyright 2013, with permission from Elsevier. *Data on inflammatory bowel diseases are lacking.

Hypertension.

The second major risk factor in CAD is hypertension, which is defined as a BP of 140/90 mm Hg or higher. The Hypertension Canada recommendations for diagnosis of hypertension and follow-up are presented in Figure 35-2 in Chapter 35.

The stress of a constantly elevated BP increases the rate of atherosclerotic development. The pressure in the vessel is related to the shearing stress that causes endothelial injury. Atherosclerosis, in turn, causes narrowing and thickening of the arterial walls and decreases the distensibility and elasticity of vessels. More force is required to pump blood through diseased arterial vasculature, and this increased force is reflected in a higher BP. This increased workload is also manifested by left ventricular hypertrophy and decreased stroke volume with each contraction. Salt intake is positively correlated with elevated BP, adding volume and increasing systemic vascular resistance (SVR) to the cardiac workload. (See Chapter 35 for a complete discussion of hypertension.) Lifestyle modifications are a critical component of hypertension management. Lifestyle factors that increase risk for hypertension include obesity, poor dietary habits, high sodium intake, low activity levels, high alcohol consumption, and high stress levels (Hypertension Canada, 2015).

Tobacco Use.

A third major risk factor in CAD is tobacco use. The risk of developing CAD is two to six times higher in those who smoke tobacco or use smokeless tobacco than in those who do not. Further, tobacco smoking decreases estrogen levels, placing premenopausal women at greater risk for CAD. Risk is proportional to the number of cigarettes smoked. Changing to lower nicotine or filtered cigarettes does not affect risk.

Nicotine in tobacco smoke causes catecholamine (e.g., epinephrine, norepinephrine) release. These neurohormones cause an increased heart rate (HR), peripheral vasoconstriction, and increased BP. These changes increase the cardiac workload. Tobacco smoke is also related to an increase in LDL level, a decrease in HDL level, and a release of toxic oxygen radicals. All of these add to vessel inflammation and thrombosis (Huether & McCance, 2012).

Carbon monoxide, a byproduct of combustion found in tobacco smoke, affects the oxygen-carrying capacity of hemoglobin by reducing the sites available for oxygen transport. Thus the effects of an increased cardiac workload, combined with the oxygen-depleting effect of carbon monoxide, significantly decrease the oxygen available to the myocardium. There is also some indication that carbon monoxide is a chemical irritant and causes injury to the endothelium.

The benefits of smoking cessation are dramatic and almost immediate. CAD mortality rates drop to those of nonsmokers within 12 months. However, nicotine is highly addictive, and often intensive intervention is

required to assist people to quit. Individual and group counselling sessions, nicotine replacement therapy, smoking cessation medications (e.g., bupropion [Zyban], varenicline [Champix]), and hypnosis are examples of smoking cessation strategies. (For information on smoking cessation, see Chapter 11, Tables 11-10 and 11-11, and the Resources at the end of the chapter.)

Chronic exposure to environmental tobacco (second-hand smoke) also increases the risk for CAD (Smith, Benjamin, Bonow, et al., 2011). People who live in the same household as the patient should be encouraged to stop smoking. By doing so, they reinforce the patient's effort and decrease the risk for ongoing exposure to environmental smoke. Pipe and cigar smokers, who often do not inhale, have an increased risk of CAD similar to those exposed to environmental tobacco smoke.

Physical Inactivity.

Physical inactivity is the fourth major modifiable risk factor. Physical inactivity implies a lack of adequate physical exercise on a regular basis. An example of health-promoting regular physical activity is brisk walking (3 to 4 miles per hour) for at least 30 minutes five or more times a week (James, Oparil, Carter, et al., 2014).

The mechanism by which physical inactivity predisposes a person to CAD is mostly still unknown. Physically active people have increased HDL levels, and exercise improves thrombolytic activity, thus reducing the risk for clot formation. Exercise may also encourage the development of collateral circulation in the heart.

Exercise training for those who are physically inactive decreases the risk for CAD through more efficient lipid metabolism, increased HDL production, and more efficient oxygen extraction by the working muscles, thereby decreasing the cardiac workload. For those individuals with CAD, regular physical activity reduces symptoms, improves functional capacity, and improves other risk factors such as insulin resistance and glucose intolerance.

Obesity.

The mortality rate from CAD is statistically higher among obese individuals, and the risk for CAD is proportional to a person's degree of obesity. *Obesity* is defined as a body mass index (BMI) of more than 30 kg/m^2 and a waist circumference of 102 cm or larger for men and 88 cm or larger for women (Heart and Stroke Foundation of Canada, 2016b). BMI is a calculation of body fat based on height and weight and can be calculated

online (see the Resources section at the end of this chapter). In the past, BMI was the key indicator of health risk related to obesity, but waist circumference is now regarded as the factor that indicates the greatest health risk related to obesity (Smith, Benjamin, Bonow, et al., 2011). Obese persons may produce more LDLs and triglycerides, which are strongly related to atherosclerosis. Obesity is also often associated with hypertension. As well, evidence suggests that people who tend to store fat in the abdomen (i.e., have an "apple" figure) rather than in the hips and buttocks (i.e., have a "pear" figure) have a higher incidence of CAD; see Table 43-2). As obesity increases, the heart grows and uses more oxygen. In addition, there is an increase in insulin resistance in obese individuals (Huether & McCance, 2012).

Modifiable Contributing Risk Factors

Diabetes Mellitus.

The incidence of CAD is two to four times greater among persons who have diabetes, even those with well-controlled blood glucose levels, than in the general population. Patients with diabetes manifest CAD not only more frequently but also at a younger age (Huether & McCance, 2012), with no age difference noted in the onset of symptoms between male and female patients. The presence of diabetes virtually eliminates the lower incidence of CAD in premenopausal women.

Undiagnosed diabetes is frequently discovered at the time a person has an MI. People with diabetes have an increased tendency toward endothelial dysfunction, which may account for the development of fatty streaks in these patients. Diabetic patients also have alterations in lipid metabolism and tend to have high cholesterol and triglyceride levels. Management of diabetes should include lifestyle changes and drug therapy to achieve a glycosylated hemoglobin (A1C or Hb A1C) level of less than 7% (Imran, Rabasa-Lhoret, & Ross, 2013).

Metabolic Syndrome.

Metabolic syndrome refers to a cluster of risk factors for CAD whose underlying pathophysiology may be related to insulin resistance. These risk factors include obesity as defined by large waist circumference, hypertension, abnormal serum lipids, and an elevated fasting blood glucose (Huether & McCance, 2012) (see Table 43-5). These interrelated risk factors of metabolic origin appear to promote the development of CAD. (Chapter 43 discusses metabolic syndrome.)

Psychological States.

The Framingham study provided early evidence that certain behaviours and lifestyles contribute to the development of CAD and correlate with CAD. However, the study of these behaviours remains controversial and complex. One type of behaviour, referred to as *type A,* includes perfectionism and a hardworking, driven personality. Type A people often suppress anger and hostility, feel a sense of time urgency, are impatient, and create stress and tension. These people may be more prone to MIs than those who are *type B,* characterized by being more easygoing, taking upsets in stride, knowing personal limitations, taking time to relax, and not being overachievers. However, findings from studies regarding these relationships are inconsistent.

Studies now are focusing on specific psychological risk factors thought to increase risk for CAD. These include depression; acute and chronic stress (e.g., poverty, serving as a caregiver); anxiety, hostility, and anger; and lack of social support (Burg, Edmondson, Shimbo, et al., 2013; Cohen, Edmondson, & Kronish, 2015). In particular, depression is a risk factor for both the development of and the worsening of CAD. Patients with depression have elevated levels of circulating catecholamines that may contribute to endothelial injury and inflammation and platelet activation. Depression is also a risk factor for adverse outcomes post-ACS (Lichtman, Froelicher, Blumenthal, et al., 2014). More research on the treatment of depression and other negative psychological states (e.g., anger) in patients with or at risk for CAD is needed to improve the emotional and physical health of these patients.

Stressful states correlate with the development of CAD (Jhamnani, Patel, Heimlich, et al., 2015). Sympathetic nervous system (SNS) stimulation—and its effect on the heart—is the physiological mechanism by which stress predisposes one to the development of CAD. SNS stimulation causes an increased release of catecholamines (e.g., epinephrine, norepinephrine). This stimulation increases HR and intensifies the force of myocardial contraction, resulting in increased myocardial oxygen demand. Also, stress-induced mechanisms can cause elevated lipid and glucose levels and changes in blood coagulation, which can lead to increased atherogenesis.

Homocysteine.

High homocysteine levels in the blood have been linked to an increased risk for CAD and other cardiovascular diseases (Burg, Edmonson, Shimbo, et al., 2013). Homocysteine is produced by the breakdown of the essential

amino acid methionine, which is found in dietary protein. High homocysteine levels possibly contribute to atherosclerosis by (a) damaging the inner lining of blood vessels, (b) promoting plaque buildup, and (c) altering the clotting mechanism to make clots more likely to occur (see Chapter 34, Table 34-6).

Research is ongoing to determine whether a decline in homocysteine can reduce the risk for heart disease. B-complex vitamins (B_6, B_{12}, folic acid) have been shown to lower blood levels of homocysteine. Generally, a screening test for homocysteine is limited to those suspected of having elevated levels, such as older patients with pernicious anemia or people who develop CAD at an early age.

Substance Use.

The use of illicit drugs, such as cocaine and methamphetamine, can produce coronary spasm resulting in myocardial ischemia and chest pain. Most people who are seen in the emergency department (ED) with drug-induced chest pain are initially indistinguishable from those with CAD. Although MI can occur, these patients more often have sinus tachycardia, high BP, angina, and anxiety (National Institute on Drug Abuse, 2016).

Health Promotion

The appropriate management of risk factors in CAD may prevent, modify, or retard the progression of the disease. Emphasis on prevention and early treatment of heart disease must be ongoing.

Identification of High-Risk People.

Clinical manifestations of CAD are not apparent in the early stages of the disease. Therefore, regardless of the health care setting, it is extremely important to identify people at risk for CAD. Risk screening involves obtaining a thorough health history that includes questioning the patient about (a) family history of heart disease in parents and siblings; (b) the presence of any cardiovascular symptoms; (c) environmental factors, such as eating habits, type of diet, and level of exercise; (d) psychosocial factors, such as tobacco use, alcohol ingestion, recent stressful events (e.g., loss of a spouse), and any negative psychological states (e.g., anxiety, depression, anger); and (e) the place and type of employment to determine the kind of activities performed, exposure to pollutants or noxious chemicals, and the degree of stress associated with work.

Identifying the patient's attitudes and beliefs about health and illness can give some indication of how disease and lifestyle changes may affect the patient and can also reveal possible misconceptions about heart disease. Knowledge of the patient's educational background can help to determine teaching needs. If the patient is taking medications, it is important to know the names and dosages and whether the patient is compliant with the medication regimen.

Management of High-Risk People.

Preventive measures should be recommended for all persons at risk for CAD. Risk factors such as age, sex, ethnicity, and genetics cannot be modified. However, people with these risk factors can still reduce their risk for CAD by controlling the additive effects of modifiable risk factors. For example, a young man with a family history of heart disease can decrease his risk by maintaining an ideal body weight, getting adequate physical exercise, reducing intake of saturated fats, and avoiding tobacco use.

Nurses can play a major role in teaching health-promoting behaviours and in encouraging patients who have modifiable risk factors to make lifestyle changes to reduce their risk for CAD (Table 36-2). Highly motivated people may just need to know how to reduce their risk in order to get started. For people who are less motivated to take charge of their health, the idea of reducing risk factors may be so remote that they are unable to perceive a threat of CAD. Few people want to make lifestyle changes, especially in the absence of symptoms. First, the nurse should assist these patients in clarifying their personal values. Then, by explaining the risk factors, the nurse may help them recognize their susceptibility to CAD. This information may help patients set realistic goals and allow them to choose which risk factor(s) to change first. Some people are reluctant to change until they begin to manifest overt symptoms or actually suffer an MI. Others, having suffered an MI, may find the idea of changing lifelong habits still unacceptable. Help them identify such choices and respect their final decision.

TABLE 36-2

PATIENT & CAREGIVER TEACHING GUIDE
Decreasing Risk Factors for Coronary Artery Disease

Risk Factor	Health-Promoting Behaviours
Hypertension	• Have regular BP checkups. • Take prescribed medications for BP control. • Reduce salt intake. • Never smoke or stop smoking. • Control or reduce weight. • Exercise regularly.
Elevated serum lipids	• Reduce total fat intake. • Reduce animal (saturated) fat intake. • Adjust total caloric intake to achieve and maintain ideal body weight. • Engage in a regular exercise program. • Increase amount of complex carbohydrates and vegetable proteins in diet.
Smoking*	• Enroll in program to stop smoking. • Change daily routines associated with smoking to reduce desire to smoke. • Substitute other activities for smoking. • Ask family members to support efforts to stop smoking.
Physical inactivity	• Develop and maintain routine for physical activity that is performed at least three or four times a week. • Increase activities to a level compatible with physical fitness.
Stressful lifestyle	• Increase awareness of behaviours that are detrimental to health. • Alter patterns that are conducive to stress and rushing (e.g., get up 30 min earlier so that breakfast is not eaten on way to work). • Set realistic goals for self. • Reassess priorities in view of health needs. • Learn effective coping strategies. • Avoid excessive and prolonged stress. • Take 20 min/day to meditate. • Plan time for adequate rest and sleep.
Obesity	• Change eating patterns and habits. • Reduce caloric intake. • Exercise regularly to increase caloric expenditure. • Avoid fad and crash diets, which are not effective over the long term. • Avoid large, heavy meals.
Diabetes mellitus†	• Follow the recommended diet. • Reduce weight and control diet. • Monitor blood glucose levels regularly.

*See Registered Nurses' Association of Ontario. (2007). *Integrating smoking cessation into daily nursing practice: Nursing Best Practices Guideline.* Toronto: Author. Available at *http://rnao.ca/bpg/guidelines/integrating-smoking-cessation-daily-nursing-practice*.

†See Chapter 52 for additional health-promoting behaviours.

BP, blood pressure.

Physical Activity.

A physical activity program should be designed to improve physical fitness by following the FITT formula: **f**requency (how often), **i**ntensity (how hard), **t**ime (how long), and **t**ype (isotonic). Everyone should aim for at least 30 minutes of moderate physical activity on most days of the week

(James, Oparil, Carter, et al., 2014). In addition, adding weight training to an exercise program two days a week can help treat metabolic syndrome and improve muscle strength. Examples of moderate physical activity include brisk walking, hiking, biking, and swimming. Regular physical activity contributes to weight reduction, a reduction in systolic BP, and, in men more than in women, an increase in HDL cholesterol. The American Heart Association (AHA) has developed a program to encourage people, especially women, to increase their daily physical activity. (See the Resources at the end of this chapter.)

In Canada, the interest in attaining and maintaining health has made physical activity a field of major importance. Communities are developing or promoting exercise programs, such as aerobic exercise classes and cardiac walking and jogging groups, for people of all ages and with varying health needs. Local YMCAs often sponsor jogging, bicycling, swimming, and related courses. Many shopping malls open their doors in the early morning to allow people to walk indoors. The Heart and Stroke Foundation of Canada organizes many events that emphasize the need for physical activity in the promotion of health. Many large corporations provide gymnasiums in which their employees can exercise. For many people, running may be inadvisable; however, these people should be encouraged to pursue walking, swimming, or whatever exercise will accommodate their individual physical abilities.

Health Education in Schools.

Awareness of the body and the maintenance of physical health is also emphasized in Canada's school systems. Schoolteachers play an important role in educating children and youths about good health practices. Besides teaching physical fitness topics, teachers often instruct students in how the body functions and responds to daily living. Lifestyle habits can be positively influenced at an early age to decrease the need for drastic changes later in life, such as those that may confront the students' parents. Teachers are largely taking advantage of the social climate that promotes health and health practices by finding innovative ways to present these values to a receptive, youthful audience before habits become ingrained. The Heart and Stroke Foundation of Canada has established school programs such as “Heart Smart,” which provides teaching materials for teachers to incorporate into their curriculum. Printed and electronic materials are also available to help teachers educate students about healthy habits for better cardiac health.

Nutritional Therapy.

The National Heart, Lung, and Blood Institute recommends *therapeutic lifestyle changes* for all people to reduce the risk of CAD by lowering LDL cholesterol. These recommendations, as well as recommendations from the Heart and Stroke Foundation of Canada, emphasize decreasing intake of saturated fats and cholesterol and increasing intake of complex carbohydrates (e.g., whole grains, fruit, vegetables) and fibre (Eckel, Jakicic, Ard, et al., 2014; Heart and Stroke Foundation of Canada, 2016c) (Tables 36-3 and 36-4). Fat intake should account for about 30% of calories, with most coming from mono- and polyunsaturated fats (Figure 36-5). Red meat, egg yolks, and whole milk products are major sources of saturated fat and cholesterol and should be reduced or eliminated from diets. If a person's serum triglyceride level is elevated, the guidelines recommend reducing or eliminating alcohol intake and simple sugars.

TABLE 36-3

NUTRITIONAL THERAPY
Therapeutic Lifestyle Changes Diet

Nutrient	Recommended Daily Intake
Total fat (includes saturated-fat calories)	25%–35% of total daily calories
Saturated fat	<7% of total daily calories
Cholesterol	<200 mg
Plant stanols or sterols (e.g., margarines, nuts, seeds, legumes, vegetable oils)*	2 g
Dietary fibre*	10–25 g of soluble fibre
Total calories	Only enough calories to reach or maintain a healthy weight
Physical activity	At least 30 min of a moderate-intensity physical activity (e.g., brisk walking) on most, or preferably all, days of the week

*Diet options for additional lowering of low-density lipoprotein (LDL).

TABLE 36-4

NUTRITIONAL THERAPY
Tips to Implement Diet and Lifestyle Recommendations

General Tips
• Know your caloric needs to achieve and maintain a healthy weight. • Know the calorie content of the foods and beverages you consume. • Track your weight, physical activity, and caloric intake. • Prepare and eat smaller, more frequent meals. • Track your activities and, whenever possible, decrease sedentary activities (e.g., television watching, computer time). • Incorporate physical movement into daily activities (e.g., take extra steps when possible). • Do not smoke or use tobacco products. • If you consume alcohol, do so in moderation (i.e., no more than one drink for women or two drinks for men a day).
Tips Related to Food Choices and Preparation

• Use the Nutrition Facts panel on food labels and ingredients list when choosing foods to buy.
• Select frozen and canned vegetables and fruits without high-calorie sauces or added salt and sugars.
• Replace high-calorie foods with fresh fruits and vegetables.
• Increase fibre intake by eating beans (legumes), whole-grain products, fruits, and vegetables.
• Use liquid vegetable oils in place of solid fats.
• Limit beverages and foods high in added sugars (e.g., sucrose, glucose, fructose, maltose, dextrose, corn syrups, concentrated fruit juice, honey).
• Choose foods made with whole grains (e.g., whole wheat, oats/oatmeal, rye, barley, corn, popcorn, brown rice, wild rice, buckwheat, cracked wheat, sorghum).
• Eliminate pastries and high-calorie bakery products (e.g., muffins, doughnuts).
• Select milk and dairy products that are either fat free or low fat.
• Reduce salt intake by:
  • Comparing the sodium content of similar products (e.g., different brands of tomato sauce) and choosing products with less sodium
  • Choosing versions of processed foods that are reduced in salt, including cereals and baked goods
  • Limiting condiments (e.g., soy sauce, ketchup)
• Use lean cuts of meat and remove skin from poultry before cooking or eating.
• Avoid processed meats that are high in saturated fat and sodium (e.g., deli meats).
• Grill, bake, or broil fish, meat, and poultry.
• Incorporate vegetable-based meat substitutes into favourite recipes (e.g., soy).
• Consume whole vegetables and fruits in place of juices.

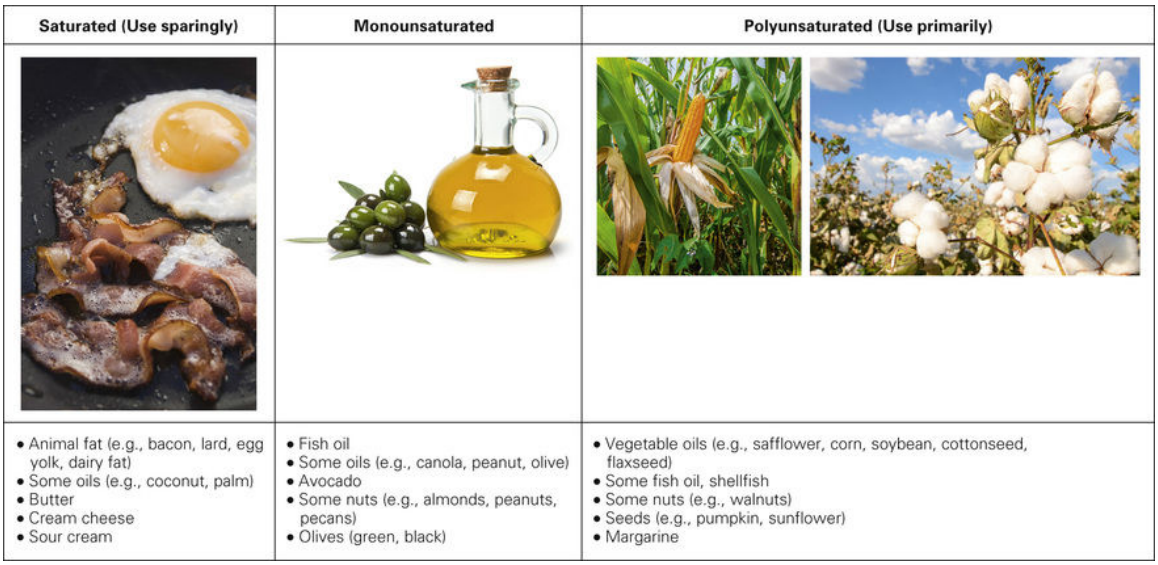

FIGURE 36-5 Types of dietary fat. Source: Photos © *(left to right):* Fotosearch/Shutterstock.com; Angel Simon/Shutterstock.com; petcharaPJ/Shutterstock.com; Jerry Horbert/Shutterstock.com.

Omega-3 fatty acids, when eaten regularly, reduce the risks associated with CAD. For individuals without CAD, the AHA recommends eating fatty fish twice a week because fatty fish such as salmon and tuna contains two types of omega-3 fatty acids: eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). Patients with CAD are encouraged to take EPA and DHA supplements with their diet. The AHA also recommends eating tofu and other forms of soybean, canola, walnut, and flaxseed because these products contain alpha-linolenic acid, which becomes omega-3 fatty acid in the body. (For more information on the AHA's nutritional recommendations, see its website, listed in the Resources at the end of this chapter.)

Lifestyle changes, including eating a low-saturated-fat, high-fibre diet, avoiding tobacco, and increasing physical activity, can promote the reversal of CAD and reduce coronary events.

Cholesterol-Lowering Drug Therapy

An estimated 10 million Canadians have high cholesterol levels (≥5.2 mmol/L) (Heart and Stroke Foundation of Canada, 2016a). A complete lipid profile should be obtained every 5 years beginning at age 20. A person with a serum cholesterol level exceeding 5.2 mmol/L is at risk for CAD and should be treated. The Canadian guidelines for treatment focus on LDL levels (Figure 36-6). Treatment usually begins with smoking cessation, dietary caloric restriction (if overweight), decreased dietary fat

and cholesterol intake, increased physical activity, and stress management (Smith, Benjamin, Bonow, et al., 2011). Serum cholesterol levels are reassessed after 6 months of diet therapy. If they remain elevated, additional dietary options or drug therapy may be started (Table 36-5).

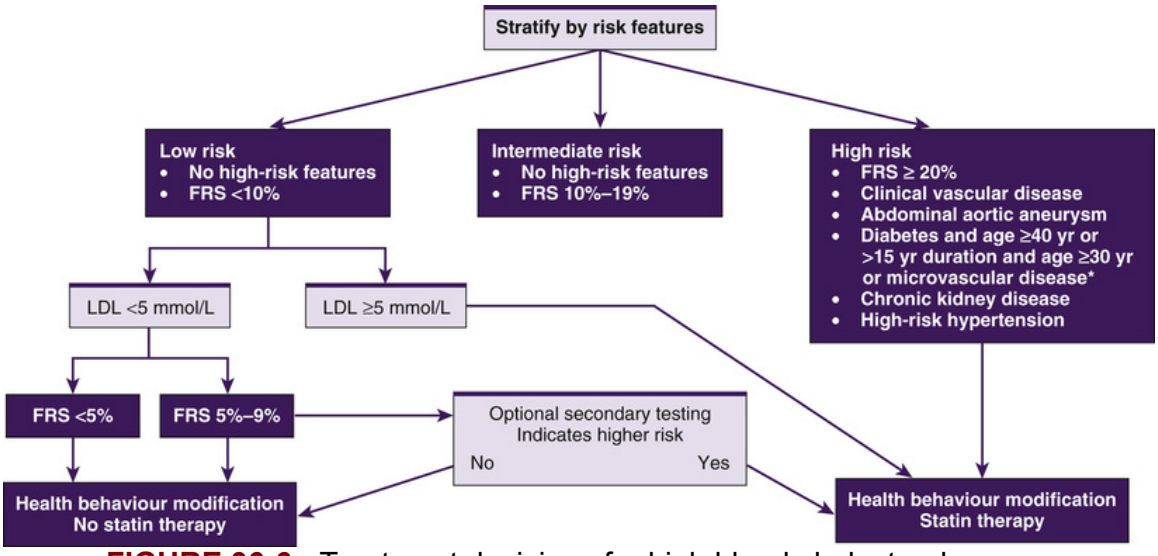

FIGURE 36-6 Treatment decisions for high blood cholesterol, based on low-density lipoprotein levels. *FRS,* Framingham Risk Score; *LDL,* low-density lipoprotein. TABLE 36-5

DRUG THERAPY
Hyperlipidemia

Type and Name	Mechanism of Action	Adverse Effects	Nursing Considerations
Bile Acid Sequestrants and Cholesterol Absorption Inhibitors			
Colestipol (Colestid) Ezetimibe (Ezetrol)	Binds with bile acids in intestine, forming insoluble complex, and is excreted in feces	Unpleasant gritty quality to taste GI disturbances (e.g., nausea, dyspepsia, constipation)	Effective and safe for long-term use; adverse effects diminish with time; interferes with absorption of digoxin, thiazides, β-adrenergic blockers, fat-soluble vitamins, folic acid, vancomycin (Vancocin)
Niacin			
Nicotinic acid (niacin, Niaspan)	Inhibits synthesis and secretion of VLDL and LDL ↑ HDL level	Hot flashes and pruritus in upper torso and face GI disturbances (e.g., nausea and vomiting, dyspepsia, diarrhea)	Most adverse effects subside with time; decreased liver function and dysrhythmias may occur with high doses Acetylsalicylic acid (ASA; Aspirin) 30 min to 1 hr before niacin may prevent flushing; should be taken with food
Fibrates			
Bezafibrate (Bezalip) Fenofibrate (Lipidil) Gemfibrozil	↓ triglycerides by ↓ VLDL level ↓ hepatic synthesis and secretion of VLDL ↑ HDL level	Mild GI disturbances (e.g., nausea, diarrhea)	May ↑ effects of anticoagulants and hypoglycemic medications
Statins			
Atorvastatin (Lipitor) Fluvastatin (Lescol) Lovastatin Pravastatin (Pravachol) Rosuvastatin (Crestor) Simvastatin (Zocor)	Block synthesis of cholesterol ↓ LDL and triglyceride levels ↑ HDL level	Rash, mild GI disturbances, insomnia, elevated liver enzyme levels, lens opacities, rhabdomyolysis (specifically with lovastatin)	Well tolerated with few adverse effects Monitoring includes liver function tests and eye examinations

GI, gastro-intestinal; *HDL*, high-density lipoprotein; *LDL*, low-density lipoprotein; *VLDL*, very-low-density lipoprotein.

Drugs That Restrict Lipoprotein Production.

The "statin" drugs (e.g., lovastatin, pravastatin [Pravachol], simvastatin [Zocor], atorvastatin [Lipitor], and rosuvastatin [Crestor]) are the most widely used and studied lipid-lowering drugs. These drugs inhibit the synthesis of cholesterol in the liver by blocking 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase. An unexplained result of the inhibition of cholesterol synthesis is an increase in hepatic LDL receptors. Consequently, the liver is able to remove more LDLs from the

blood. In addition, levels of HDLs increase slightly with the use of statins (Pagana, Pagana, & Pike-MacDonald, 2013). Serious adverse effects of these drugs can include liver damage and myopathy that can progress to rhabdomyolysis (breakdown of skeletal muscle), but these are rare. Liver enzymes (e.g., aspartate aminotransferase, alanine aminotransferase) must be monitored regularly and checked any time dosage is increased. Creatine kinase (CK) enzymes are assessed if symptoms of myopathy (e.g., muscle aches, weakness) occur (Pagana, Pagana, & Pike-MacDonald, 2013).

Drugs That Increase Lipoprotein Removal.

The major process of cholesterol elimination begins with its conversion to bile acids in the liver. Bile acid sequestrants such as cholestyramine and colestipol (Colestid) increase conversion of cholesterol to bile acids and decrease hepatic content of total cholesterol and LDLs.

Complaints associated with these drugs are related to palatability and a variety of upper and lower GI symptoms, including belching, heartburn, nausea, abdominal pain, and constipation. Bile acid sequestrants may interfere with absorption of other drugs (e.g., warfarin [Coumadin], thiazides, thyroid hormones, β-adrenergic blockers). Administering these drugs at a different time than other drugs may decrease this adverse effect (Pagana, Pagana, & Pike-MacDonald, 2013).

Drugs That Decrease Cholesterol Absorption.

Drug therapy for hyperlipidemia is likely to be prolonged, perhaps continuing for a lifetime. It is essential that diet be modified in order to minimize the need for drug therapy. The patient must fully understand the rationale and goals of treatment, as well as the safety and adverse effects of lipid-lowering drug therapy (Pagana, Pagana, & Pike-MacDonald, 2013).

Antiplatelet Therapy

Acetylsalicylic acid (ASA; Aspirin) is recommended for most people at risk for cardiovascular disease. Low-dose ASA (81 mg) is recommended for adults 50 to 59 years old who have a calculated 10-year cardiovascular disease risk of 10% or more, are not at increased risk for bleeding (e.g., history of gastro-intestinal bleeding), have a life expectancy of at least 10 years, and are willing to take low-dose ASA for at least 10 years. For adults 60 to 69 years old who have a calculated 10-year cardiovascular disease risk of 10% or more, the decision to take low-dose ASA is an individual

one. Adults who have no contraindications (e.g., history of stroke), have a life expectancy of at least 10 years, and are willing to take low-dose ASA daily for at least 10 years are more likely to benefit. Currently, there is insufficient evidence to recommend low-dose ASA for those younger than 50 or older than 70 (Bibbins-Domingo, Grossman, Curry, et al., 2016).

Evidence-Informed Practice

Research Highlight

Does Dietary Fat Modification Improve Cardiovascular Disease Outcomes?

Clinical Question

For adults (P), what is the effect of dietary fat modification or reduction (I) versus placebo, usual, or control diet (C) on overall mortality and cardiovascular morbidity and mortality (O)?

Best Available Evidence

Systematic review of randomized controlled trials (RCTs)

Critical Appraisal and Synthesis of Evidence

- 48 RCTs with 60 comparisons (n = 81 327) of adults with or without existing cardiovascular disease. Intervention was reduced or modified dietary fat intake compared with placebo, usual, or control diet.
- Low-fat diet reduced energy intake to <30% from fat and partially replaced fats with carbohydrates (simple or complex), protein, or fruit and vegetables.
- Modified-fat diet had 30% or more energy intake from total fats, with more monounsaturated or polyunsaturated fats than usual diet.

Conclusions

- Reducing saturated fat by reducing or modifying dietary fat reduced the risk of cardiovascular events.

- Risk for cardiovascular disease decreased in men (not women) by dietary fat modification.

Implications for Nursing Practice

- Counsel patients on modifying dietary fat intake by substituting monounsaturated or polyunsaturated fats for saturated fats.
- Assist the patient in collaboration with the dietitian to maintain long-term dietary fat changes.

P, patient population of interest; *I,* intervention or area of interest; *C,* comparison of interest or comparison group; *O,* outcomes of interest (see Chapter 1).

Chronic Stable Angina

CAD is a progressive disease, and patients may be asymptomatic for many years, or they may develop chronic but stable chest pain syndromes. When the demand for myocardial oxygen exceeds the ability of the coronary arteries to supply the heart with oxygen, myocardial ischemia occurs. **Angina,** or chest pain, is the clinical manifestation of reversible myocardial ischemia. Either an increased demand for oxygen or a decreased supply of oxygen can lead to myocardial ischemia (Table 36-6). The primary reason for insufficient blood flow is narrowing of coronary arteries by atherosclerosis (Huether and McCance, 2012).

TABLE 36-6
FACTORS DETERMINING MYOCARDIAL OXYGEN NEEDS

Decreased Oxygen Supply	Increased Oxygen Demand or Consumption
Noncardiac Factors	
Anemia Hypoxemia Pneumonia Asthma Chronic obstructive pulmonary disease Low blood volume	Anxiety Cocaine use Hypertension Hyperthermia Hyperthyroidism Physical exertion
Cardiac Factors	
Coronary artery spasm Coronary artery thrombosis Dysrhythmias Heart failure Valve disorders	Aortic stenosis Cardiomyopathy Dysrhythmias Tachycardia

On the cellular level, the myocardium becomes hypoxic within the first 10 seconds of coronary occlusion. With total occlusion of the coronary arteries, contractility ceases after several minutes, depriving the myocardial cells of oxygen and glucose for aerobic metabolism. Anaerobic metabolism begins, and lactic acid accumulates. Myocardial nerve fibres are irritated by the increased lactic acid and transmit a pain message to the cardiac nerves and the upper thoracic posterior nerve roots. This is the reason for referred cardiac pain to the left shoulder and arm. In ischemic conditions, cardiac cells are viable for approximately 20 minutes. With restoration of blood flow, aerobic metabolism resumes, contractility is restored, and cellular repair begins.

Chronic stable angina refers to chest pain that occurs intermittently over a long period with the same pattern of onset, duration, and intensity

of symptoms. When questioned (Table 36-7), some patients may deny feeling pain but describe a pressure or ache in the chest. It is an unpleasant feeling, often described as a "constrictive," "squeezing," "heavy," "choking," or "suffocating" sensation. Angina is rarely sharp or stabbing, and it usually does not change with position or breathing. Many people with angina complain of indigestion or a burning sensation in the epigastric region. Although most of the pain experienced by people with angina is substernal, the sensation may occur in the neck or radiate to various locations, including the jaw, the shoulders, and down the arms (Figure 36-7). Sometimes the person may complain of pain between the shoulder blades and dismiss it as not being related to their heart.

TABLE 36-7
"PQRST" ASSESSMENT OF ANGINA

"PQRST" can be used as a mnemonic to assist in obtaining information from the patient who has chest pain, as follows:

Factor		Questions to Ask Patient
P	Precipitating events	What events or activities precipitated the pain/discomfort (e.g., argument, exercise, resting)?
Q	Quality of pain	What does the pain/discomfort feel like (e.g., pressure, dull, aching, tight, squeezing)?
R	Radiation of pain	Where is the pain/discomfort located? Does the pain radiate to other areas (e.g., back, arms, jaw, teeth, shoulder, elbow)?
S	Severity of pain	On a scale of 0 to 10, with 10 being the most severe pain you could imagine, how would you rate the pain/discomfort?
T	Timing	When did the pain/discomfort begin? Has the pain/discomfort changed since this time? Have you had pain like this before?

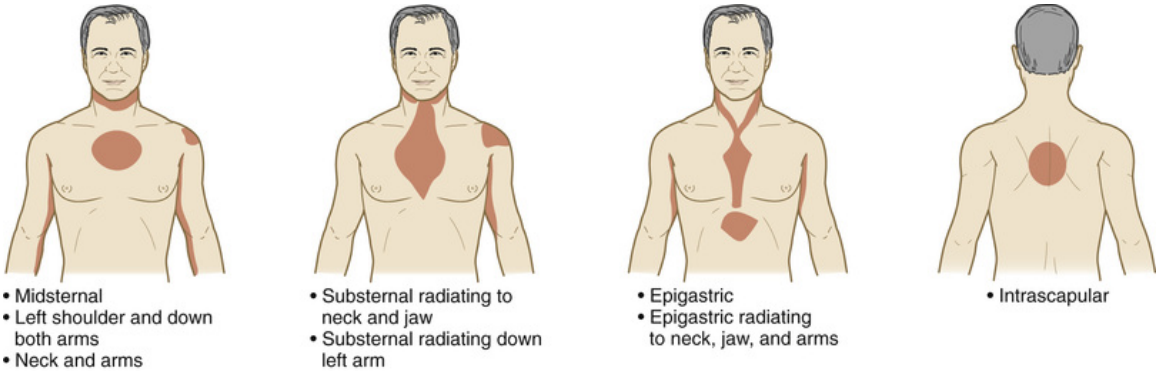

FIGURE 36-7 Common locations of pain during angina or myocardial infarction.

The pain is usually brief (lasting 3 to 5 minutes) and commonly subsides when the precipitating factor is relieved (Table 36-8). Pain at rest is

unusual. Electrocardiography (ECG) usually reveals transient ST-segment depression, indicative of ischemia (see Chapter 38).

TABLE 36-8
FACTORS PRECIPITATING ANGINA

Physical Exertion
• Increased HR reduces the time the heart spends in diastole (the time of greatest coronary blood flow) and results in an increase in myocardial oxygen demand. • Isometric exercise of the arms (e.g., raking, lifting heavy objects, or shovelling snow) can cause exertional angina.
Temperature Extremes
• Workload of the heart is increased. • Blood vessels constrict in response to a cold stimulus. • Blood vessels dilate and blood pools in the skin in response to a hot stimulus.
Strong Emotions
• The sympathetic nervous system is stimulated. • The workload of the heart is increased.
Consumption of Heavy Meal
• The workload of the heart may be increased. • During the digestive process, blood is diverted to the GI system, which reduces blood flow in the coronary arteries.
Tobacco Use
• Nicotine stimulates catecholamine release, causing vasoconstriction and an increase in HR. • Tobacco diminishes available oxygen by increasing the level of carbon monoxide.
Sexual Activity
• The cardiac workload and sympathetic stimulation are increased. • In a person with CAD, the extra cardiac workload may precipitate angina.
Stimulants*
• HR and subsequent myocardial oxygen demand are increased.
Circadian Rhythm Patterns
• These patterns are related to the occurrence of chronic stable angina, Prinzmetal's angina, myocardial infarction, and sudden cardiac death. • Manifestations of CAD tend to occur in the early morning after the patient awakens.

*For example, cocaine and amphetamines.

CAD, coronary artery disease; *GI*, gastro-intestinal; *HR*, heart rate.

Chronic stable angina can be controlled with medications on an outpatient basis. Because episodes of chronic stable angina are often predictable, medications can be timed to provide peak effects during the time of day when angina is likely to occur. For example, if angina occurs on arising, the patient can take medication upon awakening and wait 30 minutes to 1 hour before engaging in activity. (The different types of angina are compared in Table 36-9.)

TABLE 36-9
COMPARISON OF MAJOR TYPES OF ANGINA

Type	Etiology	Characteristics
Chronic stable angina	Myocardial ischemia, usually secondary to CAD	• Episodic pain lasting 5–15 min • Provoked by exertion • Relieved by rest or nitroglycerin
Prinzmetal's angina	Coronary vasospasm	• Occurs primarily at rest • Triggered by smoking and increased levels of some substances (e.g., histamine, epinephrine) • May occur in presence or absence of CAD
Microvascular angina	Myocardial ischemia secondary to microvascular disease affecting the small, distal branches of the coronary arteries	• More common in women • Triggered by activities of daily living (e.g., shopping, work) vs. physical exercise (exertion) • Treatment may include nitroglycerin
Unstable angina	Rupture of thickened plaque, exposing thrombogenic surface	• New-onset angina • Chronic stable angina that increases in frequency, duration, or severity • Occurs at rest or with minimal exertion • Pain refractory to nitroglycerin

Prinzmetal's Angina

Prinzmetal's angina (also called *variant angina*) often occurs at rest, usually in response to spasm of a major coronary artery. It is a rare form of angina and occurs in many patients with a history of migraine headaches and Raynaud's phenomenon. The spasm may occur in the absence of CAD, as well as with documented disease. Prinzmetal's angina is not usually precipitated by increased physical demand. Coronary spasm can be described as a strong contraction of smooth muscle in the coronary artery caused by an increase in intracellular calcium.

Factors that may precipitate coronary artery spasm include increased myocardial oxygen demand and increased levels of certain substances (e.g., histamine, angiotensin, epinephrine, norepinephrine, prostaglandins). When spasm occurs, the patient experiences angina, and the ECG demonstrates transient ST-segment elevation (see Chapter 38). The pain may occur during rapid eye movement (REM) sleep, when myocardial oxygen consumption increases. The pain may be relieved by moderate exercise, or it may disappear spontaneously. Cyclic, short bursts of pain at a consistent time each day may also occur with this type of angina. It is usually treated with calcium channel blockers, nitrates, or both.

Collaborative Management

The treatment of chronic stable angina is aimed at decreasing oxygen demand, increasing oxygen supply, or both. Continued emphasis on the reduction of risk factors is a priority and should include those strategies discussed for patients with CAD (see pp. 818–820). In addition to antiplatelet and cholesterol-lowering drug therapy, the most common therapeutic intervention for the management of chronic stable angina is the use of nitrate therapy to enhance coronary blood flow (Table 36-10, Figure 36-8).

TABLE 36-10
MAJOR TREATMENT ELEMENTS OF CHRONIC STABLE ANGINA

Strategies for the patient with chronic stable angina should address all of the treatment elements in the "ABCDEF" mnemonic:	
A	Antiplatelet agent
	Antianginal therapy
	ACE inhibitor*
B	β-Adrenergic blocker
	Blood pressure
C	Cigarette smoking
	Cholesterol
D	Diet
	Diabetes
E	Education
	Exercise
F	Flu vaccination*

Drug Therapy

Drug therapy for chronic stable angina is aimed at preventing MI and death and reducing symptoms. Acetylsalicylic acid (ASA; Aspirin) (previously discussed) is recommended in the absence of contraindications (Table 36-11).

TABLE 36-11

DRUG THERAPY
Chronic Stable Angina and Acute Coronary Syndrome

Drug Classification	Mechanism of Action and Comments	Nursing Considerations
Antiplatelet Agents		
Acetylsalicylic acid (ASA; Aspirin)	• Inhibit cyclo-oxygenase (which produces thromboxane A_2, a potent platelet activator) • Should be administered as soon as acute coronary syndrome is suspected	
Adenosine Diphosphate Receptor Antagonists		
Clopidogrel (Plavix)	• Inhibit platelet aggregation • Alternative for patient who cannot use ASA • Oral clopidogrel, 75 mg/day, should be added to ASA therapy in patients with STEMI, regardless of whether they undergo reperfusion therapy)	Assess for signs of bleeding, stroke, thrombo-cytopenia, renal dysfunction, fever. Monitor CBC with differential and platelet count, serum bilirubin.
Nitrates		
Sublingual nitroglycerin (Nitrostat) Translingual spray nitroglycerin (Nitrolingual) Transdermal nitroglycerin (Transderm-Nitro, Minitran) Extended-release buccal tablets Isosorbide mononitrate (Imdur) IV nitroglycerin (Nitroject)	• Promote peripheral vasodilation, decreasing preload and afterload • Promote coronary artery vasodilation	Assess for headache, dizziness, and hypotension.
β-Adrenergic Blockers*		
Atenolol (Tenormin) Carvedilol Esmolol (Brevibloc) Metoprolol (Lopresor) Nadolol Propranolol (Inderal)	• Inhibit sympathetic nervous stimulation of the heart • Reduce both heart rate and contractility • Decrease afterload	Monitor apical heart rate and BP prior to administration. Assess for hypotension, dizziness, and signs of heart failure (dyspnea, crackles, weight gain, peripheral edema).
Calcium Channel Blockers*		
Amlodipine (Norvasc) Diltiazem (Cardizem) Felodipine (Plendil) Nifedipine Verapamil (Isoptin)	• Prevent calcium entry into vascular smooth muscle cells and myocytes (cardiac cells) • Promote coronary and peripheral vasodilation • Reduce both heart rate and contractility	Monitor BP and pulse prior to administration. Monitor ECG. Assess for signs of heart failure (dyspnea, peripheral edema, crackles).
Angiotensin-Converting Enzyme (ACE) Inhibitors*		

Drug Classification	Mechanism of Action and Comments	Nursing Considerations
Captopril Enalapril (Vasotec)	• Prevent conversion of angiotensin I to angiotensin II • Decrease endothelial dysfunction • Useful in treatment of heart failure, tachycardia, MI, hypertension, diabetes, and chronic kidney disease	
Unfractionated Heparins†		
Heparin	• Prevent conversion of fibrinogen to fibrin and of prothrombin to thrombin	Monitor for signs of bleeding (bleeding gums, epistaxis, black tarry stools).
Low-Molecular-Weight Heparins†		
Dalteparin (Fragmin) Enoxaparin (Lovenox)	• Bind to antithrombin III, enhancing its effect • Heparin–antithrombin III complex inactivates activated factor X and thrombin • Prevent conversion of fibrinogen to fibrin	Monitor for signs of bleeding.
Glycoprotein IIB and IIIA Inhibitors		
Abciximab (ReoPro) Eptifibatide (Integrilin) Tirofiban (Aggrastat)	• Prevent the binding of fibrinogen to platelets, thereby blocking platelet aggregation • Standard antiplatelet therapy in combination with ASA for patients at high risk for unstable angina	Monitor for signs of bleeding.
Opioid Analgesics		
Morphine, morphine sulphate	• Function as analgesic and sedative • Act as vasodilator to reduce preload and myocardial O_2 consumption	Monitor respiratory rate; assess for respiratory depression, CNS depression, and hypotension.
Fibrinolytic Therapy		
Tissue plasminogen activator (t-PA; alteplase [Activase]) Tenecteplase (TNK, TNKase)	• Break up fibrin meshwork in clots • Used only in STEMI	Monitor for signs of bleeding.

*See Chapter 35, Table 35-8.

†See Chapter 40, Table 40-10.

BP, blood pressure; *CBC,* complete blood cell count; *ECG,* electrocardiogram; *IV,* intravenous; *MI,* myocardial infarction; *STEMI,* ST-segment elevation myocardial infarction.

Short-Acting Nitrates.

Short-acting nitrates are first-line therapy for the treatment of angina. Nitrates produce their principal effects by the following mechanisms:

1. Dilating peripheral blood vessels. This results in decreased SVR, venous pooling, and decreased venous blood return to the heart. Because of the reduced cardiac workload, myocardial oxygen demand is decreased.

2. Dilating coronary arteries and collateral vessels. This may increase blood flow to the ischemic areas of the heart. However, when the coronary arteries are severely atherosclerotic, coronary dilation is difficult to achieve.

Sublingual Nitroglycerin.

Nitroglycerin administered sublingually (Nitrostat) or by translingual spray (Nitrolingual) usually relieves pain in approximately 3 minutes, and its action has a duration of approximately 30 to 60 minutes. The recommended dosage for symptoms of angina is one tablet taken sublingually (SL) or one metered spray. If symptoms are unchanged or worse after 5 minutes, the patient should be instructed to contact the emergency medical services (EMS) system.

Nitroglycerin should be easily accessible to the patient at all times, and the patient must be instructed in its proper use: place a tablet under the tongue and allow it to dissolve, or, if using the spray, direct the spray under the tongue (do not inhale it). Nitroglycerin should cause a tingling sensation. If tingling is not felt and chest pain persists, the patient should know to contact EMS. The patient should be warned that HR may increase and a pounding headache, dizziness, or flushing may occur. The patient should be cautioned against quickly rising to a standing position because orthostatic hypotension may occur after nitroglycerin use.

Nitroglycerin tablets are marketed in light-resistant bottles with metal caps and, for protection from degradation, should be kept in the tightly closed bottle. Because they tend to lose potency once a bottle has been opened, the patient should be advised to purchase a new supply every 6 months.

Long-Acting Nitrates.

Nitrates, such as isosorbide dinitrate and isosorbide mononitrate (Imdur), are longer-acting than SL or translingual nitroglycerin and can be used to reduce the incidence of anginal attacks (Pagana, Pagana, & Pike-MacDonald, 2013). The predominant adverse effect of all nitrates is headache, caused by the dilation of cerebral blood vessels. Patients can be advised to take acetaminophen (Tylenol) with their nitrate to relieve the headache. Over time, the headaches may decrease, but the principal antianginal effect remains the same.

Orthostatic hypotension is a complication of all nitrates. Nurses should monitor BP after the initial dose because the venous dilation that occurs may cause a drop in BP, especially in volume-depleted patients. In

addition, tolerance to nitroglycerin-induced vasodilation can develop. It is recommended that patients schedule an 8-hour nitrate-free period every day, usually during the night, except for patients who experience nocturnal angina (Pagana, Pagana, & Pike-MacDonald, 2013).

Transdermal Controlled-Release Nitrates.

Currently, two systems are available for transdermal nitroglycerin drug administration: reservoir and matrix. The reservoir system delivers the medication using a rate-controlled permeable membrane. The matrix system provides for a slow delivery of the medication through a polymer matrix. Both reservoir and matrix delivery systems offer the advantages of steady plasma levels within the therapeutic range during 24 hours; thus only one application a day is necessary. The reservoir system has the disadvantage of dose dumping if the reservoir seal is punctured or broken; the matrix system, in contrast, avoids this problem. Both systems achieve steady-state plasma drug levels within 2 hours.

β-Adrenergic Blockers.

β-Adrenergic blockers (e.g., propranolol [Inderal], metoprolol [Lopresor], nadolol, atenolol [Tenormin], and carvedilol) are the preferred drugs for the management of chronic stable angina (Pagana, Pagana, & Pike-MacDonald, 2013). These drugs cause decreases in myocardial contractility, HR, SVR, and BP, all of which reduce the myocardial oxygen demand. β-Adrenergic blockers also have been shown to decrease morbidity and mortality in patients with CAD, especially following MI (Pagana, Pagana, & Pike-MacDonald, 2013).

β-Adrenergic blockers have many adverse effects and are sometimes poorly tolerated. Adverse effects may include bradycardia, hypotension, wheezing, and GI complaints. Many patients also complain of weight gain, depression, and sexual dysfunction. β-Adrenergic blockers should be avoided by patients with asthma and used cautiously by patients with diabetes because their effects mask signs of hypoglycemia. Abrupt discontinuation of β-adrenergic blockers may precipitate an increase in the frequency and intensity of angina attacks, so medical supervision during discontinuation is necessary (Pagana, Pagana, & Pike-MacDonald, 2013).

Calcium Channel Blockers.

If use of β-adrenergic blockers is contraindicated or if they are poorly tolerated or do not control anginal symptoms, calcium channel blockers (e.g., nifedipine, verapamil, diltiazem [Cardizem]) are used (Pagana,

Pagana, & Pike-MacDonald, 2013). These medications are also used to manage Prinzmetal's angina. Most of these drugs are available in sustained-release formulations for longer action, which has the advantages of helping increase patient adherence to therapy and of stabilizing blood levels of the drug. The three primary effects of calcium channel blockers are (a) systemic vasodilation with decreased SVR, (b) decreased myocardial contractility, and (c) coronary vasodilation.

Cardiac muscle and vascular smooth muscle cells are more dependent on extracellular calcium than are skeletal muscles and are therefore more sensitive to calcium channel blockers. Calcium channel blockers cause smooth muscle relaxation and relative vasodilation of coronary and systemic arteries, thus increasing blood flow.

Calcium channel blockers potentiate the action of digoxin by increasing serum digoxin levels during the first week of therapy. Therefore, serum digoxin levels should be closely monitored after starting this therapy. Normal digoxin levels are 0.6–1.3 nmol/L (0.8–2 ng/mL). The patient should be taught the signs and symptoms of digoxin toxicity.

Angiotensin-Converting Enzyme Inhibitors.

Certain high-risk patients with chronic stable angina may benefit from the addition of an angiotensin-converting enzyme (ACE) inhibitor (e.g., captopril) to the drug regimen (Pagana, Pagana, & Pike-MacDonald, 2013). Such patients include those with diabetes, significant CAD as determined by coronary angiography (e.g., multivessel disease), or previous history of MI with left ventricular dysfunction. (ACE inhibitors are discussed further later in this chapter and in Chapter 35 and Table 35-8.)

Diagnostic Studies

When a patient has a history of CAD or if CAD is suspected, the physician orders a variety of studies (see Figure 36-8). After a detailed health history is documented and a physical examination is performed, a chest radiograph is usually taken to look for cardiac enlargement, aortic calcifications, and pulmonary congestion. A 12-lead ECG is obtained and, when possible, compared with an earlier tracing. Certain laboratory tests (e.g., lipid profile) and diagnostic studies (e.g., Holter monitoring, echocardiography) are ordered to confirm CAD and identify specific risk factors for CAD.

For patients with known CAD and chronic stable angina, common diagnostic studies include 12-lead ECG, echocardiography, exercise stress

testing, pharmacological nuclear imaging, and coronary angiography (Pagana, Pagana, & Pike-MacDonald, 2013). (See Chapter 34 and Table 34-6 for a discussion of these studies, including nursing considerations.) Electrocardiography and coronary angiography are discussed in further detail in the section "Diagnostic Studies of the Cardiovascular System" in Chapter 34.

Acute Coronary Syndrome

When myocardial ischemia is prolonged and not immediately reversible, **acute coronary syndrome (ACS)** develops; this syndrome encompasses the spectrum of unstable angina, non–ST-segment elevation myocardial infarction (NSTEMI), and ST-segment elevation myocardial infarction (STEMI). Although each remains a distinct diagnosis, this nomenclature (ACS) reflects the relationships among pathophysiology, diagnosis, prognosis, and interventions for these disorders.

Etiology and Pathophysiology

ACS is associated with deterioration of an atherosclerotic plaque that was once stable. The plaque ruptures, exposing the intima to blood and stimulating platelet aggregation and local vasoconstriction with thrombus formation. This unstable lesion may be partially occluded by a thrombus (manifesting as UA or NSTEMI) or totally occluded by a thrombus (manifesting as STEMI). What causes a coronary plaque to suddenly become unstable is not well understood, but systemic inflammation (described earlier) is thought to play a role. Patients with suspected ACS require immediate hospitalization.

Manifestations of Acute Coronary Syndrome

Unstable Angina

Chest pain that is new in onset, occurs at rest, or has a worsening pattern is called **unstable angina (UA).** Patients with chronic stable angina may develop UA, or UA may be the first clinical manifestation of CAD. Unlike chronic stable angina, UA is unpredictable and represents an emergency. Patients with previously diagnosed chronic stable angina describe a significant change in the pattern of angina. It occurs with increasing frequency and is easily provoked by minimal or no exertion, during sleep, or even at rest. Patients without previously diagnosed angina describe anginal pain that has progressed rapidly in the past few hours, days, or weeks, often culminating in pain at rest.

Women with symptoms of UA seek medical attention more often than do men. Studies have shown that women have prodrome symptoms that are early manifestations of CAD, but because they are not recognized as such, what brings these women to first seek care is UA, before CAD is

diagnosed. These symptoms include fatigue, shortness of breath, indigestion, and anxiety. Fatigue is the most prominent symptom. Because fatigue can be a symptom of many different diseases and syndromes, a thorough history of CAD risk factors should be obtained to identify these women.

Myocardial Infarction

A **myocardial infarction (MI)** occurs as a result of sustained ischemia, causing irreversible myocardial cell death (necrosis; Figures 36-9 and 36-10). Between 80% and 90% of all acute MIs occur secondary to thrombus formation. When a thrombus develops, perfusion to the myocardium distal to the occlusion is halted, resulting in necrosis. Contractile function of the heart stops in the necrotic areas. The degree of altered function depends on the area of the heart involved and the size of the infarction. Most MIs involve some portion of the left ventricle.

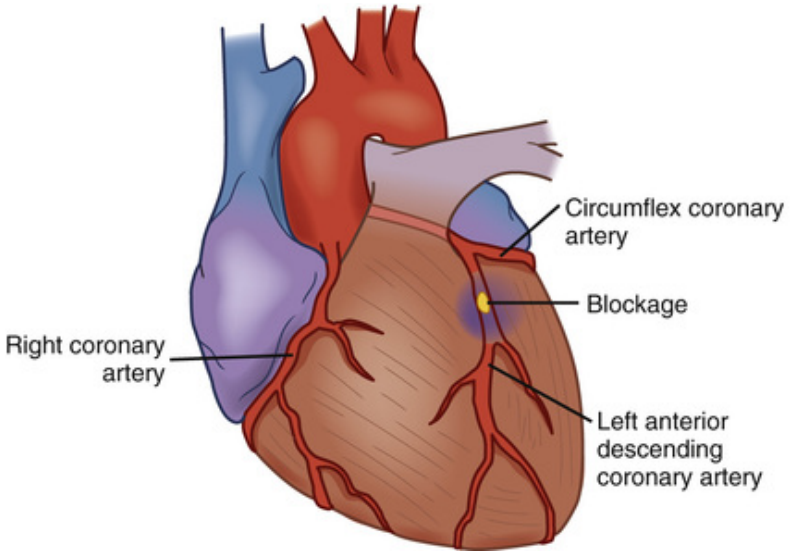

FIGURE 36-9 Diagram of occlusion of the left anterior descending coronary artery, resulting in a myocardial infarction.

FIGURE 36-10 Acute myocardial infarction in the posterolateral wall of the left ventricle, demonstrated by the absence of staining in the areas of necrosis *(white arrow)*. Note the scarring from a previous anterior wall myocardial infarction *(black arrow)*. Source: Kumar, V., Abbas, A. K., Fausto, N., et al. (2010). *Robbins and Cochran pathologic basis of disease* (8th ed., p. 6). Philadelphia: W. B. Saunders.

The acute MI process takes time. Cardiac cells can withstand ischemic conditions for approximately 20 minutes before cellular death begins. The tissue to become ischemic earliest is the subendocardium (the innermost layer of tissue in the cardiac muscle). If ischemia persists, the entire thickness of the heart muscle becomes necrosed in approximately 5 to 6 hours.

Descriptions of infarctions are usually based on the location of damage (e.g., anterior, inferior, lateral, or posterior wall infarction). Damage can occur in more than one location (e.g., anterolateral MI, anteroseptal MI). The location of the infarction correlates with the involved coronary circulation. For example, inferior wall infarctions result from occlusions in the right coronary artery. Anterior wall infarctions result from occlusions in the left anterior descending artery. Occlusions in the left circumflex artery usually cause MIs in the lateral or posterior wall or both.

The degree of pre-established collateral circulation also influences the severity of infarction (see Figure 36-2). In an individual with a history of CAD, collateral circulation may be established, and so the area surrounding the infarction site develops a blood supply. This is one explanation for why a younger person who has an MI often experiences a more serious impairment than an older person with the same degree of occlusion.

Clinical Manifestations of Myocardial Infarction

Pain.

Severe, immobilizing chest pain not relieved by rest, position change, or nitrate administration is the hallmark of an MI. Persistent and unlike any other pain, it is usually described as a feeling of heaviness, pressure, tightness, burning, or constriction or as a crushing sensation. Common locations are substernal, retrosternal, and epigastric areas. The pain may radiate to the neck, the jaw, and the arms or to the back (see Figure 36-7). It may occur while the patient is active or at rest or when the patient is asleep or awake. However, it commonly occurs in the early morning hours. It usually lasts for 20 minutes or more and is described as more severe than usual anginal pain. When epigastric pain is present, the patient may relate it to indigestion and take antacids without relief.

Not everyone has classic symptoms. Some patients may not experience pain but may have "discomfort," weakness, or shortness of breath. Although symptoms of an acute MI in women and men have more similarities than differences, some women may experience atypical discomfort, shortness of breath, or fatigue. Patients with diabetes are more likely to experience silent (asymptomatic) MIs as a result of cardiac neuropathy and seek care with atypical symptoms (e.g., dyspnea). Older patients may experience a change in mental status (e.g., confusion), shortness of breath, pulmonary edema, dizziness, or a dysrhythmia.

Sympathetic Nervous System Stimulation.

During the initial phase of MI, catecholamines (norepinephrine and epinephrine) are released from the ischemic myocardial cells that normally contain varying quantities of these substances. The increased SNS stimulation results in release of glycogen, diaphoresis, and vasoconstriction of peripheral blood vessels. On physical examination, the patient's skin may be ashen, clammy, and cool to the touch.

Cardiovascular Manifestations.

In response to the release of catecholamines, the BP and HR may initially be elevated. Later, the BP may drop because of decreased cardiac output (CO). If the drop is severe enough, renal perfusion and urine output may decrease. Crackles may be noted in the lungs, persisting for several hours to several days and suggesting left ventricular dysfunction. Jugular venous distension, hepatic engorgement, and peripheral edema may indicate right ventricular dysfunction.

Cardiac examination may reveal abnormal heart sounds that may seem distant. Careful auscultation may reveal splitting of heart sounds. Other

abnormal sounds suggestive of ventricular dysfunction are the third heart sound (S_3) and the fourth heart sound (S_4). In addition, a loud holosystolic murmur may develop and may indicate a septal defect or mitral valve dysfunction.

Nausea and Vomiting.

Nausea and vomiting can result in some patients due to reflex stimulation of the vomiting centre by the severe pain. These symptoms can also result from vasovagal reflexes initiated in the area of the infarcted myocardium.

Fever.

The patient's temperature may increase within the first 24 hours up to 38°C and occasionally as high as 39°C. The temperature elevation may last for as long as 1 week. This increase in temperature is a systemic manifestation of the inflammatory process caused by myocardial cell death.

Healing Process

The body's response to cell death is the inflammatory process (see Chapter 14). Within 24 hours, leukocytes infiltrate the area. Enzymes are released from the dead cardiac cells and are important diagnostic indicators of MI. (See the section "Serum Cardiac Markers" later in this chapter.) The proteolytic enzymes of the neutrophils and macrophages remove all necrotic tissue by the second or third day. During this time, the necrotic muscle wall is thin. The development of collateral circulation improves areas of poor perfusion and may limit the zones of injury and infarction. Once infarction takes place, catecholamine-mediated lipolysis and glycogenolysis occur. These processes allow the increased amounts of plasma glucose and free fatty acids to be used by the oxygen-depleted myocardium for anaerobic metabolism. For this reason, serum glucose levels are frequently elevated after MI.

The necrotic zone is identifiable by ECG changes (e.g., ST-segment elevation, pathological Q wave) and on nuclear scanning after the onset of symptoms. At this point, the neutrophils and monocytes have cleared the necrotic debris from the injured area, and the collagen matrix that will eventually form scar tissue is laid down.

Ten to 14 days after MI, the scar tissue beginning to form is still weak. The myocardium is considered to be especially vulnerable to increased stress because of the unstable state of the healing heart wall. It is also at

this time that the patient's activity level may be increasing, and so special caution and assessment are necessary. By 6 weeks after MI, scar tissue has replaced necrotic tissue. At this time, the injured area is said to be healed. The scarred area is often less malleable than the surrounding fibres. This condition may be manifested by uncoordinated wall motion, ventricular dysfunction, or pump failure.

These changes in the infarcted muscle also cause changes in the unaffected myocardium. In an attempt to compensate for the infarcted muscle, the normal myocardium hypertrophies and dilates. This process is called *ventricular remodelling.* Remodelling of normal myocardium can lead to the development of late heart failure (HF), especially in individuals with atherosclerosis of other coronary arteries, an anterior MI, or both.

Complications of Myocardial Infarction

Dysrhythmias.

The most common complication after an MI is a dysrhythmia, which is present in 80% of patients who have had an MI. Dysrhythmias are the most common cause of death in patients in the pre-hospitalization period. Dysrhythmias are caused by any condition that affects the myocardial cell's sensitivity to nerve impulses, such as ischemia, electrolyte imbalances, and SNS stimulation. The intrinsic rhythm of the heartbeat is disrupted, causing a fast HR (tachycardia), a slow HR (bradycardia), or an irregular beat, any of which adversely affects the ischemic myocardium.

Life-threatening dysrhythmias occur most often with anterior wall infarction, HF, or shock. Complete heart block can occur in massive infarction. Ventricular fibrillation, a common cause of sudden cardiac death (SCD), is a lethal dysrhythmia that most often occurs within the first 4 hours after the onset of pain. Premature ventricular contractions (PVCs) may precede ventricular tachycardia and fibrillation. Life-threatening ventricular dysrhythmias must be treated immediately. (See Chapter 38 for a detailed description of dysrhythmias and their management.)

Heart Failure.

Heart failure is a complication of MI in which the pumping power of the heart has diminished. Depending on the severity and extent of the injury, HF occurs initially with subtle signs such as mild dyspnea, restlessness, agitation, or slight tachycardia. Other signs indicating the onset of HF include pulmonary congestion, seen on chest radiograph; S_3 or S_4 heart

sounds, heard on auscultation; crackles, heard on auscultation of breath sounds; and jugular vein distension, caused by right-sided HF. (The treatment of acute decompensated HF is discussed in Chapter 37.)

Cardiogenic Shock.

Cardiogenic shock is a condition in which inadequate oxygen and nutrients are supplied to the tissues because of severe left ventricular failure. Cardiogenic shock has occurred less often since the advent of early and rapid treatment of MI with fibrinolytic therapy and **percutaneous coronary intervention (PCI),** an intervention in which a catheter equipped with an inflatable balloon tip is inserted into a narrowed coronary artery and the balloon is inflated. The rate of mortality from cardiogenic shock is high. Cardiogenic shock necessitates aggressive management, including control of dysrhythmias, intra-aortic balloon pump (IABP) therapy, and support of contractility with the use of vasoactive drugs. The goal of therapy is to maximize oxygen delivery, reduce oxygen demand, and prevent complications such as acute kidney injury. (Cardiogenic shock is discussed in Chapter 69.)

Papillary Muscle Dysfunction.

Papillary muscle dysfunction may occur if the infarcted area includes or is adjacent to the papillary muscle that attaches to the mitral valve (see Figure 34-2). Papillary muscle dysfunction causes mitral valve regurgitation, which increases the volume of blood in the left atrium. This condition aggravates an already compromised left ventricle by reducing CO even further. Papillary muscle dysfunction is detected by a systolic murmur at the cardiac apex radiating toward the axilla.

Papillary muscle rupture is a rare but life-threatening complication that causes massive mitral valve regurgitation, which results in dyspnea, pulmonary edema, and decreased CO. The patient's condition deteriorates rapidly. Treatment consists of rapid afterload reduction with nitroprusside, IABP therapy and immediate open-heart surgery with mitral valve replacement, or both. (See Chapter 39 for discussion of valvular disorders.)

Ventricular Aneurysm.

Ventricular aneurysm results when the infarcted myocardial wall becomes thinned and bulges out during contraction. The patient with a ventricular aneurysm may experience refractory HF, dysrhythmias, and angina.

Besides ventricular rupture, which is fatal, ventricular aneurysms harbour thrombi, which can cause an embolic stroke.

Pericarditis.

Acute pericarditis—an inflammation of the visceral or parietal pericardium or both—may result in cardiac compression, decreased ventricular filling and emptying, and HF. It may occur 2 to 3 days after an acute MI as a common complication. Pericarditis is characterized by chest pain, which may vary from mild to severe, and is aggravated by inspiration, coughing, and movement of the upper body. The pain may be relieved by sitting in a forward position. The pain is usually different from the pain associated with an MI.

Assessment of a patient with pericarditis may reveal a friction rub over the pericardium. The sound may be best heard with the diaphragm of the stethoscope at the midsternal to lower sternal border. It may be persistent or intermittent. Fever may also be present.

Diagnosis of pericarditis can be made with serial 12-lead ECGs. Characteristic ECG changes are diffuse and reflect the inflammation of the pericardium. Treatment may include pain relief by ASA, corticosteroids, or nonsteroidal anti-inflammatory drugs (NSAIDs). (Pericarditis is discussed further in Chapter 39.)

Dressler's Syndrome.

Dressler's syndrome is characterized by pericarditis with effusion and fever that develops 4 to 6 weeks after MI. It may also occur after open-heart surgery. It is thought to be caused by an antigen–antibody reaction to the necrotic myocardium. The patient experiences pericardial pain, fever, a friction rub, pleural effusion, and arthralgia. Laboratory findings include an elevated white blood cell count and an elevated sedimentation rate. Short-term courses of corticosteroids are used to treat this condition. (Dressler's syndrome is discussed further in Chapter 39.)

Diagnostic Studies

Unstable Angina and Myocardial Infarction

In addition to the patient's history of pain, risk factors, and health history, the primary diagnostic studies used to determine whether a person has UA or an MI include an ECG and measurement of serum cardiac markers (see Figure 36-8).

Electrocardiographic Findings.

ECG is the primary tool to rule out or confirm UA or an MI. Changes in the QRS complex, the ST segment, and the T wave caused by ischemia and infarction can develop quickly with UA and MI. For diagnostic and treatment purposes, it is important to distinguish among STEMI, UA, and NSTEMI. Patients with STEMI tend to have a more extensive MI associated with prolonged and complete coronary occlusion and the development of a pathological Q wave on the ECG. Patients with UA or NSTEMI usually have transient thrombosis or incomplete coronary occlusion and usually do not develop pathological Q waves. Areas of ischemia or infarction may be noted on the ECG. Because MI is a dynamic process that evolves with time, the ECG often reveals the time sequence of ischemia, injury, infarction, and resolution of the infarction.

The ECG may also be normal or nondiagnostic when the patient comes to the ED with a complaint of chest pain. Within a few hours, the ECG may change to reflect the infarction process. These changes take place when cellular damage has occurred, interrupting the normal electrical depolarization of the ventricles. When the initial ECG is nondiagnostic, serial ECGs are obtained every 2 to 4 hours (Aehlert, 2013). (See Chapter 38 for discussion of ECG changes associated with ischemia and MI.)

Serum Cardiac Markers.

After an MI, certain proteins called *serum cardiac markers* are released into the blood in large quantities from necrotic heart muscle. These markers, specifically serum cardiac enzymes and troponin, are important in the diagnosis of MI. When cardiac cells die, their intracellular enzymes are released into circulation. The increase in serum cardiac markers that occurs after cellular death can indicate whether cardiac damage is present and the approximate extent of the damage. CK and troponin are typically measured to diagnose an MI. Figure 36-11 indicates the peak levels and durations of these markers in the presence of MI.

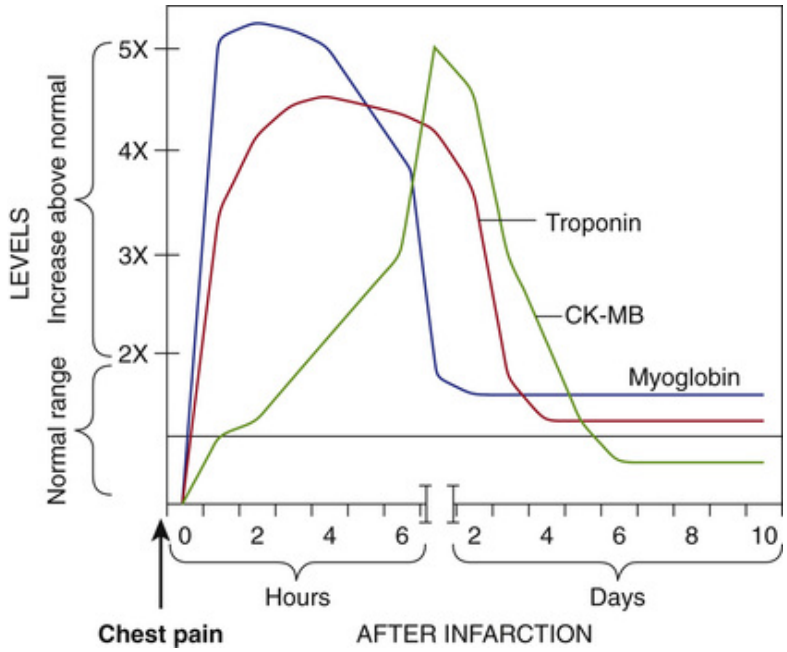

FIGURE 36-11 Levels of serum cardiac markers in the blood after myocardial infarction. *CK-MB*, MB isoenzyme of creatine kinase.

CK levels begin to rise approximately 3 to 12 hours after an MI, peak in 24 hours, and return to normal within 2 to 3 days. The CK enzymes may be fractionated into bands, including the MB band. The MB isoenzyme of creatine kinase (CK-MB) band is specific to myocardial cells and can help quantify myocardial damage.

Cardiac-specific troponin is a myocardial muscle protein released into circulation after myocardial injury. In the heart, there are two subtypes: cardiac-specific troponin T (cTnT) and cardiac-specific troponin I (cTnI). These markers are highly specific indicators of MI, and their tests have greater sensitivity and specificity for myocardial injury than that for CK-MB (Pagana, Pagana, & Pike-MacDonald, 2013). The troponin level rises as quickly as the CK level. Troponins are usually measured for diagnostic purposes in conjunction with total CK and the MB fraction. Serum levels of cTnI and cTnT increase 3 to 12 hours after the onset of MI, peak at 24 to 48 hours, and return to baseline over 5 to 14 days.

Myoglobin is released into circulation within a few hours after an MI. Although it is one of the first serum cardiac markers whose levels increase after an MI, it lacks cardiac specificity. In addition, it is rapidly excreted in urine so that blood levels return to normal range within 24 hours after an MI (see Chapter 34, Table 34-6).

Coronary Angiography.

The patient with UA or NSTEMI may undergo coronary angiography to evaluate the extent of the disease and to determine the most appropriate therapeutic modality. If appropriate, PCI may be performed at this time. Other patients may be treated with conservative medical management. Coronary angiography is the only way to confirm the diagnosis of Prinzmetal's angina.

Other Measures

When the ECG and serum cardiac marker levels do not confirm MI, other measures for diagnosing UA may be considered (see Chapter 34, Table 34-6). Exercise stress testing and echocardiography may be conducted when a patient has an abnormal but nondiagnostic baseline ECG. Dobutamine stress echocardiography can be performed in patients unable to exercise. (See Chapter 34 for additional information on cardiac assessment.)

Collaborative Care

It is extremely important that ACS be rapidly diagnosed and treated to preserve cardiac muscle. Initial management of chest pain most often occurs in the ED. Emergency care of patients with chest pain is described in Table 36-12. An intravenous (IV) route is established to provide an accessible means for emergency drug therapy. Sublingual nitroglycerin and chewable ASA (Aspirin) are administered if not done by emergency medical personnel before arrival at the ED. Morphine sulphate is given by IV route for pain unrelieved by nitroglycerin. Oxygen is administered by nasal cannula at a rate of 2 to 4 L/min. Patients usually receive ongoing care in an intensive care unit or telemetry unit, in which continuous ECG monitoring is available. Dysrhythmias may be detected, and appropriate treatment can be instituted. The collaborative care of ACS is described in Figure 36-8.

TABLE 36-12

EMERGENCY MANAGEMENT
Chest Pain

Etiology	Assessment Findings	Interventions
Cardiovascular • Angina • Myocardial infarction • Dysrhythmia • Pericarditis • Aortic aneurysm • Aortic valve disease **Respiratory** • Costochondritis • Pleurisy • Pneumonia • Pneumothorax • Pulmonary edema • Pulmonary embolus **Chest Trauma** • Rib or sternal fracture • Flail chest • Cardiac tamponade • Pneumothorax • Pulmonary contusion • Great vessel injury **Gastro-Intestinal** • Esophagitis • GERD • Hiatal hernia • Peptic ulcer • Cholecystitis **Others** • Stress • Strenuous exercise • Drugs • Acute anxiety	• Pain in chest, neck, arm, or shoulder • Cold, clammy skin • Diaphoresis • Nausea and vomiting • Epigastric pain • Indigestion or heartburn • Dyspnea • Weakness • Anxiety • Feeling of impending doom • Tachycardia • Irregular HR, murmurs • Palpitations • Dysrhythmias • Decreased BP • Narrowed pulse pressure • Unequal BP readings in upper extremities • Syncope, loss of consciousness • Decreased O_2 saturation • Decreased or absent breath sounds • Crackles, wheezes • Pericardial friction rub	**Initial** • Ensure patent airway. • Administer O_2 by nasal cannula or nonrebreather mask. • Obtain 12-lead ECG. • Insert two IV catheters. • Assess pain, using "PQRST" mnemonic (see Table 36-7). • Medicate for pain as ordered (e.g., morphine, nitroglycerin). • Initiate continuous ECG monitoring and identify underlying rhythm. • Obtain baseline blood test results (e.g., cardiac markers). • Obtain portable chest radiograph. • Assess for antiplatelet, anticoagulation, or fibrinolytic therapy or for PCI as appropriate. • Administer ASA (Aspirin) and β-adrenergic blockers for cardiac-related chest pain unless contraindicated. • Administer antidysrhythmic medications as indicated. **Ongoing Monitoring** • Monitor vital signs, level of consciousness, cardiac rhythm, and O_2 saturation. • Monitor response to medications (e.g., decrease in chest pain) and readminister or titrate medications (e.g., nitroglycerin) as needed. • Provide reassurance and emotional support to patient and family. • Explain all interventions and procedures to patient in simple terms. • Anticipate need for intubation if respiratory distress is evident. • Prepare for CPR, defibrillation, transcutaneous pacing, or cardioversion.

ASA, acetylsalicylic acid; *BP,* blood pressure; *CPR,* cardiopulmonary resuscitation; *GERD,* gastro-esophageal reflux disease; *HR,* heart rate; *IV,* intravenous; *O_2,* oxygen; *PCI,* percutaneous coronary intervention.

Vital signs, including pulse oximetry, are monitored frequently during the first few hours after admission and are monitored closely thereafter.

Bed rest and limitation of activity for 12 to 24 hours are initially ordered, with a gradual increase in activity unless it is contraindicated.

For patients with UA or NSTEMI who have increased levels of cardiac markers and ongoing angina, a combination of ASA (Aspirin), heparin (unfractionated [UH] or low-molecular-weight [LMWH]), and a glycoprotein IIb/IIIa inhibitor (e.g., abciximab [ReoPro], eptifibatide [Integrilin], tirofiban [Aggrastat]) is recommended. PCI is a common elective procedure considered once the patient is stabilized and angina is controlled or if angina returns or increases in severity.

For patients with STEMI or NSTEMI with elevated levels of cardiac markers, reperfusion therapy is initiated (see Figure 36-8). Reperfusion therapy—therapy to open the coronary artery that was occluded and restore blood flow to the myocardium—can include emergent PCI or fibrinolytic (thrombolytic) therapy. The goal in the treatment of MI is to salvage as much myocardial muscle as possible.

Emergent Percutaneous Coronary Intervention

In centres that perform at least 200 PCI procedures a year and have trained interventional cardiologists and cardiac surgical capability, emergent PCI is recommended as the first line of treatment for patients with confirmed MI (i.e., definitive ECG changes, presence of cardiac markers, or both). The goal is to open the affected artery within 90 minutes of the patient's arrival at the ED. In this situation, the patient undergoes cardiac catheterization to locate the blockage or blockages, to assess the severity of the blockages, to determine the presence of collateral circulation, and to evaluate left ventricular function. With actual visualization of the coronary artery system and left ventricular function, treatment modalities most beneficial to the patient can be selected. Usually PCI with the placement of one or more drug-eluting stents will be performed. Patients with severe left ventricular dysfunction may require the addition of IABP therapy, and a small percentage of patients may require emergency coronary artery bypass graft (CABG) surgery.

The advantages of PCI are that (a) it is an alternative to surgical intervention; (b) it is performed with the use of local anaesthetic; (c) the patient is ambulatory 24 hours after the procedure; (d) the length of hospital stay is approximately 1 to 3 days compared with the 4- to 6-day stay necessary with CABG surgery, thus reducing hospital costs; and (e) the patient can make a rapid return to work (approximately 5 to 7 days after PCI) instead of the 2- to 8-week convalescence period after CABG.

PCI is performed more frequently than CABG surgery. Techniques have been developed to provide blood flow to the distal myocardium during balloon inflation, which increases the safety of the procedure. Dilation may also be performed for stenotic grafts from previous CABG surgery.

The most serious complication of PCI is dissection of the newly dilated coronary artery. If the damage is extensive, the coronary artery could rupture, which would cause cardiac tamponade, ischemia and infarction, decreased CO, and possibly death. There is also danger of infarction if the lesion is calcified and a portion of the plaque becomes dislodged and occludes the vessel distal to the catheter. Coronary spasm can occur from the mechanical irritation of the catheter or the balloon or from chemical irritation from the contrast medium used to visualize the artery. Abrupt closure is a complication that can occur in the first 24 hours after PCI. Re-stenosis after PCI can also occur, and risk is greatest in the first 30 days after the procedure. Nursing care of the patient after PCI is similar to that after cardiac catheterization (see Chapter 34, Table 34-6).

Fibrinolytic Therapy

Fibrinolytic therapy offers the advantages of availability and rapid administration for patients who attend facilities without an interventional cardiac catheterization laboratory or for patients who are too far from such a facility for safe transfer. Treatment of MI with fibrinolytic therapy is aimed at stopping the infarction process by dissolving the thrombus in the coronary artery and reperfusing the myocardium. To be of most benefit, fibrinolytic therapy must be given as soon as possible, ideally within the first hour, and preferably within the first 6 hours, after the onset of symptoms. When reperfusion occurs within 6 hours, the mortality rate is reduced by 25%.

Indications and Contraindications.

All fibrinolytics are given by IV (see Table 36-11). The choice of a thrombolytic agent is guided by considerations of cost, efficacy, and ease of administration. Although these drugs have different mechanisms of action and different pharmacokinetics, they all open the artery by lysis of the thrombus in the coronary artery. Administration of a fibrinolytic is targeted to occur within 30 minutes of the patient's arrival at the ED. Optimal outcomes can be achieved if the fibrinolytic is administered within 60 minutes after onset of symptoms (Pagana, Pagana, & Pike-MacDonald, 2013).

Because all the fibrinolytics produce lysis of the pathological clot, they may also lyse other clots (e.g., a postoperative site). Therefore, patient selection is important because minor or major bleeding can be a complication of therapy (Pagana, Pagana, & Pike-MacDonald, 2013). Inclusion criteria for fibrinolytic therapy include (a) chest pain typical of acute MI and less than 6 hours in duration, (b) 12-lead ECG findings consistent with acute MI, and (c) no absolute contraindications (Table 36-13).

TABLE 36-13
CONTRAINDICATIONS FOR THE USE OF FIBRINOLYTIC THERAPY

Absolute Contraindications	Relative Contraindications
• Active internal bleeding or bleeding diathesis (except for menstruation) • Known history of cerebral aneurysm or arteriovenous malformation • Known intracranial neoplasm (primary or metastatic) • Previous cerebral hemorrhage • Ischemic stroke within past 3 mo • Significant closed head or facial trauma within past 3 mo • Suspected aortic dissection	• Active peptic ulcer disease • Current use of anticoagulants • Pregnancy • Prior ischemic stroke not within past 3 mo; dementia; or known intracranial disease not covered under absolute contraindications • Surgery (including laser eye surgery) or puncture of noncompressible vessel within past 3 wk • Internal bleeding within past 2–4 wk • Serious systemic disease (e.g., advanced or terminal cancer, severe liver or kidney disease) • Severe uncontrolled hypertension (BP >180/110 mm Hg) on patient's arrival for care or chronic, severe, poorly controlled hypertension • Traumatic or prolonged (>10 min) cardiopulmonary resuscitation

BP, blood pressure.

Procedure.

Each hospital has its own protocol to follow for administration of fibrinolytic therapy. However, all protocols have several common factors. Blood for baseline laboratory studies is collected, two to three lines for IV therapy are started, and all other invasive procedures are performed before the fibrinolytic agent is given. This sequence reduces the possibility of bleeding in the patient.

Depending on the drug selected, therapy may be administered in one IV bolus or over time (30 to 90 minutes). The time at which therapy begins is noted, and the patient is monitored during and after administration. ECG, vital signs measurement, pulse oximetry, and heart and lung assessments are completed frequently to evaluate the patient's response to therapy. When reperfusion occurs, several clinical markers may change. The most reliable marker is the return of the ST segment to baseline values on the ECG. Other markers include a resolution of chest pain and a rapid rise of

the CK-MB enzyme levels that occurs within 3 hours of therapy and peaks within 12 hours. The CK-MB levels increase as the necrotic myocardial cells release CK-MB enzymes into the circulation after perfusion has been restored to the area. The presence of reperfusion dysrhythmias (e.g., accelerated idioventricular rhythm) is a less reliable marker of reperfusion. These dysrhythmias are generally self-limiting and do not necessitate aggressive treatment. (See Chapter 38 for management of dysrhythmias.)

A major concern with fibrinolytic therapy is reocclusion of the artery. The site of the thrombus is unstable, and another clot may form, or spasm of the artery may occur. Because of these possibilities, most physicians begin IV heparin therapy. If another clot develops, the patient reports similar complaints of chest pain, and ECG changes return. The patient is re-evaluated and may receive a second dose of the fibrinolytic or be transferred to a cardiac catheterization laboratory for rescue PCI.

The major complication with fibrinolytic therapy is bleeding. Ongoing nursing assessment is essential. Minor bleeding (e.g., surface bleeding from IV sites or gingival bleeding) is expected and can be controlled by applying a pressure dressing or ice packs. If signs and symptoms of major bleeding occur (e.g., a drop in BP, an increase in HR, a sudden decrease in the patient's level of consciousness, blood in the urine or stool), the physician should be notified, and the therapy should be stopped.

Drug Therapy

IV nitroglycerin, ASA, β-adrenergic blockers, and systemic anticoagulation with either subcutaneous LMWH or IV UH are the initial drug treatments of choice for ACS (Pagana, Pagana, & Pike-MacDonald, 2013). IV antiplatelet drugs (e.g., glycoprotein IIb/IIIa inhibitor) may also be used if PCI is anticipated. ACE inhibitors are added for select patients after MI (discussed in the section "Angiotensin-Converting Enzyme Inhibitors"). Calcium channel blockers or long-acting nitrates can be added if the patient is already receiving adequate doses of β-adrenergic blockers, cannot tolerate β-adrenergic blockers, or has Prinzmetal's angina (Pagana, Pagana, & Pike-MacDonald, 2013).

Drug therapy for patients with ACS is described in Table 36-11. These drugs are discussed on pp. 824–827. ACS-specific drugs are discussed in the following sections.

Intravenous Nitroglycerin.

IV nitroglycerin is used in the initial treatment of patients with ACS. The goal of therapy is to reduce anginal pain and improve coronary blood flow. Nitroglycerin has an immediate onset of action and can be titrated to prevent, treat, and stop UA (Pagana, Pagana, & Pike-MacDonald, 2013).

IV nitroglycerin is used to decrease preload and afterload while increasing the myocardial oxygen supply. The dose is usually titrated to relieve pain. Because hypotension is a common adverse effect, BP is closely monitored during this time. Tolerance is another adverse effect of IV nitroglycerin therapy. An effective strategy to manage this phenomenon is to administer a lower dosage at night and during sleep and a higher dosage during the day.

Morphine Sulphate.

Morphine is given for chest pain that is unrelieved by nitroglycerin. As a vasodilator, it decreases cardiac workload by lowering myocardial oxygen consumption, reducing contractility, and decreasing BP and HR. In addition, morphine can help reduce anxiety and fear. In rare situations, morphine can depress respiration. Patients should be monitored for signs of bradypnea or hypoxia, a condition to be prevented when at all possible in myocardial ischemia and infarction.

β-Adrenergic Blockers.

IV β-adrenergic blockers should not be given to patients with STEMI. They may be considered for treatment of hypertension in patients with no contraindications such as HF or low CO. Oral β-adrenergic blocker therapy should be initiated within 24 hours of STEMI in patients with no contraindications. β-Adrenergic blockers are used to decrease myocardial oxygen demand by reducing HR, BP, and contractility. (See Table 36-11 and Chapter 35, Table 35-8 for a discussion of β-adrenergic blockers.)

Angiotensin-Converting Enzyme Inhibitors.

ACE inhibitors (e.g., captopril) are recommended after anterior wall MIs or MIs that result in decreased left ventricular function (ejection fraction <40%) or pulmonary congestion. The use of ACE inhibitors can help prevent ventricular remodelling and prevent or slow the progression of HF. ACE inhibitor therapy should be continued indefinitely. For patients who cannot tolerate ACE inhibitors, angiotensin receptor blockers (e.g., losartan [Cozaar]) should be considered. (See Table 36-11 and Chapter 35, Table 35-8.)

Antidysrhythmia Medications.

Dysrhythmias are the most common complications after an MI. In general, they are not treated aggressively unless they are life-threatening. (The medications used in the treatment of dysrhythmias are discussed in Chapter 38.)

Cholesterol-Lowering Drugs.

A fasting lipid panel should be obtained for all patients admitted with ACS. Cholesterol-lowering drugs are recommended for all patients with elevated LDL cholesterol levels (see Figure 36-6 and Table 36-5).

Stool Softeners.

After an MI, patients may be predisposed to constipation as a result of bed rest and opioid administration. Stool softeners such as docusate sodium (Colace) are given to facilitate and promote the comfort of bowel evacuation. These medications prevent straining and the resultant vagal stimulation from the Valsalva manoeuvre. Vagal stimulation produces bradycardia and can provoke dysrhythmias.

Nutritional Therapy

Initially, patients may be kept NPO (nothing by mouth) except for sips of water until stable (e.g., pain alleviated, nausea resolved). Diet is advanced as tolerated to one of low salt, low saturated fats, and low cholesterol.

Coronary Surgical Revascularization

Coronary revascularization (an intervention to restore blood flow to the affected myocardium) with CABG surgery is recommended for patients who (a) fail medical management, (b) have left main coronary artery or three-vessel disease, (c) are not candidates for PCI (e.g., lesions are long or difficult to access), (d) have failed PCI and continue to have chest pain, (e) have diabetes mellitus, or (f) are expected to have longer-term benefits with CABG than with PCI.

Coronary Artery Bypass Graft Surgery.

CABG surgery consists of the placement of conduits to transport blood between the aorta or other major arteries and the myocardium distal to the blocked coronary artery (or arteries). The procedure may involve one or more grafts using the internal mammary artery (IMA), saphenous vein,

radial artery, gastro-epiploic artery, inferior epigastric artery, or a combination of these (Figure 36-12).

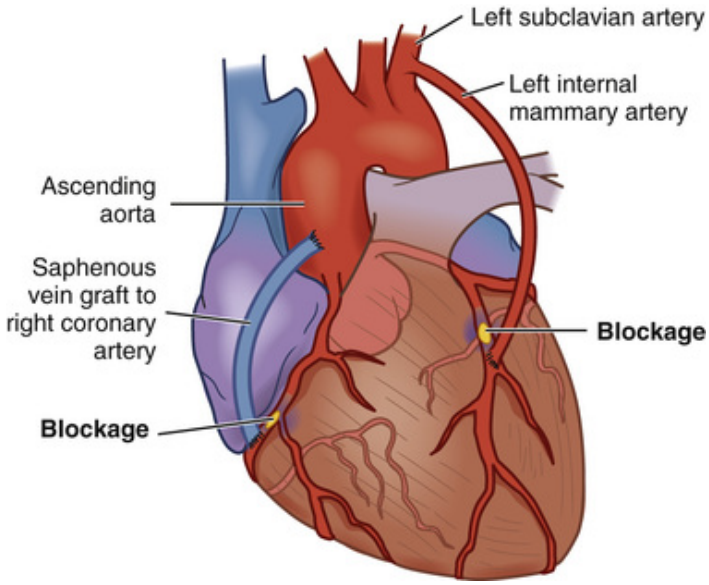

FIGURE 36-12 The distal end of the left internal mammary artery is grafted below the area of blockage in the left anterior descending artery. The proximal end of the saphenous vein is grafted to the aorta, and the distal end is grafted below the area of blockage in the right coronary artery.

CABG surgery requires a sternotomy (opening of the chest cavity) and *cardiopulmonary bypass* (CPB). During CPB, blood is diverted from the patient's heart to a machine, where it is oxygenated and returned (via a pump) to the patient. This allows the surgeon to operate on a quiet, nonbeating, bloodless heart while perfusion to vital organs is maintained.

The IMA is the most common artery used for bypass graft. It is left attached to its origin (the subclavian artery) but then dissected from the chest wall. Next, it is *anastomosed* (connected with sutures) to the coronary artery distal to the blockage.

When using the saphenous vein for a bypass graft, the surgeon removes the vein from one or both legs endoscopically. Sections are attached to the ascending aorta and then to a coronary artery distal to the blockage. Saphenous vein grafts do develop diffuse intimal hyperplasia, which contributes to future stenosis and graft occlusions. The use of antiplatelet therapy and statins after surgery improves vein graft patency. Patency rates of these grafts are 50% to 60% at 10 years (Hillis, Smith, Anderson, et al., 2011).

The radial artery is a thick, muscular artery that is prone to spasm. Perioperative calcium channel blockers and long-acting nitrates can control the spasms. Patency rates at 5 years are as high as 84%. There have been no reports of extremity complications (e.g., hand ischemia, wound infection) after removal of this artery (Hillis, Smith, Anderson, et al., 2011).

The gastro-epiploic and inferior epigastric artery are rarely used because the dissection of these arteries is extensive, increasing the length of surgery and the risk for wound complications at the harvest site, especially in an obese or diabetic patient (Hillis, Smith, Anderson, et al., 2011). Like the radial artery, these are prone to spasms. One-year patency rate for the epigastric artery is 90%, and 10-year patency rate for the gastro-epiploic artery is 62% (Hillis, Smith, Anderson, et al., 2011).

CABG surgery remains a palliative treatment for CAD and not a cure. Studies have shown improved patient outcomes, quality of life, and survival after CABG surgery. However, postoperative complications and mortality increase with age.

Women have higher operative mortality rates than men. This has been attributed to the late treatment of CAD in women because women first present with the disease at an older age and are more ill (e.g., decreased left ventricular function) at the time of surgery. Other possible factors include smaller-diameter coronary vessels and the less frequent use of the IMA.

Minimally Invasive Direct Coronary Artery Bypass.

Minimally invasive direct coronary artery bypass (MIDCAB) offers patients with limited disease an approach to surgical treatment that does not involve a sternotomy and CPB. In many cases, these patients are too high risk for traditional bypass surgery (Bojar, 2011). The technique requires several small incisions between the ribs. A thoracoscope is used to dissect the IMA. The heart is slowed using a β-adrenergic blocker (e.g., esmolol [Brevibloc]) or stopped temporarily with adenosine. A mechanical stabilizer immobilizes the operative site. The IMA is then sutured to the left anterior descending or right coronary artery. A radial artery or saphenous vein graft can be used if the IMA is not available.

Off-Pump Coronary Artery Bypass.

The *off-pump coronary artery bypass* (OPCAB) procedure uses full or partial sternotomy to access all coronary vessels. OPCAB is performed on a beating heart using mechanical stabilizers and without CPB. It is usually reserved for patients who have limited disease but are at high risk for

traditional surgery secondary to multiple comorbidities. Patients who are typically candidates for OPCAB have a very low ejection fraction, severe lung disease, acute or chronic kidney disease, a high risk for stroke, or a calcified aorta (Bojar, 2011).

Robot-Assisted Cardiothoracic Surgery.

This technique incorporates the use of a robot in performing CABG or mitral valve replacement. The benefits of robotic surgery include increased precision, smaller incisions, decreased blood loss, less pain, and shorter recovery time.

Transmyocardial Laser Revascularization.

Transmyocardial laser revascularization (TMR) is an indirect revascularization procedure. It is used for patients with advanced CAD who are not candidates for traditional CABG surgery and who have persistent angina after maximum medical therapy. The procedure involves the use of a high-energy laser to create channels in the heart to allow blood flow to ischemic areas. The procedure is performed during cardiac catheterization as a percutaneous TMR or during surgery using a left anterior thoracotomy incision as an adjunct to CABG.

Nursing Management Chronic Stable Angina and Acute Coronary Syndrome

Nursing Assessment

Subjective and objective data that should be obtained from a patient with ACS are listed in Table 36-14.

TABLE 36-14

NURSING ASSESSMENT
Acute Coronary Syndrome

Subjective Data
Important Health Information
Current health history: Family history of heart disease; sedentary lifestyle; tobacco use *Past health history:* Previous history of CAD, angina, MI, aortic stenosis, HF, or cardiomyopathy; hypertension; diabetes; anemia; lung disease; hyperlipidemia *Medications:* Use of ASA (Aspirin), nitrates, β-adrenergic blockers, calcium channel blockers, ACE inhibitors, antihypertensive drugs, cholesterol-lowering drugs, vitamin or herbal supplements
Symptoms
• Substernal chest pain or pressure (squeezing, constricting, aching, sharp, tingling), possible radiation to jaw, neck, shoulders, back, or arms • Indigestion, heartburn, nausea, belching, vomiting • Palpitations, dyspnea, dizziness, weakness • Fatigue, anxiety, feeling of impending doom
Objective Data
General
Anxiety, fear, restlessness
Integumentary
Cool, clammy, pale skin
Cardiovascular
Tachycardia or bradycardia, pulsus alternans (alternating weak and strong heartbeats), dysrhythmias (especially ventricular), S_3, S_4, higher or lower BP, murmur
Possible Findings
Elevated or nonelevated levels of serum cardiac markers, increased levels of serum lipids; increased WBC count; positive results of exercise stress test and thallium scans; ST-segment and T-wave abnormalities on ECG; cardiac enlargement, calcifications, or pulmonary congestion on chest radiograph; evidence of abnormal wall motion on stress echocardiogram; positive findings on coronary angiogram

ACE, angiotensin-converting enzyme; *ASA*, acetylsalicylic acid; *BP*, blood pressure; *CAD*, coronary artery disease; *ECG*, electrocardiogram; *HF*, heart failure; *MI*, myocardial infarction; S_3, third heart sound; S_4, fourth heart sound; *WBC*, white blood cell.

Nursing Diagnoses

Nursing diagnoses for the patient with ACS may include but are not limited to those presented in Nursing Care Plan (NCP) 36-1.

Nursing Care Plan 36-1

Acute Coronary Syndrome

NURSING DIAGNOSIS	***Decreased cardiac output*** (related to altered contractility and altered heart rate and rhythm as evidenced by decrease in BP, elevation in HR, dyspnea, dysrhythmias, diminished pulses, peripheral edema, pulmonary edema, or a combination of these).
Expected Patient Outcomes	**Nursing Interventions and *Rationales***
• Maintains stable signs of effective cardiac perfusion	*Cardiac Care* • Monitor vital signs frequently *to determine baseline and ongoing changes*. • Monitor for cardiac dysrhythmias, including disturbances of both rhythm and conduction, *to identify and treat significant dysrhythmias*. • Monitor respiratory status for symptoms of heart failure *to maintain appropriate levels of oxygenation and to detect signs of pulmonary edema*. • Monitor fluid balance (e.g., intake and output, daily weight) *to monitor renal perfusion and observe for fluid retention*. • Arrange exercise and rest periods *to prevent fatigue and decrease the oxygen demand on the myocardium*.
NURSING DIAGNOSIS	***Acute pain*** related to *biological injury agent* (imbalance between myocardial O_2 supply and demand) as evidenced by *self-report of pain characteristics using standard pain instrument*
Expected Patient Outcomes	**Nursing Interventions and *Rationales***
• Reports relief of pain	*Cardiac Care* • Evaluate chest pain (e.g., PQRST [see Table 36-7]) *to accurately evaluate, treat, and prevent further ischemia*. • Monitor vital signs frequently *to determine baseline and detect ongoing changes*. • Obtain 12-lead ECG during pain episode *to help differentiate angina from extension of MI or pericarditis*. *Pain Management* • Provide optimal pain relief with prescribed analgesics *because pain exacerbates tachycardia and increases BP*. • Consider the type and source of pain when selecting pain relief strategy *because angina responds to opioids and measures that increase myocardial perfusion*.
NURSING DIAGNOSIS	***Anxiety*** related to *threat of death, threat to current status* (pain, lifestyle changes) as evidenced by *restlessness, distress, helplessness*
Expected Patient Outcomes	**Nursing Interventions and *Rationales***
• Reports decreased anxiety and increased sense of self-control	*Anxiety Reduction* • Observe for verbal and nonverbal signs of anxiety. • Identify changes in level of anxiety *because anxiety increases the need for oxygen*. • Use a calm, reassuring approach *so as not to increase patient's anxiety*. • Instruct patient in use of relaxation techniques (e.g., relaxation breathing, imagery) *to enhance the patient's self-control*. • Encourage family members to stay with patient *to provide comfort*. • Encourage verbalization of feelings, perceptions, and fears *to decrease anxiety and stress*. • Provide factual information concerning diagnosis, treatment, and prognosis *to decrease fear of the unknown*. *Coping Enhancement* • Provide the patient with realistic choices about certain aspects of care *to support decision making*. • Assist the patient in identifying positive strategies *to deal with limitations and manage needed lifestyle or role changes*. • Help the patient to grieve and work through the losses of chronic illness *to provide support*.
NURSING DIAGNOSIS	***Activity intolerance*** related to *physical deconditioning* (decreased cardiac output, poor lung perfusion) as evidenced by *fatigue, generalized weakness, abnormal heart rate response to activity*
Expected Patient Outcomes	**Nursing Interventions and *Rationales***
• Achieves a realistic program of activity that balances physical	*Cardiac Care* • Monitor patient's response to antidysrhythmic medications before activity *because these medications affect blood pressure and pulse*.

activity with energy-conserving activities	• Arrange exercise and rest periods *to prevent fatigue and to increase activity tolerance without rapidly increasing cardiac workload.* *Energy Management* • Assist patient to understand energy conservation principles (e.g., the requirement for restricted activity) *to promote healing by conserving energy.* • Teach patient and significant others techniques of self-care that will minimize oxygen consumption (e.g., self-monitoring and pacing techniques for performance of activities of daily living) *to promote independence as well as minimize O_2 consumption.*
NURSING DIAGNOSIS	***Ineffective health management*** related to *insufficient knowledge of therapeutic regimen* (rehabilitation process, home activities, medications) as evidenced by *difficulty with prescribed regimen*
Expected Patient Outcomes	**Nursing Interventions and *Rationales***
• Describes risk factors, the disease process, and rehabilitation activities necessary to manage the therapeutic regimen	*Cardiac Care: Rehabilitative* • Encourage realistic expectations for the patient, caregiver(s), and family member(s) *to promote realistic decision making.* • Instruct patient, caregiver(s), and family member(s) on appropriate prescribed and over-the-counter drugs *to promote adherence to drug regimens.* • Instruct the patient and caregiver on cardiac risk-factor modification (e.g., smoking cessation, diet, exercise) *to increase patient's control of the illness.* • Instruct the patient on self-care of chest pain (e.g., take sublingual nitroglycerin every 5 minutes three times; if chest pain unrelieved, seek emergency medical care). • Instruct the patient and caregiver on the exercise regimen, including warm-up, endurance, and cool-down, *to reduce cardiac risk factors.* • Instruct the patient and caregiver on wound care and precautions (e.g., sternal incision or catheterization site), if appropriate, *to prevent infection and promote healing after invasive therapies.* • Instruct the patient and caregiver on access to emergency services available in their community *to enable them to obtain immediate care if needed.*

Planning

The overall goals for a patient with ACS include (a) relief of pain, (b) preservation of the myocardium, (c) immediate and appropriate treatment of ischemia, (d) effective coping with illness-associated anxiety, (e) participation in a rehabilitation plan, and (f) reduction of risk factors.

Nursing Implementation: Chronic Stable Angina

Health Promotion.

Behaviours to reduce the risk for CAD are presented in Table 36-2 and discussed on pp. 818–820.

Acute Intervention.

If a nurse is present during an anginal attack, the following measures should be instituted: (a) administration of supplemental oxygen; (b) measurement of vital signs; (c) 12-lead ECG; (d) prompt pain relief, first with a nitrate and then, if necessary, an opioid analgesic; (e) auscultation of heart sounds; and (f) comfortable positioning of the patient. The patient

is likely to appear distressed and to have pale, cool, clammy skin. The BP and HR are probably elevated, and an atrial gallop sound (S_4) may be heard. A ventricular gallop sound (S_3) may indicate left ventricular dysfunction. A murmur heard during an anginal attack may be secondary to ischemia of a papillary muscle of the mitral valve. The murmur is likely to be transient and to disappear with the cessation of symptoms.

The nurse should ask the patient to rate the pain on a scale of 0 to 10 before and after treatment, to evaluate the effectiveness of the interventions. It is important to use the same words that patients use to describe their pain. Some patients may not always verbalize pain. The nurse must be attuned to other manifestations of pain, such as restlessness; elevated HR, respiratory rate, or BP; clutching of the bedclothes; or other nonverbal cues. Supportive and realistic reassurance and a calm, soothing manner help reduce the patient's anxiety during an anginal attack.

Ambulatory and Home Care.

Patients with a history of angina should be reassured that a long, productive life is possible. Prevention of angina is preferable to its treatment, and this is why teaching is important. Patients should be provided information regarding CAD, angina, precipitating factors for angina, risk-factor reduction, and medications.

Patient teaching can be handled in a variety of ways. One-to-one contact between the nurse and the patient is often the most effective strategy. The time spent providing daily care is often an ideal teaching period. Teaching tools such as pamphlets, video recordings, heart models, and especially written information are necessary components of patient and family teaching (see Chapter 4).

Patients should be assisted in identifying factors that precipitate angina (see Table 36-8) and given instruction on how to avoid or control precipitating factors. For example, patients should be taught to avoid exposure to extremes of weather and to avoid consumption of large, heavy meals. If a heavy meal is ingested, adequate rest should be planned for 1 to 2 hours after the meal because blood is shunted to the GI tract to aid in digestion and absorption.

Patients should be assisted in identifying personal risk factors for CAD. Once these are known, methods of decreasing any modifiable risk factors should be discussed (see Table 36-2).

Teaching the patient and the family or caregivers about diets with low sodium and saturated-fat content may be appropriate (see Tables 36-3 and

36-4). Maintaining ideal body weight is important in controlling angina because weight above this level increases the myocardial workload.

Adhering to a regular, individualized program of physical activity that conditions the heart rather than overstressing the myocardium is important. As well, the patient and the caregivers must be instructed in the proper use of nitroglycerin (see pp. 824–825). Nitroglycerin tablets or ointments may be used prophylactically before an emotionally stressful situation, sexual intercourse, or physical exertion (e.g., climbing a long flight of stairs).

Counselling should be provided to assess the psychological adjustment of the patient and the family to the diagnosis of CAD and the resulting angina. Many patients feel a threat to their identity and self-esteem and may be unable to fill their usual roles in society. These emotions are normal and real.

Nursing Implementation: Acute Coronary Syndrome

Acute Intervention.

Priorities for nursing interventions in the initial phase of ACS include pain assessment and relief, physiological monitoring, promotion of rest and comfort, alleviation of stress and anxiety, and understanding of the patient's emotional and behavioural reactions. Proper management of these priorities decreases the oxygen needs of a compromised myocardium and reduces the risk for complications. In addition, the nurse should institute measures to avoid the hazards of immobility and yet encourage rest.

Pain.

Nitroglycerin, morphine sulphate, and supplemental oxygen should be provided as needed to eliminate or reduce chest pain. Ongoing evaluation and documentation of the effectiveness of the interventions is important. Once pain is relieved, the nurse may have to deal with denial in a patient who interprets the absence of pain as an absence of cardiac disease.

Monitoring.

Patients undergo continuous ECG monitoring while in the ED and the intensive care unit and usually after transfer to a step-down or general unit. The nurse should be educated in interpretation of the ECG so that dysrhythmias causing further deterioration of the cardiovascular status can be identified and treated. During the initial period after MI, ventricular

fibrillation is the most common lethal dysrhythmia. In many patients, this dysrhythmia is often preceded by PVCs or ventricular tachycardia. The nurse should also monitor the patient for the presence of silent ischemia by monitoring the ST segment for shifts above or below the baseline of the ECG. **Silent ischemia** occurs without clinical symptoms such as chest pain. It is noted by ST-segment changes only and may place a patient at higher risk for adverse outcomes and even death (Conti, Bavry, & Petersen, 2012). If episodes of silent ischemia are observed, the physician should be notified. (See Chapter 38 for a complete discussion of ECG monitoring.)

In addition to frequent assessment of vital signs, intake and output should be evaluated at least once per shift, and physical assessment should be carried out to detect deviations from a patient's baseline parameters. Included is an assessment of lung sounds and heart sounds and inspection for evidence of early HF (e.g., dyspnea, tachycardia, pulmonary congestion, distended neck veins).

Assessment of the patient's oxygenation status is important, especially if the patient is receiving oxygen. Also, the nares should be checked for irritation or dryness, which can cause considerable discomfort if the nasal route is used for oxygen administration.

Rest and Comfort.

With a severe insult to the myocardium, as in the case of ACS, it is important for the nurse to promote rest and comfort. Bed rest may be ordered for the first few days after an MI involving a large portion of the ventricle. A patient with an uncomplicated MI (e.g., angina resolved, no signs of complications) may rest in a chair within 8 to 12 hours after the event. The use of a commode or bedpan is based on patient preference.

When sleeping or resting, the body requires less work from the heart than it does when active. It is important to plan nursing and therapeutic actions to ensure adequate rest periods free from interruption. Comfort measures that can promote rest include frequent oral care, adequate warmth, a quiet atmosphere, use of relaxation therapy (e.g., guided imagery), and assurance that personnel are nearby and responsive to the patient's needs.

It is important that patients understand the reasons for limited activity. However, in spite of this limitation, patients are not completely restricted. Gradually, the cardiac workload is increased through more demanding physical tasks so that patients can achieve a discharge activity level

adequate for home care. Phases of cardiac rehabilitation are outlined in Table 36-15.

TABLE 36-15
PHASES OF REHABILITATION AFTER ACUTE CORONARY SYNDROME

Phase I: Hospital
• Occurs while the patient is still hospitalized. • Activity level depends on severity of angina or MI. • Patient may initially sit up in bed or chair, perform range-of-motion exercises and self-care (e.g., washing, shaving), and progress to ambulation in hallway and limited stair climbing. • Attention focuses on management of pain, anxiety, dysrhythmias, and complications.
Phase II: Early Recovery
• Phase begins after the patient is discharged. • Phase usually lasts 2–12 wk and is conducted in an outpatient facility. • Activity level is gradually increased under the supervision of the cardiac rehabilitation team and with electrocardiographic monitoring. • Team may suggest that physical activity (e.g., walking) be initiated at home. • Information regarding risk-factor reduction is provided at this time.
Phase III: Late Recovery
• Long-term maintenance program is followed. • Individual physical activity programs are designed and implemented at home, a local gym, or the rehabilitation centre. • Patient and family may restructure lifestyles and roles as possible. • Lifestyle changes should become lifelong habits. • Medical supervision is still recommended.

MI, myocardial infarction.

Anxiety.

Anxiety is present to various degrees in all patients with ACS. The nurse's role is to identify the source of anxiety and assist the patient in reducing anxiety. If the patient is afraid of being alone, a family member should be allowed to sit quietly by the bedside or to check in with the patient frequently. If a source of anxiety is fear of the unknown, the nurse should explore these concerns with the patient and help with appropriate reality testing.

If anxiety is caused by lack of information, the nurse should provide teaching appropriate to the patient's stated need and level of understanding. The nurse should answer the patient's questions with clear, simple explanations sufficient to reduce the patient's anxiety.

It is important to start teaching at the patient's level rather than to present a prepackaged protocol. Many patients are not yet ready to hear about the pathogenesis of CAD. The earliest questions usually relate to how the disease affects perceived control and independence. These questions include the following:

- When will I leave the intensive care unit?
- When can I be out of bed?
- When will I be discharged?
- When can I return to work?
- How much change will I have to make in my life?
- Will this happen again?

The nurse should advise patients to begin a more complete teaching program once they are feeling stronger. Many patients may not be able to consciously examine the most pervasive and typical concern: "Am I going to die?" Even if a patient denies this concern, it is helpful for the nurse to initiate conversation by remarking that fear of dying is a common concern reported by most patients who have experienced ACS. This information gives the patient "permission" to talk about an uncomfortable and frightening topic (Table 36-16).

TABLE 36-16

EMOTIONAL AND BEHAVIOURAL RESPONSES TO ACUTE CORONARY SYNDROME

Denial
• May have history of ignoring symptoms related to heart disease • Minimizes severity of medical condition • Ignores activity restrictions • Avoids discussing illness or its significance
Anger
• Is commonly expressed as "Why did this happen to me?" • Possibly directed at family, staff, or medical regimen
Anxiety and Fear
• Fears long-term disability and death • Overtly manifests apprehension, restlessness, insomnia, tachycardia • Less overtly manifests increased verbalization, projection of feelings to others, hypochondriasis • Fears activity • Fears recurrent angina, heart attacks, and sudden death
Dependency
• Is totally reliant on staff • Is unwilling to perform tasks or activities unless approved by health care provider • Wants to be monitored by ECG at all times • Is hesitant to leave the intensive care unit or hospital
Depression
• Mourns loss of health, altered body function, and changes in lifestyle • Realizes seriousness of situation • Begins to worry about future implications of health problem • Shows manifestations of withdrawal, apathy • May be more evident after hospital discharge
Realistic Acceptance
• Focuses on optimum rehabilitation • Plans changes compatible with altered cardiac function

ECG, electrocardiogram.

Emotional and Behavioural Reactions.

The emotional and behavioural reactions of a patient are varied and frequently follow a predictable response pattern (see Table 36-16). The role of the nurse is to understand what the patient is currently experiencing, to assist the patient in testing reality, and to support the use of constructive coping styles, recognizing that denial may be a positive coping style in the early phase of recovery from ACS.

The nurse has a duty to maximize and enhance the patient's social support systems. This entails assessing the support structure of the patient and family and allowing it to function. Often the patient is separated from the most significant support system at the time of hospitalization. The nurse's role can include talking with the family members, allowing the patient and the family to interact as necessary, and supporting the family members who will be able to provide the necessary support to the patient.

Open visitation is helpful in decreasing anxiety and increasing support for the patient with ACS. It is important for the nurse to help the patient identify additional support systems (e.g., spiritual care) that can help the patient after discharge.

Coronary Revascularization.

Patients with ACS may undergo coronary revascularization with PCI or CABG surgery. The major nursing responsibilities for the care of the patient after PCI involve monitoring for signs of recurrent angina; frequently assessing vital signs, including HR and rhythm; evaluating the groin site for signs of bleeding; and maintaining bed rest per institution policy.

Patients undergoing CABG surgery receive care in the intensive care unit for the first 24 to 36 hours. Ongoing and intensive monitoring of patients' hemodynamic status is critical. For such patients, much invasive equipment for monitoring cardiac status and other vital organs is present (see Chapter 68). This equipment includes a pulmonary artery catheter for measuring CO and other hemodynamic parameters, an intra-arterial line for continuous BP monitoring, pleural and mediastinal chest tubes for chest drainage, ECG leads for continuous monitoring to detect dysrhythmias, an endotracheal tube connected to mechanical ventilation, epicardial pacing wires for emergency pacing of the heart, a urinary catheter to monitor urine output, and a nasogastric tube for gastric decompression. Most patients are extubated within 12 hours after surgery and transferred to a step-down unit within 24 hours for continued monitoring of cardiac status.

Many of the postoperative complications that develop after CABG surgery are related to the use of CPB. Major consequences of CPB include bleeding and anemia from damage to red blood cells and platelets, fluid and electrolyte imbalances, and hypothermia because blood is cooled as it passes through the CPB machine. Nursing care focuses on assessing the patient for bleeding (e.g., chest tube drainage, incision sites), monitoring fluid status, replacing electrolytes as needed, and restoring temperature (e.g., with use of warming blankets).

Postoperative dysrhythmias, specifically atrial dysrhythmias, are common in the first 3 days after CABG surgery. Between 20% and 40% of patients develop postoperative atrial fibrillation. Discharge is often delayed in these patients as a result of the need for anticoagulation. (See Chapter 38 for information on treatment of atrial fibrillation.)

Nursing care for patients with a CABG also involves caring for the surgical sites: the chest, the arm, the leg, the abdomen, or some combination of these. Care of the radial artery harvest site includes careful observation of the incision site, as well as monitoring of sensory and motor function of the distal thumb and fingers. The patient with radial artery harvest should receive therapy with a calcium channel blocker for approximately 3 months to decrease the incidence of arterial spasm at the arm or the anastomosis site.

The care of the leg wound is similar to the postoperative care after the stripping of varicose veins (see Chapter 40). The management of the chest wound, which involves a sternotomy, is similar to that for other chest surgical procedures (see Chapter 30).

Elective CABG is generally well tolerated by older patients. However, the nurse caring for older adults must be aware that although the benefits of treatment may outweigh risks in this population, the incidence of complications—including dysrhythmias, stroke, and infection—is higher than that in younger individuals.

Postoperative nursing care of patients who have undergone a MIDCAB or OPCAB procedure is similar to that of patients who have undergone CABG surgery. Pain management is essential because patients with thoracotomy incisions report higher levels of pain than those with sternotomy incisions. The recovery time is somewhat shorter with these procedures, and patients often resume routine activities sooner than do patients who have CABG surgery.

Ambulatory and Home Care.

Rehabilitation may be defined as the process of helping the patient adjust to a disability by teaching integration of all resources and concentrating more on existing abilities than on permanent disabilities. *Cardiac rehabilitation* is the restoration of a person to an optimal state of function in six areas: physiological, psychological, mental, spiritual, economic, and vocational. Many people recover from ACS physically, but they may never attain psychological well-being because of misconceptions about the illness or a need to practise illness behaviours. Returning to work and resuming all activities have long been outcome measures of cardiac rehabilitation and are important in terms of the cost-effectiveness of cardiac care and rehabilitation. (See the "Evidence-Informed Practice" box.)

Evidence-Informed Practice

Research Highlight

What Is the Most Effective Cardiac Rehabilitation Program?

Clinical Question

In patients with coronary CAD (P), are comprehensive cardiac rehabilitation programs (I) more effective than exercise-only cardiac rehabilitation programs (C) in reducing mortality (O)?

Best Available Evidence

Systematic review of randomized controlled trials

Critical Appraisal and Synthesis of Evidence

- 47 randomized controlled trials (n = 10 794).
- Reduction in overall and cardiovascular mortality.
- Reduction in hospital readmissions.
- Comprehensive cardiac rehabilitation (e.g., exercise in addition to psychosocial and educational interventions): 13%.
- Of 10 trials, 7 revealed significantly higher quality of life with exercise-based cardiac rehabilitation than with usual care.

Conclusions

- Exercise-based cardiac rehabilitation is effective in reducing cardiac deaths and other causes of mortality in patients with CAD.
- A broader sample that includes more women and is more ethnically diverse is needed for subsequent studies.

Implications for Nursing Practice

- Counsel patients at risk for CAD on the benefits of exercise.
- Include an exercise component in health and wellness programs for patients with CAD and those who have suffered a cardiac event.

CAD, coronary artery disease; *PICO: P,* patient population of interest; *I,* intervention or area of interest; *C,* comparison of interest or comparison group; *O,* outcome(s) of interest (see Chapter 1).

Reference for Evidence

Heran B, Ebrahim S, Moxham T, et al. Exercise-based rehabilitation for coronary heart disease. *The Cochrane Database of Systematic Reviews*. 2011;(7); 10.1002/14651858.CD001800.pub2 [CD001800].

In considering rehabilitation, the nurse and the patient must recognize that CAD is a chronic disease. It will not be cured, nor will it disappear by itself. Therefore, basic changes in lifestyle must be made to promote recovery and health. In many cases, these changes must be made at a time when the patient is middle-aged or older. The patient must also realize that recovery takes time. Resumption of physical activity after ACS or CABG surgery is slow and gradual. However, with appropriate and adequate supportive care, recovery is likely.

Patient Teaching.

Patient teaching begins with the nurse in the ED, progresses through the care provided by the staff nurse, and continues with the community health nurse. The purpose of teaching is to give the patient and the family the tools they need to make informed decisions about attainment of health. For teaching to be meaningful, the patient must be aware of the need to learn. Careful assessment of the patient's learning needs helps the nurse set goals and objectives that are realistic.

The timing of the teaching is important. When patients or families are in crisis (either physiological or psychological), they may not be able to learn new information. It is important to remember that early questions should be answered initially in simple, brief terms, without detailed elaboration, and that the answers to these questions often require repetition with elaboration later. When the shock and disbelief accompanying a crisis subside, the patient and the family are better able to focus on new information.

In addition to teaching the patient and the family what they wish to know, the nurse should recognize that several types of information are necessary for achieving optimal health. A teaching guide for the patient with ACS is presented in Table 36-17.

TABLE 36-17

PATIENT & CAREGIVER TEACHING GUIDE
Acute Coronary Syndrome

The following guidelines should be included when teaching the patient and caregiver about acute coronary syndrome.
• Signs and symptoms of angina and MI and reasons why they occur* • Anatomy and physiology of the heart and vessels • Cause and effect of atherosclerosis • Definitions of terms (e.g., CAD, angina, MI, sudden cardiac death, HF) • Healing after MI • Identification of risk factors and ways to decrease risk* (see Table 36-2) • Rationale for tests and treatments, including ECG, blood tests, and angiography, and for monitoring, rest, diet, and medications* • Appropriate expectations about recovery and rehabilitation (anticipatory guidance) • Resumption of work, physical activity, sexual activity • Measures to take to promote recovery and health • Importance of the gradual, progressive resumption of activity* • When and how to seek help (e.g., contact EMS)

*Identified by patients as most important to learn before discharge.

CAD, coronary artery disease; *ECG*, electrocardiogram; *EMS*, emergency medical services; *HF*, heart failure; *MI*, myocardial infarction.

When medical terminology is used, its meaning should be explained in lay terms. For example, it can be explained that the heart, a four-chambered pump, is a muscle that, like all other muscles, needs oxygen to work properly. When blood vessels supplying the heart muscle with oxygen become narrowed by atherosclerosis, less oxygen reaches the heart muscle. It is a good idea for the nurse to have a model of the heart or to use a pad and pencil to sketch what is being explained. Literature written for a nonmedical audience is available through the Heart and Stroke Foundation of Canada. Video recordings are also helpful tools that can be used to teach patients.

Anticipatory guidance involves preparing the patient and the family for what to expect in the course of recovery and rehabilitation. By learning what to expect during treatment and recovery, the patient gains a sense of control over life. This sense of perceived control allows the patient to consciously consider stressors and thus possibly to promote recovery.

Physical Activity.

Physical activity is an integral part of the rehabilitation program. It is necessary for optimal physiological functioning and psychological well-being. It has a direct, positive effect on maximal oxygen uptake, increasing CO, decreasing blood lipids, decreasing BP, increasing blood flow through the coronary arteries, increasing muscle mass and flexibility, improving

the psychological state, and assisting in weight loss and control. A regular schedule of physical activity, even when begun after many years of sedentary living, is beneficial. The Canadian Guidelines for Physical Activity outline recommended activities and duration for all ages (Canadian Society for Exercise Physiology, 2011).

In the hospital, the patient's activity level is gradually increased so that by the time of discharge, the patient can tolerate moderate-energy activities of 3 to 6 metabolic equivalents (METs). Many patients with UA that has resolved or with an uncomplicated MI are in the hospital for approximately 3 to 4 days. By day 2, patients can ambulate in the hallway and begin limited stair climbing (e.g., three to four steps). Because of the short hospital stay, it is critical to give patients specific guidelines for physical activity so as to avoid overexertion. The nurse should stress to patients that they must "listen to what the body is saying"—the most important facet of recovery.

Teaching patients to check their pulse rate is a nursing responsibility. Patients should be taught the parameters within which to exercise. They should be told the maximum rate that the heart should beat at any point. If the HR exceeds this level or does not return to the rate of the resting pulse within a few minutes, patients should stop and rest. Patients should also be instructed to stop exercising if angina or dyspnea occurs. Basic physical activity guidelines for patients after ACS are based on the formula for frequency, intensity, time, and type (FITT) and are presented in Table 36-18.

TABLE 36-18

PATIENT & CAREGIVER TEACHING GUIDE
FITT Physical Activity Guidelines After Acute Coronary Syndrome

Warm-Up and Cool-Down
Mild stretching for 3–5 min before the physical activity and 5 min after the activity is important. Activity should not be started or stopped abruptly.
Frequency
The patient should perform physical activity five or more times per week.
Intensity
Activity intensity should be determined by the patient's HR. If a treadmill test has not been performed, the person recovering from MI should not exceed 20 beats/min over the resting HR.
Type of Physical Activity
Physical activity should be regular, rhythmic, and repetitive; large muscles should be used to build up endurance (as in walking, cycling, swimming, and rowing).
Time
Duration of physical activity can be 30–60 min. It is important to begin slowly according to personal tolerance (perhaps only 5–10 min) and build up to 30 min.

FITT, frequency, intensity, time, and type; *HR,* heart rate; *MI,* myocardial infarction.

The basic categories of physical activity are static *(isometric)* and dynamic *(isotonic).* Most daily activities are a mixture of the two. Static activities involve the development of tension during muscular contraction but produce little or no change in muscle length or joint movement. Lifting, carrying, and pushing heavy objects are primarily isometric activities. Because the HR and BP increase rapidly during isometric work, exercise programs involving isometric exercises should be limited.

Isotonic activities involve changes in muscle length and joint movement with rhythmic contractions at relatively low muscular tension. Walking, jogging, swimming, bicycling, and jumping rope are examples of activities that are predominantly isotonic. Isotonic exercise can put a safe, steady load on the heart and lungs and improve the circulation in many organs.

Many patients are referred to an outpatient cardiac rehabilitation program (see Table 36-15). These programs have been found to be beneficial to patients, but not all patients choose or are able to participate in them. Home-based cardiac rehabilitation programs have been developed as an alternative. Maintaining contact with patients appears to be the key to the success of these programs.

Older women (65 years or older) who experience MI frequently have poor adherence to a regular physical activity program. These women often describe a continued post-MI fatigue that is poorly understood. Another factor that has been linked to poor adherence to a physical activity program after MI is depression. Depression is common among patients

with CAD, especially women (European Society of Cardiology, 2014). All patients with CAD should routinely be screened for depression and treatment recommended as appropriate.

The "Evidence-Informed Practice" box "What Is the Most Effective Cardiac Rehabilitation Program?" outlines recent research on cardiac rehabilitation.

Resumption of Sexual Activity.

It is important to include sexual counselling for cardiac patients and their partners. This often-neglected area of discussion may be difficult for both the patient and the health care provider to approach. However, the patient's concern about resumption of sexual activity after hospitalization for ACS often produces more stress than the physiological act itself. Most of these patients change their sexual behaviour not because of physical problems but because they are concerned about sexual inadequacy, death during intercourse, and impotence. A concerned and knowledgeable health care provider could clarify any misconceptions with specific counselling.

Before providing guidelines on resumption of sexual activity, the nurse must know the patient's physiological status, the physiological effects of sexual activity, and the psychological effects of having a heart attack. Sexual activity for most middle-aged men and women with their usual partners is considered a moderate-energy activity equivalent to climbing two flights of stairs (Levine, Steinke, Bakaeen, et al., 2012).

Nurses may feel uncertain about how and when to begin counselling about resumption of sex. It is helpful to consider sex a physical activity and to discuss or explore feelings about it when discussing other physical activities with the patient. The dialogue may be opened with, for example, "Many people who have had a heart attack wonder when they will be able to resume sexual activity. Has this been of concern to you?" The nurse might also state, "Sexual activity is like other forms of activity and should be gradually resumed after MI. If your ability to perform sexually is concerning you, the energy you use is no more than that when walking briskly." Providing the patient with reading material on resumption of sexual activity can also facilitate discussion, introduced as so: "If resuming sexual activity has been of concern to you, this information should be helpful." This type of nonthreatening statement brings up the topic, allows the patient to explore personal feelings, and gives the patient an opportunity to raise questions with you or another health care provider

(European Society of Cardiology, 2014). Common guidelines are presented in Table 36-19.

TABLE 36-19

SEXUAL ACTIVITY AFTER ACUTE CORONARY SYNDROME

- When planning for resumption of sexual activity, the patient's goal should correspond to sexual activity before hospitalization for acute coronary syndrome.
- Physical training seems to improve the physiological response to coitus; therefore, daily physical activity during recovery should be encouraged.
- Consumption of food and alcohol should be reduced before intercourse is anticipated (e.g., waiting 3 to 4 hr after ingesting a large meal before engaging in sexual activity).
- Familiar surroundings and a familiar partner reduce anxiety.
- Masturbation may be a useful sexual outlet and may reassure the patient that sexual activity is still possible.
- Hot or cold showers should be avoided just before and just after intercourse.
- Foreplay is desirable because it allows a gradual increase in heart rate before orgasm.
- Positions during intercourse are a matter of individual choice.
- Orogenital sex places no undue strain on the heart.
- A relaxed atmosphere free of fatigue and stress is optimal.
- Prophylactic use of nitrates is effective in decreasing angina during sexual activity.
- Use of erectile agents (e.g., sildenafil [Viagra]) is contraindicated if the patient is taking nitrates in any form.
- Anal intercourse may cause undue cardiac stress because of the possibility of inducing a vasovagal response.

Evaluation

The expected outcomes for the patient with an ACS are presented in NCP 36-1.

Sudden Cardiac Death

Sudden cardiac death (SCD) is unexpected death resulting from various causes, including cardiac arrest. In many cases, SCD is not actually sudden. Teaching people about the symptoms of impending cardiac arrest and the actions to take can save lives. Rapid cardiopulmonary resuscitation (CPR) and defibrillation with an automated external defibrillator (AED), in combination with early advanced cardiac life support, can enhance the chances for long-term survival after a witnessed arrest.

Etiology and Pathophysiology

In SCD, cardiac function is disrupted abruptly, causing immediate loss of CO and cerebral blood flow. The affected person may or may not have a known history of CAD. SCD is the first sign of illness for 25% of people who die from heart disease (Mitrani & Myerburg, 2016). Death usually

occurs within 1 hour of the onset of acute symptoms (e.g., angina, palpitations).

Acute ventricular dysrhythmias (e.g., ventricular tachycardia, ventricular fibrillation) cause the majority of cases of SCD. Less commonly, SCD occurs because of a primary left ventricular outflow obstruction (e.g., aortic stenosis, hypertrophic cardiomyopathy) or extreme slowing of the heart (bradycardia).

People who experience SCD because of CAD are categorized as (a) those who did not have an acute MI and (b) those who did have an acute MI. The first group accounts for the majority of cases of SCD. In this instance, victims usually have no warning signs or symptoms. Patients who survive are at risk for another episode of SCD because of the continued electrical instability of the myocardium that led to the initial event.

The second, smaller group of patients includes those who have had an MI and have suffered SCD. In these cases, patients usually do have prodrome symptoms, such as chest pain, palpitations, and dyspnea.

It is difficult to predict who is at risk for SCD. Risk factors for SCD include (a) male sex (especially Black men), (b) family history of premature atherosclerosis, (c) tobacco use, (d) diabetes mellitus, (e) hypercholesterolemia, (f) hypertension, and (g) cardiomyopathy.

Nursing and Collaborative Management Sudden Cardiac Death

People who survive an episode of SCD generally require a diagnostic workup to determine whether they have had an MI. Thus serial analyses of cardiac markers and ECGs are done, and treatment is planned accordingly. (See section on collaborative care of ACS.) In addition, because most people with SCD have CAD, cardiac catheterization is indicated to determine the possible location and extent of coronary artery occlusion. PCI or CABG surgery may also be indicated.

Most patients with SCD have a lethal ventricular dysrhythmia that has a high incidence of recurrence. Thus it is useful to know when those people are most likely to have a recurrence and what drug therapy is the most effective treatment. Assessment of dysrhythmias in these patients includes 24-hour Holter monitoring or other type of event recorder, exercise stress testing, signal-averaged ECG, and electrophysiological study (EPS) performed with fluoroscopy. Pacing electrodes are placed in select intracardiac areas, and stimuli are selectively used to attempt to produce dysrhythmias. The patient's response to various antidysrhythmic

medications is determined and monitored in a controlled environment. (EPS is discussed in Chapters 34 and 38.)

The most common approach to preventing a recurrence is the use of an implantable cardioverter–defibrillator (ICD). Drug therapy with amiodarone may be used in conjunction with an ICD to decrease episodes of ventricular dysrhythmias.

When caring for these patients, the nurse should be alert to the patient's psychosocial adaptation to this sudden "brush with death." Many of these patients develop a "time bomb" mentality. They fear the recurrence of cardiopulmonary arrest and may become anxious, angry, and depressed. Their caregivers are likely to experience the same feelings.

Patients and caregivers may need to deal with additional issues, such as possible driving restrictions and change in occupation. The grief response varies among patients and caregivers. The nurse should be attuned to the specific needs of the patient and caregiver and teach them accordingly while providing appropriate emotional support.

Case Study

Myocardial Infarction

Source: Sergey Furtaev/Shutterstock.com.

Patient Profile

Owen Matthews, a 51-year-old successful executive, is rushed to the hospital by ambulance after experiencing crushing substernal chest pain that radiates down his left arm. He also complains of dizziness and nausea.

Subjective Data

- Has a history of chronic stable angina and hypertension
- States that he is "borderline diabetic"
- Overweight but recently lost 10 pounds
- Rarely exercises
- Has three teenage children who are causing "problems"
- Recently experienced loss of best friend and business partner, who died from cancer

Objective Data

Physical Examination

- Diaphoresis, shortness of breath, nausea
- BP, 165/100 mm Hg; pulse rate, 120; respiratory rate, 26/min

Diagnostic Studies

- ECG shows occasional premature ventricular contractions and ST elevation in leads II, III, aV_F, V_5, and V_6.
- Cardiac-specific troponin I level is elevated.
- Cholesterol level is 9.1 mmol/L.
- Hb A1C level is 9.0%.
- Inferolateral wall MI is diagnosed.

Collaborative Care

Emergency Department

- Oxygen, 2 L/min via nasal cannula, titrated to keep O_2 saturation >93%
- Continuous ECG monitoring
- ASA, 324 mg (chewable)
- Eptifibatide (Integrilin), IV
- Weight-based heparin, IV
- Nitroglycerin intravenously, titrated to relieve chest pain; withheld for systolic BP <100 mm Hg

- Morphine, 2 to 4 mg, IV q5min PRN for chest pain unrelieved by nitroglycerin
- Metoprolol (Lopresor), 5 mg IV q5min × 3 doses
- Vital sign measurements and pulse oximetry q10min
- Preparation of patient for transfer to cardiac catheterization laboratory for possible PCI

Discussion Questions

1. Which coronary arteries are probably occluded in Mr. Matthews's coronary circulation?
2. What risk factors contribute to its development? What risk factors were present in Mr. Matthews's life?
3. What is angina? How does angina differ from myocardial infarction?
4. What is the pathophysiological basis for the clinical manifestations that Mr. Matthews exhibited?
5. What is the significance of the results of the laboratory tests and ECG findings?
6. What is the rationale for each treatment measure ordered for Mr. Matthews?
7. ***Priority decision:*** What are the priority nursing interventions for Mr. Matthews immediately after his MI?
8. ***Priority decision:*** Based on the assessment data presented, what are the priority nursing diagnoses? Identify any collaborative problems.
9. ***Evidence-informed practice:*** Two days after an uncomplicated PCI and the placement of two stents, Mr. Matthews wants to know what the most effective strategies are to prevent another MI. Based on his clinical situation, what should the nurse recommend?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. How many people in Canada will experience a myocardial infarction in a given year?
   a. 20 000
   b. 50 000
   c. 70 000
   d. 100 000

2. A nurse is teaching a client about coronary artery disease. Which changes occur in this disorder and should be included in the explanation? *(Select all that apply)*
   a. Diffuse involvement of plaque formation in coronary veins
   b. Abnormal levels of cholesterol, especially low-density lipoproteins
   c. Accumulation of lipid plaques or calcification within the coronary arteries
   d. Development of angina due to a decreased blood supply to the heart muscle
   e. Chronic vasoconstriction of coronary arteries leading to permanent vasospasm

3. Which statement indicates that the client requires additional instruction in reducing cardiac risk factors?
   a. "I would like to add weightlifting to my exercise program."
   b. "I can't keep my blood pressure normal without medication."
   c. "I can change my diet to decrease my intake of saturated fats."
   d. "I will change my lifestyle to reduce activities that increase my stress."

4. A hospitalized client with angina tells the nurse that she is having chest pain. What best describes the nature of anginal pain?
   a. It will be relieved by rest, nitroglycerin, or both.
   b. It is less severe than the pain of a myocardial infarction.
   c. It indicates that irreversible cellular damage is occurring.
   d. It is frequently associated with vomiting and extreme fatigue.

5. What does the clinical spectrum of ACS include?

a. Unstable angina and STEMI

b. Unstable angina and NSTEMI

c. Stable angina and sudden cardiac death

d. Unstable angina, STEMI, and NSTEMI

6. In a client recovering from an MI, in which period is the heart most vulnerable to stress?

a. 3 weeks after the infarction

b. 4 to 6 days after the infarction

c. 10 to 14 days after the infarction

d. When healing is complete, at 6 to 8 weeks

7. A client is admitted to the ED with chest pain of 2 hours' duration, ECG findings consistent with an acute MI, and occasional ventricular dysrhythmias. With what pharmacological therapy would the nurse expect the client to be managed initially?

a. Diuretics

b. Nitroglycerin spray

c. β-Adrenergic blockers

d. Thrombolytic therapy with tissue plasminogen activator

8. Five days after an MI, a client is restless and apprehensive. How can the nurse assist the client?

a. By providing all care and doing everything for the client

b. By structuring the environment and the routine so that the client can rest

c. By allowing the client to participate in planning and carrying out activities

d. By encouraging the family to provide for the client's physical care and give emotional support

9. What is the most common pathological finding in individuals experiencing SCD?

a. Cardiomyopathies

b. Mitral valve disease

c. Atherosclerotic heart disease

d. Left ventricular hypertrophy

1. c; 2. b, c, d; 3. a; 4. a; 5. d; 6. c; 7. b; 8. c; 9. c.

CHAPTER 37

Nursing Management

Heart Failure

Written by, Carolyn Moffa

Adapted by, Annemarie F. Kaan

LEARNING OBJECTIVES

1. Compare the pathophysiology of heart failure with preserved and reduced ejection fraction.
2. Relate the compensatory mechanisms involved in heart failure to the development of acute decompensated heart failure and chronic heart failure.
3. Select the appropriate nursing and collaborative interventions to manage a patient with acute decompensated heart failure.
4. Select the appropriate nursing and collaborative interventions to manage a patient with chronic heart failure.
5. Describe the indications for cardiac transplantation and the nursing management of cardiac transplant recipients.

KEY TERMS

cardiac transplantation, p. 854
heart failure (HF), p. 845
heart failure with preserved ejection fraction (HF-PEF), p. 846

heart failure with reduced ejection fraction (HF-REF), p. 846
paroxysmal nocturnal dyspnea, p. 849
pulmonary edema, p. 848

Heart Failure

Heart failure (HF) is an abnormal clinical syndrome involving impaired cardiac pumping or filling, or both. *Heart failure,* formerly called *congestive heart failure,* is the term preferred today because not all patients with HF have pulmonary congestion or volume overload. HF is associated with numerous types of cardiovascular diseases, particularly longstanding hypertension, coronary artery disease (CAD), and myocardial infarction (MI) (Table 37-1). HF is characterized by ventricular dysfunction, reduced exercise tolerance, diminished quality of life, and shortened life expectancy.

TABLE 37-1

COMMON CAUSES OF HEART FAILURE

Chronic	Acute
Coronary artery disease	Acute myocardial infarction
Hypertension	Dysrhythmias
Rheumatic heart disease	Pulmonary embolus
Congenital heart disease	Thyrotoxicosis
Ventricular septal defect	Hypertensive crisis
Pulmonary disease	Rupture of papillary muscle
Cardiomyopathy	Myocarditis
Anemia	Bacterial endocarditis
Bacterial endocarditis	
Valvular disorders	

Globally, HF has become a major health problem. In contrast to other cardiovascular diseases, HF is projected to increase in incidence. The prevalence of HF increases with age, which is of particular concern to Canada's aging population (Braunwald, 2015).

In Canada, it is estimated that one in five people older than 40 will suffer from HF during their lifetime. The burden of HF will continue to rise with the growing population. It was projected that between 1994 and 2050, readmissions to hospital for HF would triple. Multiple hospitalizations translate to a significant economic burden on communities (O'Meara, Thibodeau-Jarry, Ducharme, et al., 2014).

Despite improvements in therapy since the late 1980s, the mortality rate 1 year after diagnosis remains high, at 23.4% (O'Meara, Thibodeau-Jarry, Ducharme, et al., 2014).

Etiology and Pathophysiology

Coronary artery disease (CAD) and hypertension are the primary risk factors for HF. In Canada, CAD and hypertension are responsible for up to 47.7% and 26% of patients, respectively (Yeung, Van Dyke, Maclagan, et al., 2013).

Diabetes mellitus predisposes an individual to HF regardless of the presence of concomitant CAD or hypertension. The etiology is thought to be complex and related in part to insulin resistance and its effect on ventricular remodelling (Blair, Huffman, & Shah, 2013). Other risk factors for the development of HF include cigarette smoking, obesity, and high serum levels of cholesterol (Liu, Arnold, Howlett, et al., 2015).

HF may be caused by any interference with the normal mechanisms regulating cardiac output (CO). CO depends on (a) preload, (b) afterload, (c) myocardial contractility, and (d) heart rate (HR). (Preload, afterload, and other hemodynamic parameters are discussed in Chapter 34.) Any alteration in these factors can lead to decreased ventricular function and the resultant manifestations of HF.

In general, major causes of HF may be divided into two subgroups: primary causes (see Table 37-1) and precipitating causes (Table 37-2). Precipitating causes often increase the workload of the ventricles, which results in a decompensated condition that leads to decreased myocardial function.

TABLE 37-2

PRECIPITATING CAUSES OF HEART FAILURE

Cause	Mechanism
Anemia	↓ Oxygen-carrying capacity of the blood, stimulating ↑ in CO to meet tissue demands
Infection	↑ Oxygen demand of tissues, stimulating ↑ CO
Thyrotoxicosis	Changes in the tissue metabolic rate; ↑ HR and workload of the heart
Hypothyroidism	Indirectly predisposes to ↑ atherosclerosis; severe hypothyroidism decreases myocardial contractility
Dysrhythmias	May ↓ CO and ↑ workload and oxygen requirements of myocardial tissue
Bacterial endocarditis	Infection: ↑ metabolic demands and oxygen requirements Valvular dysfunction: causes stenosis and regurgitation
Myocarditis	↑ HR, ↓ CO, acute right and left ventricular failure
Pulmonary embolism	↑ Pulmonary pressure and exerts pressure on the RV, leading to right ventricular hypertrophy and failure
Pulmonary disease	↑ Pulmonary pressure and exerts a pressure load on the RV, leading to right ventricular hypertrophy and failure
Paget's disease	↑ Workload of the heart by ↑ vascular bed in the skeletal muscle
Nutritional deficiencies	May ↓ cardiac function by ↓ myocardial muscle mass and myocardial contractility
Hypervolemia	↑ Preload, causing volume load on the RV

CO, cardiac output; HR, heart rate; LV, left ventricle; RV, right ventricle.

Pathology of Ventricular Failure.

HF is described as being accompanied by either reduced ejection fraction (systolic) or preserved ejection fraction (diastolic) (McKelvie, Moe, Ezekowitz, et al., 2013).

Heart Failure With Reduced Ejection Fraction.

Heart failure with reduced ejection fraction (HF-REF), the most common form of HF, results from an inability of the heart to pump blood effectively. It is caused by impaired contractile function (e.g., myocardial ischemia), increased afterload (e.g., hypertension), cardiomyopathy, and mechanical abnormalities (e.g., valvular heart disease). The left ventricle (LV) loses its ability to generate enough pressure to eject blood forward through the aorta. The hallmark of HF-REF is a reduction in the left ventricular ejection fraction (EF; the percentage of total amount of end-diastolic blood volume that is ejected during each systole). Normal EF is higher than 55% of the ventricular volume. Patients with HF-REF requiring specialist intervention generally have an EF of 40% or lower (Arnold, Liu, Demers, et al., 2006).

Heart Failure With Preserved Ejection Fraction.

Heart failure with preserved ejection fraction (HF-PEF)—often referred to as diastolic HF—is the inability of the ventricles to relax and fill during diastole. Decreased filling of the ventricles results in decreased stroke volume and cardiac output (CO). HF-PEF is characterized by high filling pressures, which are increased because of poorly compliant ventricles. This results in venous engorgement in both the pulmonary and systemic vascular systems. HF-PEF is often the result of left ventricular hypertrophy from hypertension (most common), myocardial ischemia, valve disease (e.g., aortic, mitral), or cardiomyopathy. However, many affected patients do not have an identifiable heart disease. The diagnosis of HF-PEF is based on the presence of HF symptoms with a normal EF (Huether & McCance, 2012).

Mixed Heart Failure.

HF of mixed origin occurs in disease states such as dilated cardiomyopathy. Dilated cardiomyopathy is a condition in which poor systolic function (weakened muscle function) is further compromised by dilated left ventricular walls that are unable to relax and hence fill effectively. Affected patients often have an extremely poor EF (<35%), high

pulmonary pressures, and biventricular failure (both ventricles may be dilated and have poor filling and emptying capacity).

Patients with HF of any type have low systemic arterial blood pressure (BP), low CO, and poor renal perfusion. Poor exercise tolerance and ventricular dysrhythmias are also common. Whether a patient arrives at this point acutely as a result of myocardial infarction (MI) or chronically from worsening cardiomyopathy or hypertension, the body's response to this low CO is to mobilize its compensatory mechanisms to maintain CO and BP.

Determinants of Health

Heart Disease Rehabilitation

- Barriers to cardiac rehabilitation utilization include lack of time, work, family responsibilities, and distance to facility.*

Gender

- Women are 36% less likely to enroll in cardiac rehabilitation programs.†
- Use of cardiac rehabilitation is associated with a more significant reduction in mortality among women than among men.‡

Culture

- Use of cardiac rehabilitation is lower among members of minority groups because of variations in cultural beliefs, diet, and exercise.*

Education and Literacy

- The educated and higher income individuals are more likely to use cardiac rehabilitation because of availability of resources and motivation.*

Personal Health Practice and Coping Skills

- After diagnosis of a cardiovascular related illness, fewer than 5% of Canadians who smoked quit.†

Health Services

- Use of cardiac rehabilitation is associated with a 50% reduction in mortality.†
- Only 40% of participants eligible to receive cardiac rehabilitation enroll in such programs.†

Compensatory Mechanisms.

HF can have an abrupt onset, as with acute MI, or it can be a subtle process resulting from slow, progressive changes. The overloaded heart uses compensatory mechanisms to try to maintain adequate CO. The main compensatory mechanisms include (a) sympathetic nervous system (SNS) activation, (b) neuro-hormonal responses, (c) ventricular dilation, and (d) ventricular hypertrophy.

Sympathetic Nervous System Activation.

SNS activation is often the first mechanism triggered in low-CO states. However, it is the least effective compensatory mechanism. In response to an inadequate stroke volume and CO, SNS activation increases, resulting in the increased release of catecholamines (epinephrine and norepinephrine). This results in increased HR, increased myocardial contractility, and peripheral vasoconstriction. Initially, this increase in HR and contractility improves CO. Over time, however, these factors are harmful, inasmuch as they increase the already failing heart's workload and need for oxygen. The vasoconstriction causes an immediate increase in preload, which may initially increase CO; but an increase in venous return

to the heart, which is already volume overloaded, actually worsens ventricular performance.

Neuro-hormonal Responses.

As the CO falls, blood flow to the kidneys decreases. This is sensed by the juxtaglomerular apparatus in the kidneys as decreased volume. In response, the kidneys release renin, which converts angiotensinogen to angiotensin I (see Chapter 47 and Figure 47-6). Angiotensin I is subsequently converted to angiotensin II by angiotensin-converting enzyme (ACE) made in the lungs. Angiotensin II causes (a) the adrenal cortex to release aldosterone, which results in sodium and water retention, and (b) increased peripheral vasoconstriction, which increases BP. This response is known as the *renin-angiotensin-aldosterone system* (RAAS).

Low CO causes a decrease in cerebral perfusion pressure. In response, the posterior pituitary gland secretes antidiuretic hormone (ADH; also called *vasopressin*). ADH increases water reabsorption in the kidneys, which causes water retention. As a result, blood volume is increased when a volume overload state already exists.

Other factors also contribute to the development of HF. The production of endothelin, a potent vasoconstrictor produced by the vascular endothelial cells, is stimulated by ADH, catecholamines, and angiotensin II. Endothelin results in further arterial vasoconstriction and an increase in cardiac contractility and hypertrophy.

Locally, proinflammatory cytokines are released by heart cells in response to various forms of cardiac injury (e.g., MI). Two cytokines, tumour necrosis factor (TNF) and interleukin-1 (IL-1), further depress heart function by causing hypertrophy, contractile dysfunction, and cell death. Over time, a systemic inflammatory response also occurs. This accounts for the cardiac and skeletal muscle myopathy and fatigue that accompany advanced HF.

Activation of the SNS and the neuro-hormonal response lead to elevated levels of norepinephrine, angiotensin II, aldosterone, ADH, endothelin, and proinflammatory cytokines. Together, these factors result in an increase in cardiac workload, myocardial dysfunction, and ventricular remodelling. Remodelling involves hypertrophy of the ventricular myocytes, which causes contractile cells to become enlarged and abnormally shaped. This altered geometric shape of the ventricles eventually leads to increased ventricular mass, increased wall tension, increased oxygen consumption, and impaired contractility. Although the ventricles become larger, they become less effective pumps. Ventricular

remodelling is a risk factor for life-threatening dysrhythmias and sudden cardiac death.

Ventricular Dilation.

Dilation is an enlargement of the chambers of the heart. It occurs when pressure in the heart chambers (usually the left ventricle) becomes chronically elevated. The muscle fibres of the heart stretch in response to the volume of blood in the heart at the end of diastole. The degree of stretch is directly related to the force of the contraction (systole), according to Starling's law. Initially, dilation is an adaptive mechanism to cope with increasing blood volume, and this increased contraction leads to increased CO and maintenance of arterial BP and perfusion. Eventually, this mechanism becomes inadequate because the elastic elements of the muscle fibres are overstretched and can no longer contract effectively, and CO diminishes (Figure 37-1, *A*).

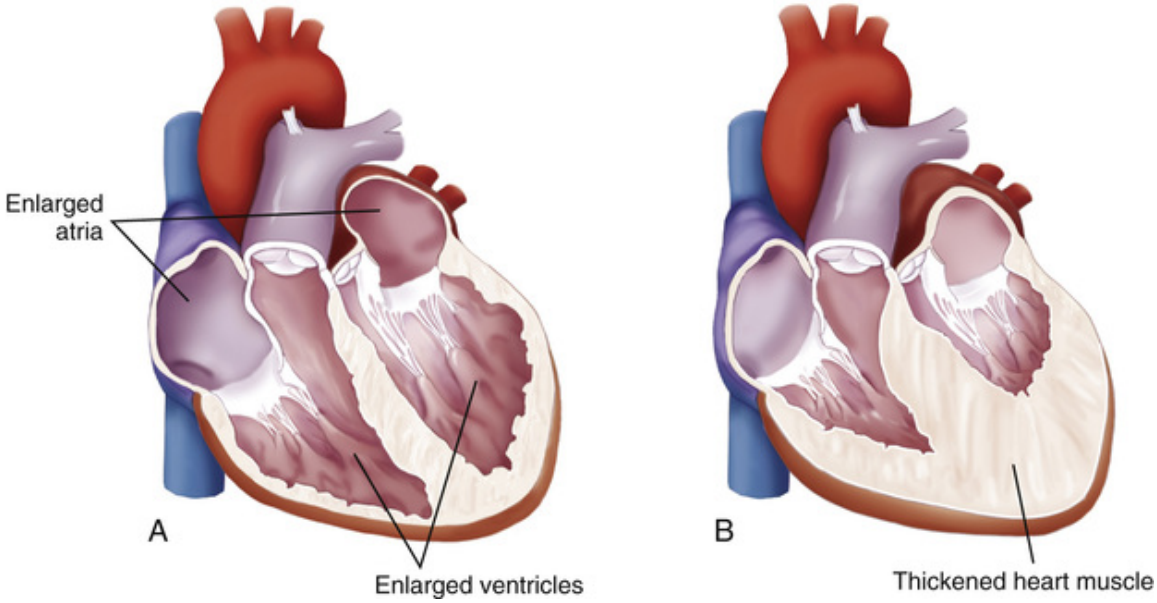

FIGURE 37-1 **A,** Dilated heart chambers. **B,** Hypertrophied heart chambers.

Ventricular Hypertrophy.

Hypertrophy is an increase in the muscle mass and cardiac wall thickness in response to overwork and strain (see Figure 37-1, *B*). It develops slowly because it takes time for muscle tissue to thicken. Initially, the increased contractile power of the muscle fibres leads to an increase in CO and

maintenance of tissue perfusion. Over time, hypertrophic heart muscle has poor contractility and requires more oxygen to perform work, coronary artery circulation becomes poor (tissue becomes ischemic more easily), and the heart is prone to dysrhythmias.

Counter-Regulatory Mechanisms.

The body's attempts to maintain balance are demonstrated by several counter-regulatory processes. Natriuretic peptides (atrial natriuretic peptide and brain, or B-type, natriuretic peptide [BNP]) are hormones produced by the heart muscle. Atrial natriuretic peptide is released from the atria and BNP is released from the ventricles in response to increased blood volume in the heart (Nawarskas, Bowman, & Anderson, 2015).

The natriuretic peptides have renal, cardiovascular, and hormonal effects. Renal effects include (a) increased glomerular filtration rate and diuresis and (b) excretion of sodium (natriuresis). Cardiovascular effects include vasodilation and decreased BP. Hormonal effects include (a) inhibition of aldosterone and renin secretion and (b) interference with ADH release. The combined effects of atrial natriuretic peptide and BNP help counter the adverse effects of the SNS and RAAS in patients with HF (Huether & McCance, 2012).

Cardiac compensation occurs when compensatory mechanisms succeed in maintaining a CO that is adequate for essential tissue perfusion. Cardiac decompensation occurs when these mechanisms can no longer maintain adequate CO and tissue perfusion becomes insufficient.

Types of Heart Failure

HF is usually evidenced by biventricular failure, although one ventricle may become dysfunctional before the other. Normally, the pumping actions of the left and right sides of the heart complement each other, producing a continuous flow of blood. However, as a result of pathological conditions, one side may fail, and the other side continues to function normally for a time. Because of the prolonged strain, both sides of the heart eventually fail, resulting in biventricular failure.

Left-Sided Heart Failure.

The most common form of initial heart failure is left-sided failure (Figure 37-2). Left-sided failure results from left ventricular dysfunction, which causes blood to back up through the left atrium and into the pulmonary

veins. The increased pulmonary pressure causes fluid extravasation from the pulmonary capillary bed into the interstitium and then the alveoli, which is manifested as pulmonary congestion and edema.

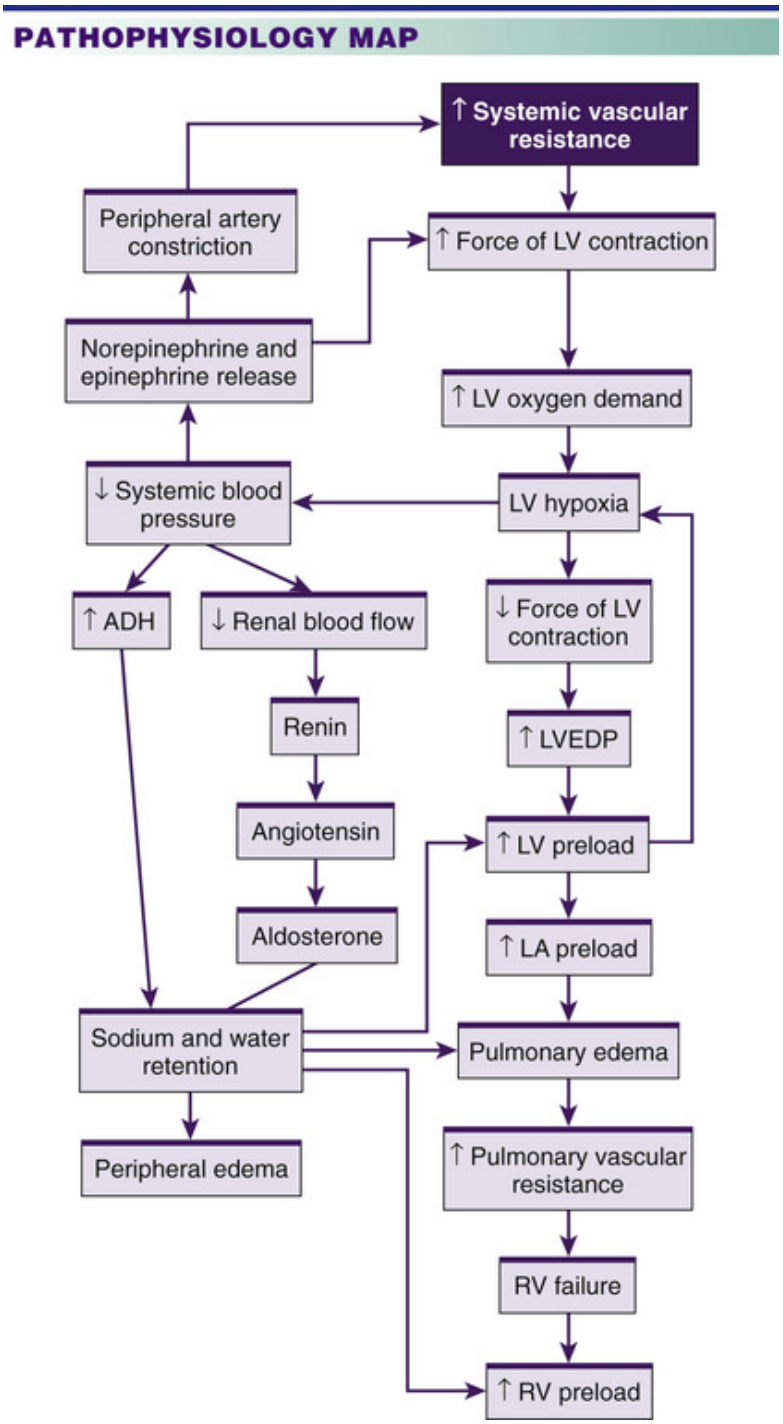

FIGURE 37-2 Illustration of how left-sided heart failure results from elevated systemic vascular resistance. Left-sided heart failure leads to right-sided heart failure. Systemic vascular resistance and preload are exacerbated by renal and adrenal mechanisms. *ADH,* antidiuretic hormone; *LA,* left atrial; *LV,* left ventricular; *LVEDP,* left ventricular end-diastolic pressure; *RV,* right ventricular. Source: Adapted from Huether, S. E., & McCance, K. L. (2004). *Understanding pathophysiology* (3rd ed.). St. Louis: Mosby.

Right-Sided Heart Failure.

Right-sided heart failure causes backward blood flow to the right atrium and venous circulation. Venous congestion in the systemic circulation results in peripheral edema, hepatomegaly, splenomegaly, vascular congestion of the gastro-intestinal tract, and jugular venous distension. The primary cause of right-sided failure is left-sided failure. In this situation, left-sided failure results in pulmonary congestion and increased pressure in the blood vessels of the lungs (pulmonary hypertension). Eventually, chronic pulmonary hypertension results in right-sided hypertrophy and failure. Cor pulmonale (right ventricular dilation and hypertrophy caused by pulmonary disease) can also cause right-sided failure. (Cor pulmonale is discussed in Chapter 30.) Right ventricular infarction may also cause right ventricular failure.

Clinical Manifestations of Heart Failure

Regardless of etiology, acute decompensated heart failure (ADHF) typically manifests as **pulmonary edema,** an abnormal, life-threatening accumulation of fluid in the alveoli and interstitial spaces of the lungs (Figure 37-3). The most common cause of pulmonary edema is acute left ventricular failure secondary to acute myocardial ischemia. (Other etiological factors for pulmonary edema are listed in Chapter 30, Table 30-24.)

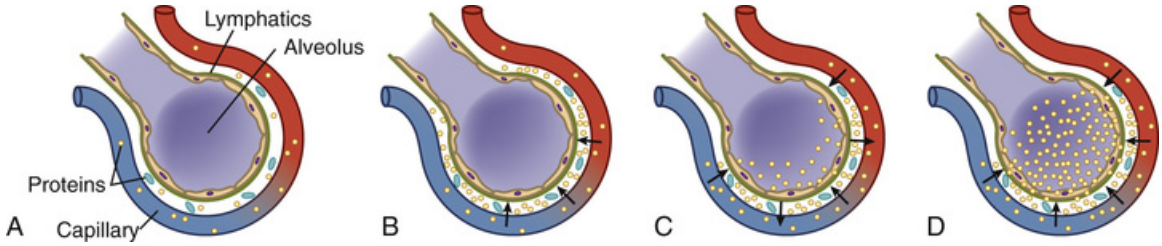

FIGURE 37-3 As pulmonary edema progresses, it inhibits oxygen and carbon dioxide exchange at the alveolar capillary interface. **A,** Normal relationship. **B,** Increased pulmonary–capillary hydrostatic pressure causes fluid to move from the vascular space into the pulmonary interstitial space. **C,** Lymphatic flow increases in an attempt to pull fluid back into the vascular or lymphatic space. **D,** Failure of lymphatic flow and worsening of left-sided heart failure result in further movement of fluid into the interstitial space and into the alveoli. Source: Redrawn from Urden, L. D., Stacy, K. M., & Lough, M. E. (2010). *Critical care nursing: Diagnosis and management* (6th ed., p. 462, Figure 19-17). St. Louis: Mosby.

In most cases of ADHF, the pulmonary venous pressure increases as a result of decreased efficiency of the left ventricle. This results in engorgement of the pulmonary vascular system. As a result, the lungs become less compliant, and there is increased resistance in the small airways. In addition, the lymphatic system increases its flow to help maintain a constant volume of the pulmonary extravascular fluid. This early stage is clinically associated with a mild increase in the respiratory rate and a decrease in partial pressure of arterial oxygen (PaO_2).

If pulmonary venous pressure continues to increase, the increase in intravascular pressure causes more fluid to move into the interstitial space than the lymphatic vessels can drain. Interstitial edema occurs at this point. Tachypnea develops, and the patient becomes symptomatic (short of breath out of proportion to activity level). If the pulmonary venous pressure increases further, the tight alveoli lining cells are disrupted, and a fluid containing red blood cells moves into the alveoli (alveolar edema). As the disruption becomes worse from further increases in the pulmonary venous pressure, the alveoli and the airways are flooded with fluid (see Figure 37-3). This is accompanied by a worsening of the blood gas values (i.e., lower PaO_2 and possible increase in partial pressure of arterial carbon dioxide [$PaCO_2$] and progressive respiratory acidemia).

Clinical manifestations of pulmonary edema are distinct. Most affected patients are anxious, pale, and possibly cyanotic. The skin is clammy and cold from vasoconstriction caused by stimulation of the SNS. The patient

has severe dyspnea, as evidenced by the use of accessory muscles of respiration, a respiratory rate greater than 30 breaths per minute, and orthopnea. There may be wheezing and coughing with the production of frothy, blood-tinged sputum. Auscultation of the lungs may reveal crackles, wheezes, and rhonchi throughout the lungs. The patient's HR is rapid, and BP may be elevated or decreased, depending on the severity of the HF.

ADHF can be categorized into one of four groups on the basis of hemodynamic and clinical status: dry-warm, dry-cold, wet-warm, and wet-cold (Figure 37-4). The most common presentation is the wet-warm status. Affected patients have adequate perfusion (warm) but volume overload (e.g., congestion, dyspnea, edema; McKelvie, Moe, Ezekowitz, et al., 2013).

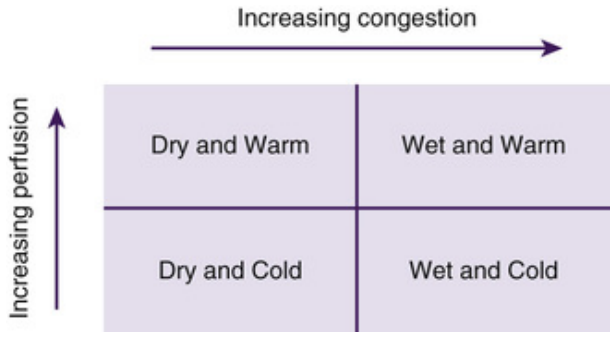

FIGURE 37-4 Categories of acute decompensated heart failure (ADHF). Source: Reprinted from *Canadian Journal of Cardiology,* 29(2), McKelvie, R. S., Moe, G. W., Ezekowitz, J. A., et al., The 2012 Canadian Cardiovascular Society heart failure management guidelines update: Focus on acute and chronic heart failure, pp. 168–181, Copyright 2013, with permission from Elsevier.

Clinical Manifestations of Chronic Heart Failure

Chronic HF is characterized as a progressive worsening of ventricular function and chronic neuro-hormonal activation that results in ventricular remodelling. This process involves changes in the size, shape, and mechanical performance of the ventricle. The clinical manifestations of chronic HF depend on the patient's age, the underlying type and extent of heart disease, and which ventricle is failing to pump effectively. Table 37-3 lists the manifestations of right-sided HF and left-sided HF. Patients with chronic HF usually have manifestations of biventricular failure.

TABLE 37-3
CLINICAL MANIFESTATIONS OF HEART FAILURE

Right-Sided Heart Failure	Left-Sided Heart Failure
Signs	
RV heaves Murmurs Peripheral edema Weight gain ↑ HR Edema of dependent body parts (sacrum, anterior tibias, pedal edema) Ascites Anasarca (massive generalized body edema) Jugular venous distension Hepatomegaly (liver enlargement) Right-sided pleural effusion	LV heaves Cheyne-Stokes respirations Pulsus alternans (alternating pulses: strong, weak) ↑ HR PMI displaced inferiorly and posteriorly (LV hypertrophy) ↓ PaO_2, slight ↑ $PaCO_2$ (poor O_2 exchange) Crackles (pulmonary edema) S_3 and S_4 (see Easy Auscultation website listed in the Resources at the end of this chapter)
Symptoms	
Fatigue Dependent edema Right upper quadrant pain Anorexia and GI bloating Nausea	Fatigue Dyspnea (shallow respirations ≤32–40/min) Orthopnea (shortness of breath in recumbent position) Dry, hacking cough Pulmonary edema Nocturia Paroxysmal nocturnal dyspnea

GI, gastro-intestinal; *HR,* heart rate; *LV,* left ventricular; *PaO_2,* arterial partial pressure of oxygen; *$PaCO_2$,* arterial partial pressure of carbon dioxide; *PMI,* point of maximal impulse; *RV,* right ventricle/ventricular; *S_3* and *S_4,* third and fourth heart sounds.

Fatigue.

Fatigue is one of the earliest symptoms of chronic HF. The patient notices fatigue after activities that normally are not tiring. The fatigue is caused by decreased CO, impaired perfusion to vital organs, decreased oxygenation of the tissues, and anemia. Anemia can result from poor nutrition, renal disease, or drug therapy (e.g., ACE inhibitors).

Dyspnea.

Dyspnea (shortness of breath) is a common manifestation of chronic HF. It is caused by increased pulmonary pressures secondary to interstitial and alveolar edema. Dyspnea can occur with mild exertion or at rest. Orthopnea is shortness of breath that occurs when the patient is in a recumbent position.

Paroxysmal Nocturnal Dyspnea.

Paroxysmal nocturnal dyspnea occurs when the patient is asleep. It is caused by the reabsorption of fluid from dependent body areas when the patient is flat. The patient awakens in a panic, has feelings of suffocation, and has a strong desire to sit or stand up.

A cough is often associated with HF and may be the first clinical symptom. It begins as a dry, nonproductive cough and may be misdiagnosed as asthma or other lung disease. The cough is not relieved by position change or over-the-counter cough medicine.

Tachycardia.

Tachycardia is an early clinical sign of HF. One of the body's first mechanisms to compensate for a failing ventricle is to increase the HR. Because of diminished CO, SNS stimulation increases, which in turn increases HR. However, many patients with chronic HF take β blocker medications and may not show an increase in response to SNS stimulation.

Edema.

Edema is a common sign of HF. It may occur in dependent body areas (peripheral edema), the liver (hepatomegaly), the abdominal cavity (ascites), and the lungs (pulmonary edema and pleural effusion). If the patient is in bed, sacral and scrotal edema may develop. Pressing on the edematous skin may leave a transient indentation (pitting edema). The development of dependent edema or a sudden weight gain of more than 2 kg (4 lb) in 2 days is often indicative of exacerbated HF.

Nocturia.

A patient with chronic HF who has decreased CO also has impaired renal perfusion and decreased urine output during the day. However, when the patient lies down at night, fluid moves from the interstitial spaces back into the circulatory system. In addition, cardiac workload is decreased at night during rest. These combined effects result in increased renal blood flow and diuresis. The patient may complain of having to void frequently throughout the night.

Skin Changes.

Because tissue capillary oxygen extraction is increased in a patient with chronic HF, the skin may appear dusky. Often the lower extremities are

shiny and swollen, and hair growth on them is diminished or absent. Chronic swelling may result in pigment changes. This causes the skin to appear brown or brawny in areas covering the ankles and lower legs (hemosiderin staining).

Behavioural Changes.

In chronic HF, cerebral circulation may be reduced as a result of decreased CO. The patient or caregiver may report unusual behaviour, including restlessness, confusion, and decreased attention span or memory. This may also be secondary to poor gas exchange and worsening HF. It often occurs in the late stages of HF. Coexisting psychological disorders, especially depression and anxiety, double the risk of mortality and are associated with higher readmission rates and health care costs in patients with HF. Approximately one in five patients with HF have clinical depression (Newhouse & Jiang, 2014). It is ideal to assess patients with HF for depression and anxiety with a validated scale and, if needed, initiate appropriate consults.

Chest Pain.

HF can precipitate chest pain (angina) because of decreased coronary artery perfusion that results from decreased CO and increased myocardial work. Chest pain may accompany either ADHF or chronic HF.

Weight Changes.

Many factors contribute to weight changes. First, a progressive weight gain may occur because of fluid retention. Renal failure may also contribute to fluid retention. Abdominal fullness from ascites and hepatomegaly frequently causes anorexia and nausea. As HF advances, the patient may have cardiac cachexia, with muscle wasting and fat loss. This can be masked by the patient's edematous condition and may not be detected until after the edema subsides.

Complications of Heart Failure

Pleural Effusion.

Pleural effusion results from increasing pressure in the pleural capillaries. Transudative pleural effusion, commonly associated with HF, occurs as a result of the increased pressure in blood vessels or low albumin levels in

the blood, which cause fluid to leak into the pleural space. (Pleural effusion is discussed in Chapter 30.)

Dysrhythmias.

Chronic HF causes enlargement of the chambers of the heart. This enlargement (stretching of the atrial and ventricular walls) can cause changes in the normal electrical pathways. When numerous sites in the atria fire spontaneously and rapidly (atrial fibrillation), the organized atrial depolarization (contraction, or "atrial kick") no longer occurs. Atrial fibrillation also promotes thrombus formation within the atria. Thrombi may break loose and form emboli. This increases the risk for stroke in patients with atrial fibrillation. They require treatment with cardioversion, antidysrhythmics, anticoagulants, or a combination of these (see Chapter 38).

Patients with HF are also at risk for ventricular dysrhythmias (e.g., ventricular tachycardia, ventricular fibrillation). Ventricular tachycardia and fibrillation can lead to sudden cardiac death. (Sudden cardiac death is discussed in Chapter 36, and dysrhythmias are discussed in Chapter 38.)

Left Ventricular Thrombus.

With ADHF or chronic HF, the enlargement of the LV and the decrease in CO combine to increase the chance of thrombus formation in the LV. Once a thrombus has formed, its volume may decrease the area of the LV, reducing left ventricular contractility, and cause a decrease in CO and worsening of the patient's perfusion. The development of emboli from the thrombus also increases the patient's risk for stroke.

Hepatomegaly.

HF can lead to severe hepatomegaly, especially with right ventricular failure. Because the venous system is backed up, the liver lobules become congested with venous blood. The hepatic congestion leads to impaired liver function. Eventually, liver cells die, fibrosis occurs, and cirrhosis can develop (see Chapter 46).

Renal Failure.

The decreased CO that accompanies acute and chronic HF results in decreased perfusion to the kidneys and can lead to renal insufficiency or

failure (see Chapter 49).

Classification of Heart Failure

The New York Heart Association (NYHA) has developed a system for classifying symptoms experienced by patients with HF. The classification is widely used across Canada and the United States (Table 37-4).

TABLE 37-4

NEW YORK HEART ASSOCIATION FUNCTIONAL CLASSIFICATION OF PEOPLE WITH CARDIAC DISEASE

Class I	No limitation of physical activity. Ordinary physical activity does not cause fatigue, dyspnea, palpitations, or anginal pain.
Class II	Slight limitation of physical activity. No symptoms at rest. Ordinary physical activity results in fatigue, dyspnea, palpitations, or anginal pain.
Class III	Marked limitation of physical activity. Usually comfortable at rest. Ordinary physical activity causes fatigue, dyspnea, palpitations, or anginal pain.
Class IV	Inability to carry on any physical activity without discomfort. Symptoms of cardiac insufficiency or of angina may be present even at rest. If any physical activity is undertaken, discomfort is increased.

Diagnostic Studies

Diagnosing HF is often difficult because neither the signs nor symptoms are highly specific, and both may mimic many other medical conditions, such as anemia or lung disease. The primary goal in diagnosis is to determine the underlying etiology of HF. Measures to assess the cause and degree of HF are included in Figure 37-5 (McKelvie, Moe, Ezekowitz, et al., 2013). Echocardiography and measurement of EF can be used to differentiate between HF-REF and HF-PEF, an important distinction to make in the early treatment of HF.

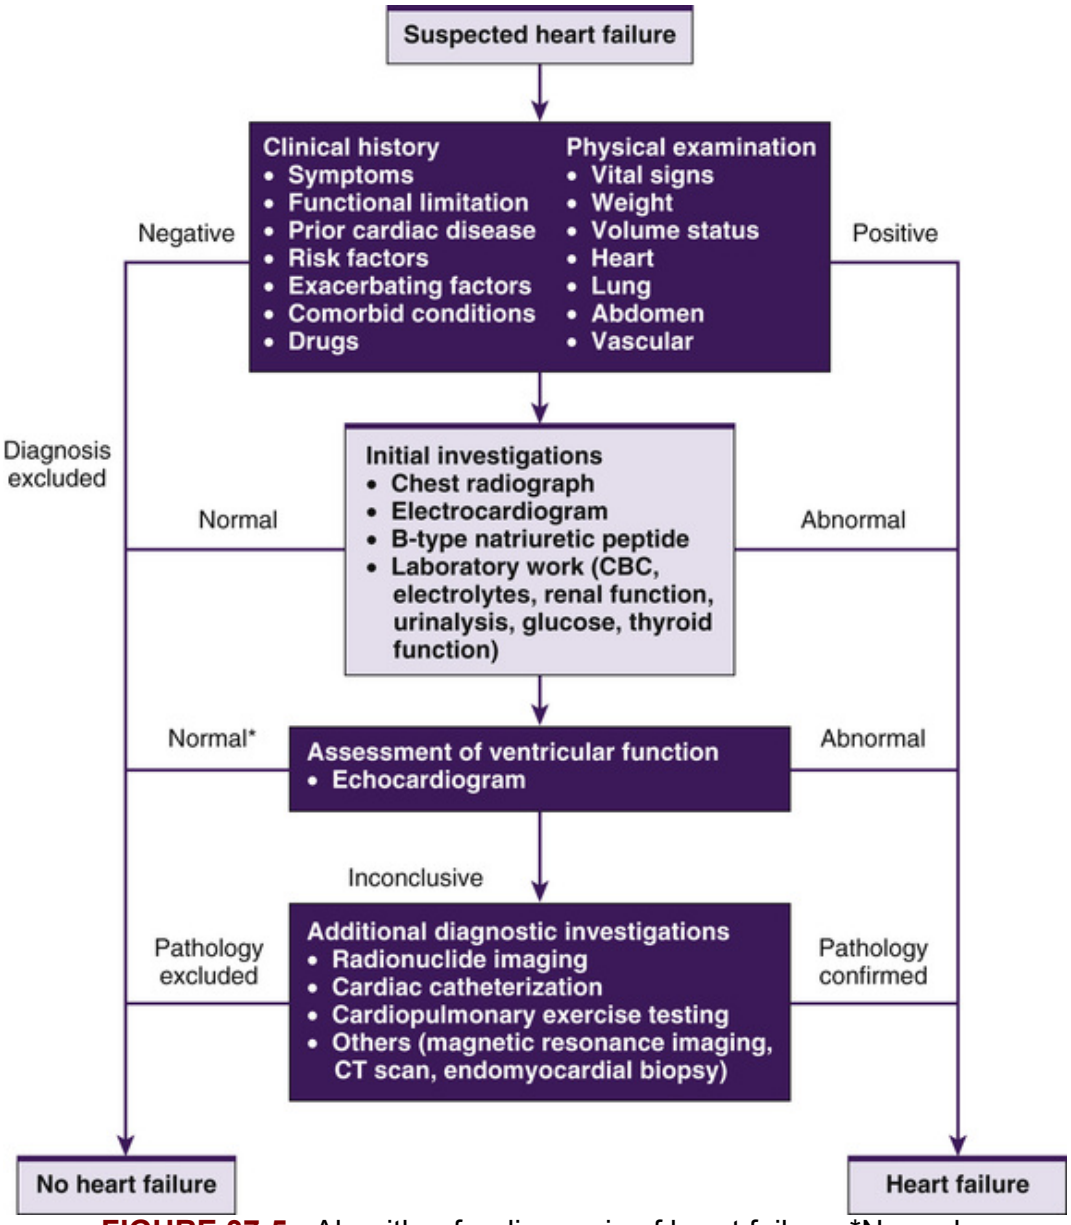

FIGURE 37-5 Algorithm for diagnosis of heart failure. *Normal ejection fraction does not rule out heart failure with preserved ejection fraction. *CBC,* complete blood count; *CT,* computed tomography. Source: Reprinted from *Canadian Journal of Cardiology,* 29(2), McKelvie, R. S., Moe, G. W., Ezekowitz, J. A., et al., The 2012 Canadian Cardiovascular Society heart failure management guidelines update: Focus on acute and chronic heart failure, pp. 168–181, Copyright 2013, with permission from Elsevier.

Measurement of either BNP or N-terminal–pro-BNP (NT–pro-BNP) levels is recommended to assist in the diagnosis of HF; in general, levels are positively correlated with the degree of left ventricular dysfunction

and can help to differentiate dyspnea caused by HF from other causes of dyspnea (Moe, Ezekowitz, O'Meara, et al., 2015; Table 37-5).

TABLE 37-5

NATRIURETIC PEPTIDES CUT POINTS FOR THE DIAGNOSIS OF HEART FAILURE*

Peptide	Age in Years	HF Unlikely	HF Possible	HF Probable
BNP	All	<100 pg/mL	100–500 pg/mL	>500 pg/mL
NT–pro-BNP	<50	<300 pg/mL	300–450 pg/mL	>450 pg/mL
	50–75	<300 pg/mL	450–900 pg/mL	>900 pg/mL
	>75	<300 pg/mL	900–1800 pg/mL	>1800 pg/mL

*Levels can be increased in the presence of renal dysfunction or sepsis and be decreased in obese patients.

Nursing and Collaborative Management Acute Decompensated Heart Failure

The goal of therapy is to improve left ventricular function by decreasing intravascular volume, decreasing venous return (preload), decreasing afterload, improving gas exchange and oxygenation, and increasing CO (McKelvie, Moe, Ezekowitz, et al., 2013).

Decreasing Intravascular Volume

Decreasing intravascular volume with the use of diuretics reduces venous return. A loop diuretic (e.g., furosemide [Lasix]) may be used to decrease volume because it may be administered by intravenous push, and its action within the kidney occurs rapidly. By decreasing venous return to the LV and thereby reducing preload, the overfilled LV may contract more efficiently and thus contribute to improving CO. This improves left ventricular function, decreases pulmonary vascular pressures, and improves gas exchange.

Ultrafiltration may be an option for a patient with volume overload. Ultrafiltration has generally been achieved through hemodialysis or with ultrafiltration by way of central venous access. (Ultrafiltration is discussed in Chapter 49.)

Decreasing Venous Return

Decreasing venous return (preload) reduces the amount of volume returned to the LV during diastole. This can be accomplished by placing the patient in high Fowler's position with the feet horizontal in the bed or dangling at the bedside. This position helps decrease venous return because of the pooling of blood in the extremities. This position also increases the thoracic capacity by decreasing intra-abdominal pressure on the lungs, allowing for improved ventilation. Intravenous nitroglycerine is a vasodilator used in the treatment of ADHF. It reduces circulating volume by decreasing preload and also increases coronary artery circulation by dilating the coronary arteries. In addition to reducing preload, it slightly reduces afterload (in high doses) and increases myocardial oxygen supply.

Decreasing Afterload

Afterload is the resistance against which the LV must pump; that is, it is the amount of work it takes for the LV to eject blood into the systemic circulation. Systemic vascular resistance (SVR) is a determinant of afterload, as is left ventricular filling. If afterload is reduced, the CO improves, and pulmonary congestion thereby decreases. Great care should be taken to ensure the patient's BP is adequate to provide cerebral and renal perfusion. Careful monitoring of vital signs is crucial.

Improving Gas Exchange and Oxygenation

Gas exchange may be improved by several measures. Intravenous morphine reduces preload and afterload and may decrease myocardial oxygen demands, which can be raised as a result of anxiety and subsequent increased musculo-skeletal and respiratory activity. Administration of oxygen could be considered if the O_2 saturation falls below 90% (McKelvie, Moe, Ezekowitz, et al., 2013). Care must be taken to avoid oxygen if it is not required because it can reduce CO and increase SVR. (Oxygen therapy is discussed in Chapter 31.) In severe pulmonary edema, the patient may need noninvasive ventilatory support (e.g., bilevel positive airway pressure) or intubation and mechanical ventilation. (Ventilatory support is discussed in Chapter 68.)

Improving Cardiac Function

In a patient who is or becomes hemodynamically unstable—that is, becomes progressively hypotensive, has an HR that is abnormally fast or slow, develops dysrhythmias, or becomes hypoxic with cool and clammy skin—nursing care is more urgent, and treatment protocols may call for aggressive, complex therapies. The use of diuretics, morphine sulphate, and vasodilators may not be sufficient to control symptoms. The addition of positive inotropic therapy may be warranted, as well as the initiation of hemodynamic monitoring to evaluate the effectiveness of interventions. Once a pulmonary artery catheter is in position, CO, pulmonary artery pressure, and pulmonary artery occlusive pressure should be measured, and therapy should be instituted and titrated to maximize CO. A pulmonary artery occlusive pressure of 14 to 18 mm Hg generally achieves the goal of increasing CO. (Hemodynamic monitoring is discussed in Chapter 68.)

Inotropic drugs (e.g., dobutamine, milrinone) that increase myocardial contractility without increasing oxygen consumption may be effective. Dobutamine and milrinone also increase peripheral vasodilation. There is

no evidence that inotropic drugs improve mortality rates. Milrinone has been linked to more frequent atrial arrhythmias, increased hypotension, and worsening HF. Therefore, use of inotropic drugs should be reserved for hemodynamically unstable patients only (McKelvie, Moe, Ezekowitz, et al., 2013).

Reducing Anxiety

Anxiety is reduced by the sedative action of morphine administered intravenously. When morphine is used, the patient must be watched closely for respiratory depression. In addition, a calm approach in providing care helps reduce anxiety.

Once the patient is more stable, the cause of pulmonary edema should be determined. Diagnosis of HF-REF or HF-PEF then guides further management protocols. Aggressive drug therapy may continue with intravenous forms of diuretics, inotropic drugs, vasodilators, and oral ACE inhibitors. Nursing care focuses on continual physical assessment, hemodynamic monitoring, and monitoring the patient's response to treatment.

Collaborative Care: Chronic Heart Failure

The main goal in the management of HF is to treat the underlying cause and contributing factors, maximize CO, and alleviate symptoms. The management of dysrhythmias is discussed in Chapter 38, hypertension in Chapter 35, valvular disorders in Chapter 39, and coronary artery disease in Chapter 36.

Referral to Multidisciplinary Clinics or Specialist Care for Heart Failure

It is recommended that patients with newly diagnosed HF and patients at higher risk for the development of heart failure should be referred to a multidisciplinary heart failure clinic. These clinics, in Canada often referred to as *heart function clinics,* consist of a multidisciplinary team providing self-management coaching and a mechanism for assessment for more advanced therapies (Arnold, Liu, Demers, et al., 2006). It is recognized that these services are not accessible to some patients, and so many centres provide remote monitoring, whereby telehealth technologies are used to provide care.

Nonpharmacological Therapies

Oxygen.

In a patient with HF, oxygen saturation of the blood may be reduced because the blood is not adequately oxygenated in the lungs. If oxygen saturation is less than 90%, administration of oxygen can improve tissue oxygenation. Thus appropriate use of oxygen therapy helps relieve dyspnea and fatigue. Pulse oximetry should be used to monitor the effectiveness of oxygen therapy.

Self-Management Teaching.

An important part of HF care is helping the patient and family understand that HF is a chronic condition and become proficient in avoiding risks for decompensation and detecting the early signs and symptoms. The Heart and Stroke Foundation of Canada makes many useful tools available to help support patients in learning to manage their illness (Heart and Stroke Foundation of Canada, 2015; see the Resources at the end of this chapter).

Exercise and Activity.

Regular activity and exercise periods should be prescribed for all patients with stable chronic HF. Even patients with NYHA class III symptoms (see Table 37-4) should exercise three to five times per week for 30 to 45 minutes at a time. A cardiac rehabilitation program provides the patient with an individualized exercise regimen (Moe, Ezekowitz, O'Meara, et al., 2014). To ensure the patient's adherence to regular exercise, the medical team must be realistic about what the patient can achieve and must work around possible barriers to enable the patient to succeed.

Devices

Cardiac Resynchronization Therapy.

For patients with HF who are receiving maximum medical therapy, continue to have NYHA functional class III or intravenous symptoms (see Table 37-4), and have a widened QRS interval, one therapy is biventricular pacing and cardiac resynchronization therapy (CRT). Traditional pacemakers pace one or two chambers (e.g., atrium or ventricle, or both). CRT coordinates contractility of the right ventricle (RV) and LV through biventricular pacing. Normal electrical conduction within the RV and LV improves left ventricular performance and CO. This additional therapy allows patients to increase their exercise capacity and decrease their overall symptoms. CRT has been shown to prolong life and improve quality of life in patients with NYHA functional class III and class IV HF (Howlett, McKelvie, Arnold, et al., 2009). CRT can be combined with traditional pacing capability, as well as with defibrillator technology.

Implantable Cardioverter–Defibrillator.

If a patient has NYHA functional class II or III HF, is on optimal medical therapy, and has an EF of less than 35%, the implementation and use of an implantable cardioverter–defibrillator (ICD) with CRT may be warranted. Life-threatening ventricular dysrhythmias (e.g., ventricular tachycardia) are a complication of the ischemic myocardium and can cause sudden cardiac death. The addition of the ICD in these patients has reduced the overall rate of mortality from sudden cardiac death (Howlett, McKelvie, Arnold, et al., 2009). (Pacemakers and defibrillators are discussed in Chapter 38.)

Mechanical Circulatory Support.

Several devices are available to sustain patients with HF in deteriorating conditions, especially those awaiting cardiac transplantation. The intra-aortic balloon pump is used for short-term support for HF patients with acute decompensation. However, the limitations of bed rest, infection, and vascular complications preclude its long-term use (see Chapter 68 for nursing management of circulatory assist devices).

Extracorporeal membrane oxygenation is a support device similar to a bypass machine used in cardiac surgery procedures. This system can be used to support critically ill patients with HF who are being assessed for more advanced therapy such as a ventricular assist device (VAD) (Figure 37-6). In Canada, VADs are used in carefully selected patients primarily as a bridge to cardiac transplantation. They provide highly effective long-term support for more than 2 years, allowing patients to live at home and even return to work while waiting for a transplant, and their use has become standard care for candidates for cardiac transplantation with acute decompensation. (Intra-aortic balloon pumps, extracorporeal membrane oxygenation, and VADs are discussed further in Chapter 68.)

Cardiac Transplantation

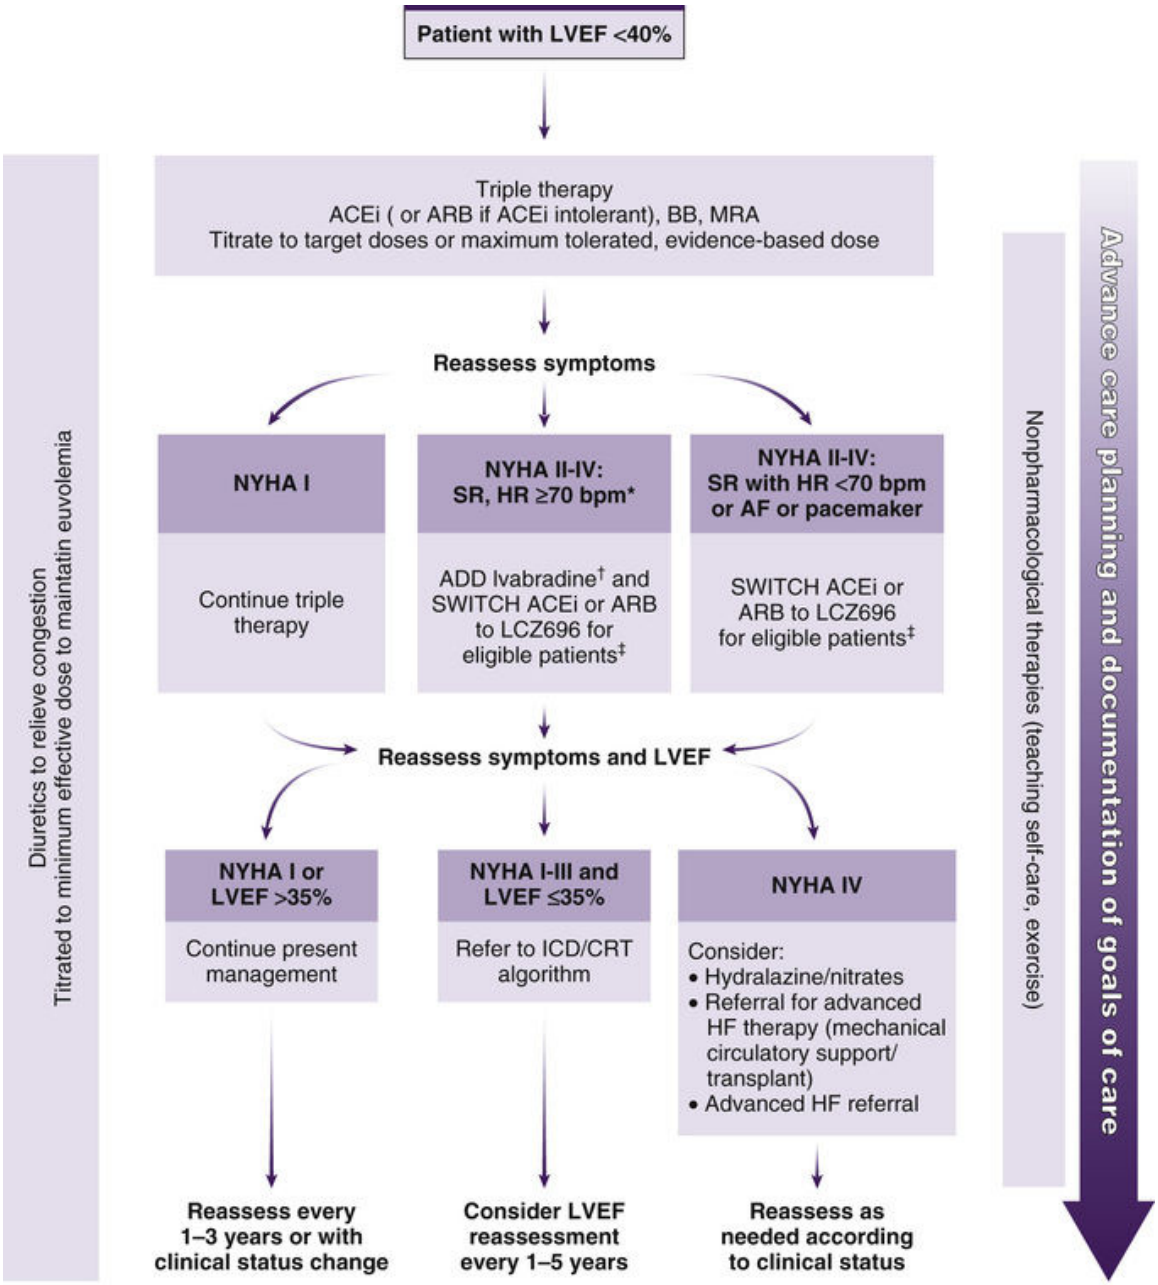
Cardiac transplantation—the transfer of a heart from one person to another—is the treatment of choice in carefully selected patients with end-stage HF. Because of the lack of donor hearts, however, it is an option for only a small number of patients with HF. (Cardiac transplantation is discussed later in this chapter.)

Advance Care Planning and Goals of Care

HF is a chronic condition suffered primarily by older adults, and the prognosis is worse than that of most cancers. For many patients, therapies such as mechanical support and cardiac transplantation are not indicated.

HF is typically characterized by periods of stability interspersed with exacerbations and readmissions to hospital. In the end stages, the patient's quality of life can be limited by the symptoms, and many patients and families are not prepared for death.

The goal of care should be directed toward optimizing guideline-driven therapies outlined in this chapter and, in addition, early discussions with the patient and their loved ones about advance care planning (Figure 37-7). This includes goal setting in terms of patient's preferences, as well as planning for end of life. The role of the ICD and other life-prolonging interventions should be discussed regularly between the HF team and the patient.



*Pending Health Canada approval
†Ivabradine may be added when available in Canada

A., et al., The Canadian Cardiovascular Society Heart Failure Companion: Bridging Guidelines to Your Practice, pp. 296–310, Copyright 2016, with permission from Elsevier.

Early intervention with palliative care support has shown to be effective at improving quality of life, helping patients and their families through these final stages (LeMond, Camacho, & Goodlin, 2015).

Drug Therapy: Chronic Heart Failure

General therapeutic objectives for drug management of chronic HF include the following: (a) identification of the type of HF and the underlying causes, (b) correction of sodium and water retention and volume overload, (c) reduction of cardiac workload, (d) improvement of myocardial contractility, and (e) control of precipitating and complicating factors. The aims of treating HF are to improve symptoms, minimize adverse effects of treatment, prevent morbidity, and prolong survival. Current therapeutic approaches stress the importance of diuretics, ACE inhibitors, β-adrenergic blockers and mineralocorticoid receptor antagonists (previously known as *aldosterone antagonists;* Howlett, Chan, Ezekowitz, et al., 2016) (see Figure 37-7).

Diuretics

Diuretics are used in patients with HF to mobilize edematous fluid, reduce pulmonary venous pressure, and reduce preload (see Chapter 35, Table 35-8). If excess extracellular fluid is excreted, blood volume returning to the heart can be reduced and cardiac function improved.

Diuretics act on the kidneys by promoting excretion of sodium and water. Many varieties of diuretics are available, and some have specific indications for use. Thiazide diuretics may be the first choice for chronic HF because of their convenience, safety, low cost, and effectiveness. They are particularly useful in treating edema secondary to HF and in controlling hypertension. The thiazides inhibit sodium reabsorption in the distal tubule, thus promoting excretion of sodium and water.

Loop diuretics (e.g., furosemide [Lasix]) are potent diuretics. These drugs act on the ascending loop of Henle to promote sodium, chloride, and water excretion. Furosemide is more commonly used in cases of acute HF and pulmonary edema because its effects are slightly more predictable. Problems in using loop diuretics include reduction in serum potassium levels, ototoxicity, and possible allergic reaction in patients who are sensitive to sulpha-containing drugs (sulphonamides).

In patients who are not responsive to high-dose loop diuretics, metolazone (Zaroxolyn) or a thiazide diuretic can be added to the treatment regimen (Arnold, Liu, Demers, et al., 2006).

Angiotensin-Converting Enzyme Inhibitors

ACE inhibitors are useful in both systolic and diastolic HF, and they are the first-line therapy in the treatment of HF. Examples of ACE inhibitors include ramipril (Altace) and enalapril (Vasotec). Other examples of ACE inhibitors are discussed in Chapter 35 and listed in Table 35-8.

The conversion of angiotensin I to the potent vasoconstrictor angiotensin II requires the presence of ACE (see Chapter 47, Figure 47-6). ACE inhibitors exert their effects by blocking production of this enzyme, which results in decreased levels of angiotensin II. As a result, plasma aldosterone levels are also reduced.

Because CO is dependent on afterload in chronic HF, the reduction in SVR seen with the use of ACE inhibitors produces a significant increase in CO. Furthermore, the improvement of CO and the redistribution of regional blood flow that result from the use of ACE inhibitors help maintain tissue perfusion, even though BP may be decreased. Other hemodynamic changes include reductions in pulmonary artery pressure, right arterial pressure, and left ventricular filling pressure. Adverse effects of ACE inhibitors include symptomatic hypotension, chronic cough, and, when it is used in high doses, renal insufficiency. Aging and baseline renal insufficiency slow the metabolism of ACE inhibitors, and their toxicity may therefore be increased (Arnold, Liu, Demers, et al., 2006). It is recommended that these drugs be started at the lowest dose and slowly increased over a 2- to 3-month period and that BP and renal function be monitored at regular intervals. Overall, ACE inhibitors are well tolerated by patients.

In patients who are unable to tolerate the ACE inhibitors because of angioedema or cough, angiotensin II receptor blockers (ARBs) such as losartan (Cozaar) or valsartan (Diovan) may be prescribed (see Chapter 35, Table 35-8). If a patient is already taking an ACE inhibitor and a β-adrenergic blocker, an ARB can be added to the combination (Arnold, Liu, Demers, et al., 2006).

Neprilysin Inhibitors

A relatively new combination drug is available in Canada containing an ARB (valsartan) and a new class of HF medication called a neprilysin inhibitor (sacubitril). This drug combination has shown that it can significantly reduce rates of death from and rehospitalizations for heart failure in selected patients with HF. This drug replaces the use of ACE inhibitors (McMurray, Packer, Desai, et al., 2014).

β-Adrenergic Blockers

The use of β-adrenergic blockers (or β blockers) in combination with ACE inhibitors in the management of HF has become standard therapy for most patients. Examples include carvedilol and metoprolol (Lopressor). Marked improvement in rates of patient survival has been shown with the use of β-adrenergic blockers. β-Adrenergic blockers directly block the negative effects of the SNS on the failing heart, such as increased HR. Because β-adrenergic blockade can reduce myocardial contractility, care must be taken to start gradually, the dosage being increased slowly (typically every 2 weeks) as tolerated by the patient, until it reaches the maximum. Major adverse effects include edema, hypotension, fatigue, asthma exacerbations, and bradycardia.

Drug Alert

β-Adrenergic Blockers

- Overdosage can produce profound bradycardia, hypotension, bronchospasm, and cardiogenic shock.
- Abrupt withdrawal may result in sweating, palpitations, and headaches.

Mineralocorticoid Receptor Antagonists

Spironolactone (Aldactone) is a potassium-sparing diuretic that promotes sodium and water excretion but blocks potassium excretion by blocking the action of aldosterone. Spironolactone appears to be additive to the benefits of ACE inhibitors, and renal function and potassium levels must be monitored carefully.

Drug Alert

Spironolactone (Aldactone)

- Potassium levels must be monitored during treatment.

- It must be used with caution in patients taking digoxin, inasmuch as hyperkalemia may reduce the effects of digoxin.
- Patients must avoid foods with high potassium content (e.g., bananas, oranges, dried apricots).
- Male patients must be assessed for gynecomastia, a common side effect of long-term use of spironolactone.

Eplerinone (Inspra) is a newer mineralocorticoid receptor antagonist that has effects similar to those of spironolactone; however, hyperkalemia seems to be less associated with this drug, as may sexual effects (e.g., gynacomastia; Barnes & Howard, 2005).

Inotropic Drugs

The use of inotropic drugs in patients with HF is directed at improving cardiac contractility to increase CO, decrease left ventricular diastolic pressure, and decrease SVR. Dobutamine and milrinone are the two agents most commonly used. Patients should be monitored carefully because these drugs may increase the risk of sudden death due to arrhythmia. Inotropic drugs are reserved primarily for hemodynamically unstable patients with ADHF (McKelvie, Moe, Ezekowitz, et al., 2013).

Sympathomimetic Agents.

Sympathomimetic agents (or β-adrenergic agonists) include dopamine, dobutamine, epinephrine (Adrenalin), and norepinephrine (Levophed). Stimulation of β-adrenergic receptors results in an increase in cyclic adenosine monophosphate within the myocardial cells and an increase in contractility (inotropic effect). The β-adrenergic agents are typically used as a short-term treatment of acute exacerbations of HF in the critical care environment. However, their role in long-term therapy for HF is controversial (McKelvie, Moe, Ezekowitz, et al., 2013). Potential problems related to long-term treatment with these agents include tolerance (tachyphylaxis), increased ventricular irritability, limb ischemia, and increased myocardial oxygen demand.

Phosphodiesterase Inhibitors.

Inhibition of phosphodiesterase enhances calcium entry into the cell and improves myocardial contractility. Phosphodiesterase inhibitors are also

potent vasodilators. They increase CO and reduce arterial pressure (decrease afterload).

Milrinone increases myocardial contraction, increases CO, promotes peripheral vasodilation, and decreases SVR, thus augmenting performance of the LV. Adverse reactions include dysrhythmias, thrombo-cytopenia, and gastro-intestinal effects.

There is little evidence that inotropic drugs have a beneficial effect on mortality rates. Therefore, their use should be confined to short-term therapy only in patients in cardiogenic shock with volume overload and who have diuretic resistance (McKelvie, Moe, Ezekowitz, et al., 2013).

Vasodilator Drugs.

Vasodilator drugs are a class of drugs that have shown to improve survival in ADHF. The goals of vasodilator therapy in the treatment of HF include (a) increasing venous capacity, (b) improving EF through improved ventricular contraction, (c) slowing the process of ventricular dysfunction, (d) decreasing heart size, and (e) avoiding stimulation of the neuro-hormonal responses initiated by the compensatory mechanisms of HF.

Nitrates cause vasodilation by acting directly on the smooth muscle of the vessel wall. Their effects primarily involve increasing venous capacitance, dilating the pulmonary vasculature, and improving arterial compliance. Therefore, the major hemodynamic effect of nitrates is to decrease preload. Nitrates are of particular benefit in the management of myocardial ischemia related to HF because they promote vasodilation of the coronary arteries. Men with HF who take nitrates should not also take an erectile agent (e.g., sildenafil [Viagra]) to manage erectile dysfunction because together these drugs could precipitate profound hypotension.

Nutritional Therapy: Chronic Heart Failure

Diet education and weight management are critical in the patient's control of chronic HF. The nurse or the dietitian should obtain a detailed diet history, determining not only what foods the patient eats and when but also the sociocultural value of food for the patient. The nurse can use this information to assist the patient in solving problems and working with a dietitian to develop an individualized diet plan. The patient should be taught what foods have low and which have high sodium content and ways to enhance food flavours without the use of salt (e.g., substituting lemon juice and various spices).

The edema of chronic HF is often treated by dietary restriction of sodium. The degree of sodium restriction depends on the severity of the HF and the effectiveness of diuretic therapy. Diets that are severely restricted in sodium are rarely prescribed because they are unpalatable and patient adherence is poor. The Dietary Approach to Stop Hypertension (DASH) diet is effective as a first-line therapy for many patients with isolated systolic hypertension (see Chapter 35, Table 35-7). A commonly prescribed diet for a patient with mild HF is a 2-g/day sodium diet. All foods with high sodium content should be eliminated. For more severe HF or with concurrent diagnosis of hypertension, sodium intake is restricted to 1.5 g/day (Heart and Stroke Foundation of Canada, 2017; see also the Heart and Stroke Foundation website listed in the Resources at the end of this chapter). The patient and caregivers should be instructed on how to read labels to look for sodium as an ingredient (Table 37-6).

TABLE 37-6

NUTRITIONAL THERAPY
Sodium Label Language*

Claim	What It Means
Free of sodium or salt	The food contains <5 mg of sodium per serving.
Low in sodium or salt	The food contains ≤140 mg of sodium per serving (or per 100 g, if the food is a prepackaged meal).
Reduced or lower in sodium or salt	The food is processed, formulated, reformulated, or otherwise modified so that it contains at least 25% less sodium than regular foods of its type.
No added sodium or salt	The food contains no added salt, other sodium salts, or ingredients that contain sodium that functionally substitute for added salt.
Lightly salted	The food contains at least 50% less sodium added than the sodium added to the similar reference food
Words to the effect that the food is "for use in a sodium-restricted diet"	The food meets the criteria for the first three claims in this table.
Words to the effect that the food is "for special dietary use" with respect to the sodium (salt) content	The food meets the criteria for either of the first two items in this table.

*Products advertised as salt replacements should be used with caution: they may contain high quantities of potassium.

Source: Adapted from Canadian Food Inspection Agency. (2015). *Sodium (salt) claims* [summary table]. Retrieved from *http://www.inspection.gc.ca/food/labelling/food-labelling-for-industry/nutrient-content/specific-claim-requirements/eng/1389907770176/1389907817577?chap=9*.

Typically, a low-sodium diet is unpalatable. In order to increase compliance with a low-sodium diet, the Heart and Stroke Foundation of Canada (2014) recommends that patients be advised to do the following:

- Stop using the salt shaker (remove it from the dinner table).
- Do not add salt to food during preparation.
- Read food labels carefully and look for foods that claim lower sodium content.
- Eat fresh fruit and vegetables whenever possible, and try to avoid pre-prepared and processed food.
- When eating out, ask about sodium content, and choose foods with less sodium.

The Canadian Cardiovascular Society recommends that all patients with fluid retention or congestion not responsive to diuretic therapy and

patients with renal dysfunction or hyponatremia should restrict fluid intake to 1.5 to 2 L/day (Arnold, Liu, Demers, et al., 2006). That equates to six to eight glasses of fluid per day. Patients should be reminded that fluid is hidden in foods such as fruits and ice cream. In practice, most Canadian HF clinics advise fluid restriction for all HF patients.

It is vital that patients weigh themselves daily to monitor fluid retention. Patients should be instructed to weigh themselves at the same time each day, preferably before breakfast, while wearing the same type of clothing. This helps ensure valid comparisons from day to day and helps reveal early signs of fluid retention. If a patient experiences a weight gain of 2 kg (4 lb) over a 2-day period or 2.5 kg (5 lb) over a 5-day period, the patient should contact the primary care provider.

General Principles

According to *Eating Well with Canada's Food Guide* (Health Canada, 2011), which contains dietary recommendations endorsed by Health Canada in 2011, all Canadians should follow a diet with low sodium content. The guide recommends that the patient read the "Nutrition Facts" label, which is mandatory on all packaged foods, before purchasing foods (see Chapter 42, Figure 42-4).

Only a small amount of sodium occurs naturally in foods. Most sodium is added during processing. Table 37-7 gives examples of varying amounts of sodium in Western foods before and after processing.

TABLE 37-7

NUTRITIONAL THERAPY: Sodium Content in Different Food Groups

Food Groups	Sodium (mg)
Grains and Grain Products	
Cooked cereal, rice, pasta, unsalted, ½ cup	0–5
Ready-to-eat cereal, 1 cup	100–360
Bread, 1 slice	110–175
Vegetables	
Fresh or frozen, cooked without salt, ½ cup	1–70
Canned or frozen with sauce, ½ cup	140–460
Tomato juice, canned, ¾ cup	820
Fruit	
Fresh, frozen, or canned, ½ cup	0–5
Low-Fat or Fat-Free Dairy Foods	
Milk, 1 cup	120
Yogourt, 250 mL	160
Natural cheeses, 45 g	110–450
Processed cheeses, 45 g	600
Nuts, Seeds, and Dry Beans	
Peanuts, salted, ⅓ cup	120
Peanuts, unsalted, ⅓ cup	0–5
Beans, cooked from dried or frozen, without salt, ½ cup	400
Meats, Fish, and Poultry	
Fresh meat, fish, and poultry, 85-g serving	30–90
Tuna, canned, water pack, no salt added, 85-g serving	34–45
Tuna, canned, water pack, 85-g serving	250–350
Ham (lean) roasted, 85-g serving	1020

The Chinese diet is usually very high in sodium. Patients with HF who adhere to a Chinese diet should be taught to consider the advice in Table 37-8. When teaching the patient with HF who adheres to an East Indian diet, the nurse should take into account the considerations presented in Table 37-9.

TABLE 37-8

CONSIDERATIONS FOR SODIUM INTAKE IN THE CHINESE DIET

Consideration	High Sodium Content	Recommended Alternatives
Protein	Barbecued meats, Chinese sausages, salted fish, dried shrimp, salted eggs, century eggs, canned fish with black beans	Fresh or frozen unsalted meats, fish, poultry, seafood, eggs, tofu
Condiments and sauces	Monosodium glutamate (MSG), soy sauce, oyster sauce, fish sauce, shrimp paste, Hoisin sauce, Teriyaki sauce, Chinese cooking wine, bean paste, miso, fermented tofu, ketchup	Fresh herbs, spices, and other flavoured substances, such as ginger, onion, garlic, garlic powder, green onion, curry powder, pepper, lemon, vinegar, honey, sesame oil, low-sodium soy sauce
Other foods	Instant noodles, instant rice with seasonings, salty soups, bouillon (cubes or powder)	Unprocessed grain products (e.g., fresh rice, rice noodles, udon noodles, congee, pasta, bread), low-sodium soups
Dining-out tips	Most food served in Chinese restaurants has high sodium content; eat in restaurants only occasionally	Plain rice rather than rice or noodles mixed with sauces (especially soy sauce or teriyaki sauce)

TABLE 37-9

CONSIDERATION FOR SODIUM INTAKE IN THE EAST INDIAN DIET

Consideration	High Sodium Content	Recommended Alternatives
Protein	Canned beans and lentils	Fresh beans and lentils to make daal
Condiments and sauces	Achaars (pickles); chutneys (made with salt); relish; tomato, curry, or mustard paste; black salt	Fresh herbs and spices: curry powder, turmeric, chili powder, mustard seeds, ginger, garlic, pepper, cumin, fenugreek (methi), garam masala
Dining out tips	Most food served in East Indian restaurants is high in sodium; eat in restaurants only occasionally	Ask for foods prepared without salt Avoid salty chutneys or relishes

Nursing Management Chronic Heart Failure

Nursing Assessment

Subjective and objective data that should be obtained from a patient with HF include those listed in Table 37-10.

TABLE 37-10

NURSING ASSESSMENT
Heart Failure

Subjective Data

Important Health Information

Family, cultural and psychosocial history: availability of caregivers, living situation, pets at home, smoking, alcohol, illicit drug use, advance directives if available
Past health history: CAD (including recent MI), hypertension, cardiomyopathy, valvular or congenital heart disease, diabetes mellitus, thyroid or lung disease, rapid or irregular heart rate
Medications: use of and adherence to any cardiac medications; use of diuretics, estrogens, corticosteroids, nonsteroidal anti-inflammatory drugs, over-the-counter drugs, herbal supplements

Symptoms

Fatigue, depression, anxiety
Nausea, vomiting, anorexia, stomach bloating
Weight gain, ankle swelling, nocturia, decreased daytime urinary output
Dyspnea, orthopnea, cough
Chest pain or heaviness; palpitations, dizziness, fainting
RUQ pain, abdominal discomfort, constipation
Behavioural changes, visual changes

Objective Data

Integumentary

Cool, diaphoretic skin; cyanosis or pallor, peripheral edema (right-sided heart failure)

Respiratory

Tachypnea, crackles particularly at the bases, rhonchi, wheezes; frothy, blood-tinged sputum (see Chapter 28 for detailed respiratory assessment)

Cardiovascular

Tachycardia, S_3, S_4, murmurs, PMI displaced inferiorly and posteriorly, jugular vein distension (see Chapter 34 for detailed cardiac assessment)

Gastro-intestinal

Abdominal distension, hepatosplenomegaly, ascites

Neurological

Restlessness, confusion, decreased attention or memory

Possible Findings

Altered levels of serum electrolytes (especially Na^+ and K^+), ↑ BUN, ↑ BNP or NT–pro-BNP, creatinine, or liver function test results; chest radiograph demonstrating cardiomegaly, pulmonary congestion, and interstitial pulmonary edema; echocardiogram showing increased chamber size and decreased wall motion; ECG showing atrial and ventricular enlargement; ↓ O_2 saturation

BNP, brain or B-type natriuretic peptide; *BUN*, blood urea nitrogen; *CAD*, coronary artery disease; *ECG*, electrocardiogram; *MI*, myocardial infarction; *NT–pro-BNP*, N-terminal pro-BNP; *PMI*, point of maximal impulse; *RUQ*, right upper quadrant; S_3, and S_4, third and fourth heart sounds.

Nursing Diagnoses

Nursing diagnoses for patients with HF include, but are not limited to, those presented in Nursing Care Plan (NCP) 37-1.

Planning

The overall goals are that the patient with HF will (a) have decreased peripheral edema, (b) have decreased shortness of breath, (c) have increased exercise tolerance, (d) adhere to drug regimen, and (5) have no complications related to HF.

Evidence-Informed Practice

Translating Research Into Practice

Tara Fahed is a 62-year-old female patient recovering from an episode of acute decompensated heart failure (ADHF). Her HF is class III according to the New York Heart Association Functional Classification of Heart Disease (see Table 37-4). Her physician has recommended biventricular pacing (cardiac resynchronization therapy) for treatment of her HF symptoms. She tells the nurse that she does not want any artificial implants and that she has researched the use of hawthorn for treatment of her heart disease.

Best Available Evidence	Clinician Expertise	Patient Preferences and Values
Strong evidence supports the use of biventricular pacing (cardiac resynchronization therapy) to improve symptoms, exercise capacity, quality of life, ejection fraction, and survival and to decrease hospitalizations in patients like Ms. Fahed.	The nurse knows the benefits of and possible complications related to biventricular pacing in patients with Ms. Fahed's situation. The nurse also knows that there is strong evidence supporting the use of hawthorn in patients with mild to moderate HF.	Patient does not want any artificial implants. She wants to consider alternative (herbal) therapy.

Decision and Action

The nurse reviews the risks and benefits of biventricular pacing and herbal (hawthorn) therapy for the treatment of HF with Ms. Fahed. Ms. Fahed remains committed to the use of hawthorn—at least for a trial period. The nurse supports her decision and informs the physician of her wishes.

Reference for Evidence

Nursing Implementation

Health Promotion.

An important measure used to prevent HF is the treatment or control of the underlying heart disease. For example, in valvular disease, valve replacement should be planned before lung congestion develops. Coronary revascularization procedures should be performed in patients with CAD. Another important preventive measure concerns early and continued treatment of hypertension. Hyperlipidemic states in people with CAD should be managed with diet, exercise, and medication. The use of antidysrhythmic agents or an ICD–pacemaker is indicated for people with continuing low EF even if they are receiving optimal medical therapy or are at risk for sudden cardiac death. In addition, patients with HF should be counselled to quit smoking and obtain yearly vaccinations against the flu.

When HF is diagnosed, preventive care should focus on slowing the progression of the disease. The patient must understand the importance of following the medication, diet, and exercise regimens. Exercise training (e.g., cardiac rehabilitation) improves symptoms of chronic HF but is often underprescribed.

Acute Intervention.

Successful HF management depends on several important principles: (a) HF is a progressive disease, and treatment plans are established with quality-of-life goals; (b) symptoms are managed by the patient with self-management tools (daily weights, drug regimens, exercise plans); (c) salt and water must be restricted; (d) a regular, prescribed level of exercise should be maintained; and (e) use of support systems is essential to the success of the entire treatment plan (Arnold, Liu, Demers, et al., 2006).

Many patients with HF experience one or more episodes of acute decompensation. When they do, they may be initially managed in a critical care area and later transferred to a general medical or cardiology unit when their condition has stabilized. Nursing Care Plan 37-1 for patients with HF applies to patients with stabilized acute or chronic HF.

Nursing Care Plan 37-1

Heart Failure

NURSING DIAGNOSIS	***Impaired gas exchange*** (related to increased preload and alveolar–capillary membrane changes as evidenced by abnormal O_2 saturation, hypoxemia, dyspnea, tachypnea, tachycardia, restlessness, and patient's statement about being short of breath).
Expected Patient Outcomes	**Nursing Interventions and *Rationales***
• Maintains adequate O_2/CO_2 exchange at the alveolar–capillary membrane to meet O_2 needs of the body	*Respiratory Monitoring* • Monitor pulse oximetry, respiratory rate, rhythm, depth, and effort of respirations *to detect changes in respiratory status.* • Auscultate breath sounds, noting areas of decreased or absent ventilation and presence of adventitious sounds *to detect presence of pulmonary edema.* • Monitor for increased restlessness, anxiety, and work of breathing *to detect increasing hypoxemia.* *Oxygen Therapy* • Administer supplemental O_2 or other noninvasive ventilator support (e.g., bilevel positive airway pressure) as needed *to maintain adequate O_2 levels.* • Monitor the O_2 litre flow rate and placement of O_2 delivery device *to ensure O_2 is adequately delivered*. • Change O_2 delivery device from mask to nasal prongs during meals as tolerated *to sustain O_2 levels while patient is eating.* • Monitor the effectiveness of O_2 therapy *to identify hypoxemia and establish range of O_2 saturation.* *Positioning* • Position patient to alleviate dyspnea (e.g., semi-Fowler's position), as appropriate, *to improve ventilation by decreasing venous return to the heart and increasing thoracic capacity.*
NURSING DIAGNOSIS	***Decreased cardiac output*** (related to altered contractility, altered preload, altered stroke volume, or a combination of these as evidenced by decreased ejection fraction, increased CVP, decreased peripheral pulses, jugular venous distension, orthopnea, chest pain, S_3 and S_4, and oliguria).
Expected Patient Outcomes	**Nursing Interventions and *Rationales***
• Maintains adequate blood pumped by the heart to meet metabolic demands of the body	*Cardiac Care* • Perform a comprehensive assessment of peripheral circulation (e.g., check peripheral pulses, edema, capillary refill, colour, and temperature of extremity) *to determine circulatory status.* • Note signs and symptoms of decreased cardiac output (e.g., chest pain, S_3, S_4, jugular venous distension) *to detect changes in status.* • Monitor fluid balance (e.g., input/output and daily weight) *to evaluate patient's fluid status.* • Monitor cardiac rhythm *to detect dysrhythmias.* • Monitor respiratory status for symptoms of heart failure (e.g., dyspnea, fatigue, tachypnea, orthopnea) *to identify involvement of respiratory system.* • Instruct patient and caregivers about activity restriction and progression *to allay fears and anxiety.* • Establish a supportive relationship with patient and caregivers *to promote adherence to the treatment plan.* • Inform patient of the purpose and benefits of the prescribed activity and exercise *to enhance adherence*.
NURSING DIAGNOSIS	***Excess fluid volume*** related to *excessive fluid intake, excessive sodium intake* (decreased renal perfusion secondary to heart failure) as evidenced by *weight gain over short period of time, edema, adventitious breath sounds, oliguria*
Expected Patient Outcomes	**Nursing Interventions and *Rationales***
• Experiences reduction or absence of edema and stable baseline weight	*Hypervolemia Management* • Administer prescribed medications to reduce preload (e.g., furosemide, spironolactone, morphine, and nitroglycerine) *to treat hypervolemia.* • Monitor for therapeutic effects of medications (e.g., increased urine output, decreased CVP, decreased adventitious breath sounds) *to assess response to treatment*. • Monitor potassium levels after diuretic medications *to detect hypokalemia*. • Weigh patient daily and monitor trends *to evaluate effect of treatment.* • Monitor intake and output *to assess fluid status.*

	• Monitor respiratory pattern for symptoms anxiety, air hunger, orthopnea, dyspnea, tachypnea, cough, frothy sputum production, and shortness of breath *to detect signs and symptoms of pulmonary edema.* • Monitor hemodynamic status, including HR, BP, MAP, PAP, PAWP, CO, and CI, if available, *to evaluate effectiveness of therapy.* • Monitor adventitious breath sounds, adventitious heart sounds, JVD, and peripheral edema *to assess response to treatment.*
NURSING DIAGNOSIS	***Activity intolerance*** related to *imbalance between oxygen supply/demand* as evidenced by *abnormal heart rate response to activity, exertional dyspnea, and fatigue.*
Expected Patient Outcomes	**Nursing Interventions and *Rationales***
• Achieves a realistic program of activity that balances physical activity with energy-conserving activities • Vital signs, O_2 saturation, and colour are within normal limits in response to activity	*Energy Management* • Encourage alternating rest and activity periods *to reduce cardiac workload and conserve energy.* • Provide calming diversionary activities to promote relaxation *to reduce O_2 consumption and to relieve dyspnea and fatigue.* • Monitor patient's O_2 response (e.g., pulse rate, cardiac rhythm, and respiratory rate) to self-care or nursing activities *to determine level of activity that can be tolerated.* • Teach patient and caregiver techniques of self-care (e.g., self-monitoring and pacing techniques for performance of ADLs) *to minimize O_2 consumption.* • Teach patient to change positions slowly from lying/sitting to standing because patient may experience a postural BP drop that causes dizziness and increases risk of falling. *Activity Therapy* • Collaborate with occupational and physical therapists *to plan and monitor activity or exercise program.* • Determine patient's commitment to increasing frequency and range of activities or exercise *to provide patient with obtainable goals.*

ADLs, activities of daily living; *BP,* blood pressure; *CI,* cardiac index; *CO,* cardiac output; *CVP,* central venous pressure; *HR,* heart rate; *JVD,* jugular venous distension; *MAP,* mean arterial pressure; *PAP,* pulmonary artery pressure; *PAWP,* pulmonary artery wedge pressure.

Ambulatory and Home Care.

HF is a chronic illness. Important nursing responsibilities are (a) teaching the patient about the physiological changes that have occurred, (b) assisting the patient to adapt to both the physiological and the psychological changes, and (c) integrating the patient and the patient's family or support system in the overall care plan (Arnold, Liu, Demers, et al., 2006). It is known that patients with HF are at risk for depression and that those who are depressed are more likely to be rehospitalized and die prematurely (Newhouse & Jiang, 2014). Depression should be treated appropriately in order for patients to adhere to medical therapy. It must be emphasized to the patient and the patient's caregivers that it is possible to live productively with this chronic illness. Managing patients with HF out of the hospital setting is a priority of care. A patient and caregiver teaching guide for the patient with HF is presented in Table 37-11.

TABLE 37-11

PATIENT & CAREGIVER TEACHING GUIDE
Heart Failure

What Is Heart Failure?
1. Provide individually tailored information about what heart failure is and how it is treated. 2. Discuss how people make the most of life with a chronic illness.
Health Promotion
1. Instruct patient to obtain annual flu vaccination. 2. Instruct patient to obtain pneumococcal vaccine (e.g., Pneumovax) and revaccination after 5 yr (for people at high risk of infection or serious disease). 3. Provide counselling regarding smoking cessation and weight reduction, if relevant.
Exercise and Rest
1. Once patient is cleared by physician, discuss the benefits of regular exercise and dispel myths. 2. Instruct patient to plan a regular activity program and scheduled rest periods throughout the day. 3. Encourage communication of concerns and fears and provide encouragement.
Drug Therapy
1. Teach patient to take each drug as prescribed by the physician or nurse practitioner. 2. Help patient develop a system (e.g., daily chart) to ensure medications have been taken. 3. Instruct patient to take pulse and BP each day before taking medications. Know what is normal for the patient. 4. Ensure that patient knows signs and symptoms of orthostatic hypotension and how to prevent them. 5. Ensure that patient knows own INR if taking warfarin (Coumadin) and how often to have blood monitored. 6. If relevant, teach patient signs and symptoms of overadministration of anticoagulation agents.
Dietary Therapy
1. Instruct patient to consult the written diet plan and list of permitted and restricted foods. 2. Teach patient to examine labels to determine sodium content and examine the labels of over-the-counter drugs such as laxatives, cough medicines, and antacids. 3. Encourage patient not to use salt in cooking or at the dining table. 4. Instruct patient to measure weight in the early morning every day after emptying bladder. Ensure that the patient knows to use the same scale and wear similar clothes. 5. Help patient keep track of daily weight and report weight gain of more than 2–2.5 kg (4–5 lb) in the course of 2 to 5 days. 6. Instruct patient to restrict fluid intake to no more than 6 to 8 cups per day and to remember that fluid can be hidden in many foods. These hidden fluids should be counted in the daily restriction.
Other Topics
1. If adverse effects are bothersome, discuss ways in which timing of medications may help to manage them. 2. Instruct patient to avoid extremes of heat and cold. 3. Encourage patient to keep regular appointments with health care provider. 4. Discuss end-of-life planning and the importance of advance directives.
Ongoing Monitoring
1. Educate patient about the signs and symptoms of recurring or progressing heart failure. 2. Instruct patient to report immediately to health care provider he development or worsening of any of the following: • Difficulty breathing, especially with exertion or when lying flat • Waking up breathless at night • Frequent dry, hacking cough, especially when lying down • Fatigue, weakness • Swelling of ankles, feet, or abdomen • Nausea with abdominal swelling, pain, and tenderness • Dizziness or fainting 3. Encourage patient to join local support networks such as cardiac rehabilitation or “Chronic Disease Management” programs. 4. Recognize depression as a major issue, and help patient seek treatment if signs and symptoms of depression occur. 5. Teach caregivers to recognize signs of cognitive impairment.

BP, blood pressure; *INR*, international normalized ratio.

Patients with chronic HF are required to take medication for the rest of their lives. This often becomes difficult because a patient may be asymptomatic when HF is under control. It must be stressed that the disease is chronic and that medication administration must be continued even through stable periods to prevent acute decompensation.

The patient and caregivers should learn to evaluate how the patient is feeling, to recognize symptoms of possible decompensation, and to report them early. They need to understand that the medications the patient is taking may cause adverse effects that—especially in the initiation phase—can make the patient feel worse for some weeks after initiation and upward titration. The patient, caregivers, and primary health providers need to know that simply stopping some HF medications may not be appropriate. For example, a reported pulse rate of 50 bpm (especially in a patient who is also taking β-adrenergic blockers) may be acceptable and does not necessarily mean that the patient should stop taking the prescribed medication.

The home health nurse, the physiotherapist, or the occupational therapist can instruct the patient in energy-saving and energy-efficient behaviours after daily activities have been evaluated. The nurse can help link the patient with a cardiac rehabilitation or chronic disease program in the community to facilitate the recommended weekly exercise (30–40 minutes, three to five times per week, including aerobic activity and resistance training).

Using home health care services is essential in the care of HF patients and their caregivers. Many patients have multiple comorbidities conditions, and a degree of cognitive impairment is common. Frequent physical assessments, including vital signs and weight, are extremely important. The home care nurse can coach the patient and the patient's caregivers to implement systems to remember medications and times; identify problems, such as an increase in weight as evidence of worsening failure; and institute interventions to prevent hospitalization. This may include altering medications and fluid restrictions. The home care nurse can also help identify the need for respite services to reduce caregiver burden.

Evidence-Informed Practice

Research Highlight

Can Exercise Help Alleviate Depression in Patients With Heart Failure?

Clinical Question

For patients with heart failure (P), what is the effect of aerobic exercise (I) versus usual care (C) on depressive symptoms (O) at 3 and 12 months (T)?

Best Available Evidence

Randomized controlled trial (RCT)

Critical Appraisal and Synthesis of Evidence

RCT of 82 medical centres (*N* = 2 322) of patients with stable chronic heart failure.

- Intervention was aerobic exercise with a goal of 90 min/wk for months 1–3, followed by home exercise for ≥120 min/wk for months 4–12. Usual care was education and guideline-based heart failure care.
- Outcome measure was depressive symptoms.
- Patients engaged in aerobic exercise had fewer depressive symptoms at 3 and 12 months than did patients receiving usual care.

Conclusion

- Exercise resulted in a significant decrease in depressive symptoms.

Implications for Nursing Practice

- The nurse should encourage patients with heart failure to discuss with their health care provider reasonable exercise goals.
- The nurse should emphasize the mental and physical benefits to patients of engaging in supervised regular aerobic exercise.

P, Patient population of interest; *I*, intervention or area of interest; *C*, comparison of interest or comparison group; *O*, outcomes of interest; *T*, timing (see Chapter 1).

Evaluation

The expected outcomes for the patient with HF are presented in Nursing Care Plan 37-1.

Cardiac Transplantation

Heart transplantation was first performed in 1967. Since that time, cardiac transplantation has become the treatment of choice for carefully selected patients with end-stage HF. The main indications for transplantation are ischemic heart disease and dilated cardiomyopathy. Indications for and contraindications to heart transplantation are listed in Table 37-12.

TABLE 37-12

INDICATIONS FOR AND CONTRAINDICATIONS TO CARDIAC TRANSPLANTATION

Indications: Transplantation Centre–Specific
• End-stage heart disease refractory to medical therapy • Refractory, life-threatening cardiac dysrhythmias • Functional NYHA class III or IV status with demonstrated poor exercise capacity
Contraindications
• Pulmonary hypertension unrelieved with medication • Primary systemic disease that would limit survival (e.g., malignancies) • Renal dysfunction (creatinine level >200 mmol/L): patient could be considered for combined transplantation • Active infection • Technical issues • Current tobacco use (6-month abstinence required) • Illicit drug or excessive alcohol use (3-month abstinence required) • Unstable psychiatric conditions • Documented life-threatening nonadherence to medical regimen • Malignancy (generally must be cancer free for 5 yr) • Severe osteoporosis • Significant peripheral vascular disease • Diabetes mellitus with end-organ damage

Among the patients who meet the criteria for cardiac transplantation, the goal of the evaluation process is to identify patients who would most benefit from a new heart. After a complete physical examination and diagnostic workup, the patient and family undergo a comprehensive psychological profile that includes assessment of coping skills, family support systems, and motivation to follow the rigorous regimen that is essential to a successful transplantation. The complexity of the transplantation process may be overwhelming to a patient with inadequate support systems and a poor understanding of the lifestyle changes required after transplantation.

Once an individual is accepted as a transplantation candidate (this may happen rapidly during an acute illness or over a longer period, depending on the patient's condition), he or she is placed on a transplant list. Patients may wait at home and receive ongoing medical care if their medical condition is stable. If their condition is not stable, they may require hospitalization for more intensive therapy, including long-term mechanical cardiac support with a VAD. Unfortunately, the overall waiting period for a cardiac transplant is difficult to define but is usually between 6 and 9 months, depending on donor availability.

Donor and recipient matching is based on body and heart size and ABO blood type. Negative lymphocyte crossmatch (explained in Chapter 16) is also important.

Most donor hearts are obtained at sites away from the institution where the transplantation is performed. The maximum acceptable ischemic time for cardiac transplantation is 4 to 6 hours.

The recipient is prepared for surgery, and cardiopulmonary bypass is used. The usual surgical procedure involves removing the recipient's heart, except for the posterior right and left atrial walls and their venous connections. The recipient's heart is then replaced with the donor heart, which has been trimmed to match. Care is taken to preserve the integrity of the donor sinoatrial node so that a sinus rhythm may be achieved postoperatively.

Immuno-suppressive therapy begins in the operating room. Some transplantation centres administer drugs to rapidly induce immuno-suppression in the operating room and critical care area because the regimens most commonly used are nephrotoxic and, hence, cannot be started for a few days after the surgery. This induction therapy (usually with a monoclonal antibody) buys time to allow the kidneys to recover from the insult of surgery. (The mechanisms of action and adverse effects of these and other immuno-suppressants are discussed in Chapter 16 and Table 16-16.) Regimens vary, but tacrolimus [Prograf]) with mycophenolate mofetil (Cellcept) and prednisolone are most frequently used for maintenance immuno-suppression. In many Canadian programs, cardiac transplant recipients are weaned off prednisolone over a number of months, and after a year, it is uncommon for such patients to be taking prednisolone. The use of today's immuno-suppressants has resulted not only in reduced rates of rejection but also in slowing the rejection process so that early treatment can be instituted. Because of the use of immuno-suppressants, however, infection is a major complication after transplantation.

Endomyocardial biopsies via the right internal jugular vein are performed at repeated intervals to detect rejection in the first year. After 3 months, the incidence of acute rejection decreases dramatically; however, a type of CAD known as cardiac allograft vasculopathy (also known as *chronic rejection*) develops in a significant proportion of heart transplant recipients over the long term. As a result, regular surveillance of the transplanted heart by means of diagnostic tests such as coronary angiography and echocardiography is performed for the rest of the recipient's life.

Advances in surgical technique and postoperative care have improved survival rates after cardiac transplantation. It is estimated that 50% of transplant recipients will be living after 10 years. This number is an overall average and varies greatly, depending on such factors as age at transplantation, severity of illness, adherence to medication regimens and risk factor modification, and social support systems. In the first year after transplantation, the major causes of death are acute rejection and infection. Later on, malignancy (especially lymphoma) and allograft vasculopathy are major causes of death.

One factor that may affect morbidity and mortality in heart transplantation is the patient's ability to adhere to medication regimens. To determine the scope of this problem, as well as attempting to identify some of the factors related to nonadherence, the BRIGHT study (Building research initiative group: chronic illness management and adherence in transplantation) is expected to provide important information for nurses when planning the care of these patients. The research team administered questionnaires to patients, nurses, and medical directors to explore demographics, practice patterns, self-reported adherence, and clinician-reported adherence. The study included approximately 40 heart transplantation centres in 11 countries and was completed in 2015 (Berben, Denhaerynck, Dobbels, et al., 2015).

Nursing management throughout the post-transplantation period focuses on promoting patient adaptation to the transplantation process, monitoring health, managing lifestyle changes, and ongoing teaching of the patient and caregivers.

Mechanical Cardiac Support Devices

Temporary support of one or both failed ventricles has been available for many years in the form of intra-aortic balloon pumps or extracorporeal

membrane oxygenation. These circulatory support devices are designed for short-term use (days to weeks).

More recently, longer-term devices (for use over months to years) are being used in Canada as a bridge to heart transplantation or recovery of the native heart. These pumps are called *ventricular assist devices* (VADs). A number of VADs are available in Canada. Some examples include the HeartMate II (made by Thoratec Corp., Pleasanton, California; see Figure 37-6) and HeartWare HVAD (made by HeartWare Inc., Framingham, Massachusetts) electronic devices. These pumps are designed to support the LV. In many carefully selected patients, support of the LV alone will alleviate symptoms of right-sided HF by unloading the left side.

Patients carry around a battery pack with a small computer attached to their belt. With adequate social support, patients are able to live at home with these devices and, in some cases, return to work while waiting for a heart transplant. This improved mobility—the ability to live out of the hospital—and the improvement that results in the patient's nutritional state allow the patient to undergo transplantation in much improved physical condition. In the United States and Europe, instead of a transplant, some patients who are ineligible for transplantation use these devices. This practice is commonly referred to as *destination therapy*.

A totally artificial heart is available; however, it is not currently in use in Canada. For more information on mechanical cardiac support, see Chapter 68.

Ethical Dilemmas

Transplant Recipient Requests

Situation

A 60-year-old woman has been awaiting heart transplantation for 6 months. At her recent clinic appointment, she asks if there is any possibility of receiving only a woman's heart. She tells the nurse that she does not want to receive a man's heart as she feels her personality would change.

Important Points for Consideration

- Hearts are not allocated on the basis of gender except as determined by size matching. Specifically, a large man is unlikely to receive a woman's heart because women in general are smaller; however a woman could receive a man's heart if they are the same size.
- There is no evidence that people assume the personalities of their donor.
- Heart transplantation programs do not respond to requests for specific attributes of organ donors such as race, gender, or cultural or religious practices.
- Heart transplantation programs do not give heart transplant recipients information about the characteristics of their donors.
- When heart transplantation candidates make these requests, it is often due to misinformation that has been published in the media. The nurse should explore with the patient her concerns and work with the psychosocial team to help her address them.

Clinical Decision-Making Questions

1. How might the nurse respond to the patient about such a request?
2. What supports should the nurse offer to the patient to assist her in working through her concerns?

Case Study

Heart Failure

Source: Geo Martinez/Shutterstock.com.

Patient Profile

Ms. Estrela, a 70-year-old woman, was admitted to the medical unit with complaints of increasing dyspnea on exertion.

Subjective Data

- Had a myocardial infarction (MI) at 58 years of age
- Has a 25-year history of hypertension
- Has experienced increasing dyspnea on exertion during the last 2 years
- Recently had a respiratory tract infection
- Has moist, productive cough
- Has edema in both legs up to the knees
- Cannot walk two blocks without getting short of breath
- Has to sleep with head elevated on three pillows
- Does not always remember to take medication
- 5-kg weight gain in 3 days

Objective Data

Physical Examination

- In respiratory distress; use of accessory muscles; respiratory rate, 36 breaths/min
- Moist crackles at both lung bases
- Skin cool and diaphoretic
- 2+ Pitting edema in both legs
- HR, 95 bpm and regular
- BP, 160/90 mm Hg
- Oxygen saturation, 88%

Diagnostic Studies

- Chest radiographic examination results: cardiomegaly; fluid in lower lung fields
- Echocardiogram results: ejection fraction (EF), 20%

Collaborative Care

- Enalapril, 5 mg PO (orally) daily
- Furosemide (Lasix), 40 mg PO bid
- Potassium, 40 mEq PO bid
- 2-g sodium diet
- Oxygen, 6 L/min to maintain O_2 saturation >90%
- Daily weight measurements
- Daily 12-lead electrocardiography (ECG); cardiac enzyme measurements, q8h three times
- Continuous cardiac monitoring
- Measurements of serum electrolytes, urea, creatinine, and BNP; complete blood cell count (CBC)

Discussion Questions

1. Explain the probable pathophysiological process of Ms. Estrela's heart disease.
2. What clinical manifestations of heart failure did Ms. Estrela exhibit?
3. What is the significance of the findings of the diagnostic studies?
4. Explain the rationale for each of the medical orders prescribed for Ms. Estrela.
5. ***Priority decision:*** What are the nurse's priority nursing interventions for Ms. Estrela?
6. ***Priority decision:*** What priority patient teaching measures should be instituted to prevent recurrence of an acute episode of heart failure?
7. ***Priority decision:*** On the basis of the assessment data presented, write one or more appropriate nursing diagnoses. Are there any collaborative problems?
8. ***Evidence-informed practice:*** Mrs. Estrela asks the nurse why it is so important to "watch her salt." She tells the nurse that food tastes better with salt. How might the nurse respond to her?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. What are the manifestations of HF-REF that the nurse should recognize?
   a. ↓ Afterload and ↓ left ventricular end-diastolic pressure (LVEDP)
   b. ↓ Ejection fraction (EF) and ↑ pulmonary artery occlusive pressure (PAOP)
   c. ↓ PAOP and ↑ left ventricular EF
   d. ↑ Pulmonary hypertension associated with normal EF
2. Which compensatory mechanism leads to inappropriate sodium and fluid retention?
   a. Ventricular dilation
   b. Ventricular hypertrophy
   c. Neuro-hormonal response
   d. Sympathetic nervous system activation
3. Which drug used in the management of a client with acute pulmonary edema will decrease both preload and afterload and provide relief of anxiety?
   a. Morphine
   b. Amiodarone
   c. Dobutamine
   d. Aminophylline
4. How can a client with chronic HF best decrease the chances of having an acute decompensation?
   a. Resting and not making any exertions except under medical supervision
   b. Documenting fluid intake and urinary output each day
   c. Monitoring weight daily and reporting changes outside of recommended parameters
   d. Taking extra furosemide when shortness of breath occurs
5. Clients with a heart transplant are at risk for which complications in the first year after transplantation? *(Select all that apply)*
   a. Cancer

b. Infection
c. Rejection
d. Vasculopathy
e. Sudden cardiac death

1. b; 2. c; 3. a; 4. c; 5. b, c, e.

CHAPTER 38

Nursing Management

Dysrhythmias

Written by, Linda Bucher

Adapted by, Sandra Goldsworthy

LEARNING OBJECTIVES

1. Describe the nursing management of patients requiring continuous electrocardiographic (ECG) monitoring.
2. Identify the clinical characteristics and ECG patterns of normal sinus rhythm, common dysrhythmias, and acute coronary syndrome (ACS).
3. Describe the nursing and collaborative management of patients with common dysrhythmias and ECG changes associated with ACS.
4. Differentiate between defibrillation and cardioversion, identifying indications for their use and nursing implications.
5. Describe the management of patients with temporary and permanent pacemakers.
6. Describe the management of patients with implantable cardioverter–defibrillators.
7. Explain the management of patients undergoing electrophysiological testing and radiofrequency ablation therapy.

KEY TERMS

asystole, p. 879

Rhythm Identification and Treatment

The ability to recognize normal and abnormal cardiac rhythms is an essential nursing skill. Cardiac monitoring is now used in a wide range of hospital, clinic, and home settings. Prompt assessment of abnormal cardiac rhythms, called **dysrhythmias,** and of the patient's response to them is critical. This chapter describes basic principles of electrocardiographic (ECG) monitoring and recognition of common dysrhythmias, as well as ECG changes that are associated with acute coronary syndrome (ACS). For more detailed information on ECG interpretation, the reader should refer to dedicated texts on this topic.

Conduction System

Four properties of cardiac cells enable the conduction system to initiate an electrical impulse, which is transmitted through the cardiac tissue and stimulates muscle contraction (Table 38-1). The conduction system of the heart is made up of specialized neuro-muscular tissue located throughout the heart (see Chapter 34, Figure 34-4). A normal cardiac impulse begins in the sinoatrial (SA) node in the upper right atrium. It is transmitted over the atrial myocardium via the bundle of Bachmann and internodal pathways, which causes atrial contraction. The impulse then travels to the atrioventricular (AV) node through the bundle of His and down the left and right bundle branches, ending in the Purkinje fibres, which transmit the impulse to the ventricles.

TABLE 38-1

PROPERTIES OF CARDIAC CELLS

Automaticity	Ability to initiate an impulse spontaneously and continuously
Contractility	Ability to respond mechanically to an impulse
Conductivity	Ability to transmit an impulse along a membrane in an orderly manner
Excitability	Ability to be electrically stimulated

Conduction to the point just before the impulse leaves the Purkinje fibres takes place within the time of the PR interval of the ECG. When the impulse emerges from the Purkinje fibres, ventricular depolarization occurs, producing mechanical contraction of the ventricles and the QRS complex on the ECG. The electrical activity of the heart is illustrated in Chapter 34, Figure 34-4.

Nervous Control of the Heart

The autonomic nervous system plays an important role in the rate of impulse formation, the speed of conduction, and the strength of cardiac contraction. The components of the autonomic nervous system that affect the heart are the right and left vagus nerve fibres of the parasympathetic nervous system and the fibres of the sympathetic nervous system.

Stimulation of the vagus nerve causes a decrease in the rate of firing of the sinoatrial node, a slowing of impulse conduction of the atrioventricular node, and a decrease in the force of cardiac muscle contraction. Stimulation of the sympathetic nerves that supply the heart has essentially the opposite effect on the heart.

Electrocardiographic Monitoring

The **electrocardiogram (ECG)** is a graphic tracing of the electrical impulses produced in the heart. The waveforms on the ECG are produced by the movement of charged ions across the membranes of myocardial cells, representing depolarization and repolarization.

The membrane of a cardiac cell is semipermeable, allowing the intracellular concentration of potassium to remain high and the intracellular concentration of sodium to remain low. A high concentration of sodium and a low concentration of potassium are maintained outside the cell. The inside of the cell, when the cell is at rest or in the polarized state, is negative compared with the outside. When a cell or groups of cells are stimulated, each cell membrane changes its permeability and allows sodium to move rapidly into the cell, making the inside of the cell positive compared with the outside *(depolarization).* A slower movement of ions across the membrane restores the cell to the polarized state; this restoration is called *repolarization.* As shown in Figure 38-1, the phases of the cardiac action potential are as follows: phase 0 is the upstroke of rapid depolarization; phases 1, 2, and 3 represent repolarization; and phase 4 is a polarized state. Antidysrhythmia drugs have a direct effect on the various phases of the action potential. When antidysrhythmia drugs are used in a clinical setting, it is important to understand the ionic shifts in the cardiac cell and the action potential mechanism.

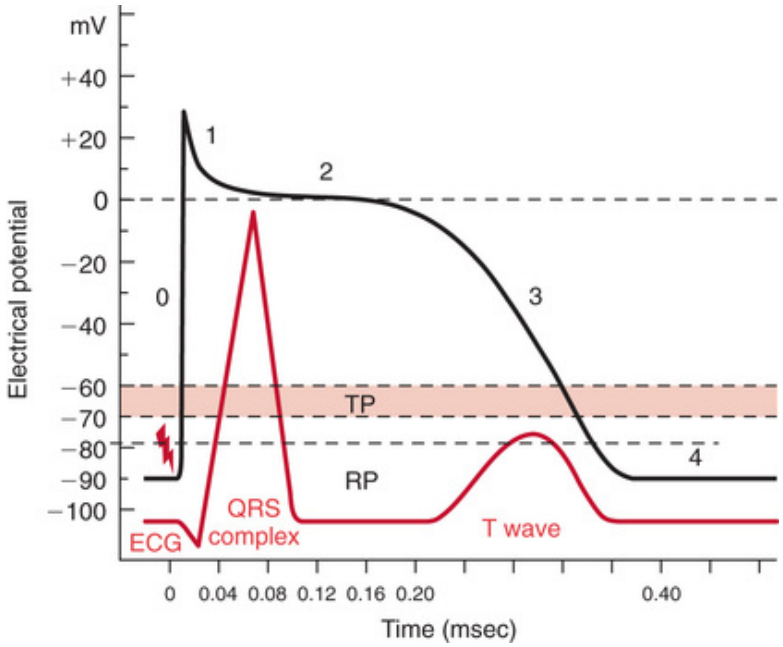

FIGURE 38-1 Phases of the cardiac action potential on an electrocardiogram (ECG). The electrical potential, measured in millivolts, is indicated along the vertical axis of the graph. Time, measured in milliseconds, is indicated along the horizontal axis. The action potential *(black line)* has five phases, labelled *0* through *4*. Each phase represents a particular electrical event or combination of electrical events. Phase 0 is the upstroke of rapid depolarization and corresponds with ventricular contraction. Phases 1, 2, and 3 represent repolarization. Phase 4 is known as *complete repolarization* (or *the polarized state*) and corresponds to diastole. *RP,* resting membrane potential; *TP,* threshold membrane potential.

Conventionally, there are 12 recording leads in the ECG. Six of the 12 ECG leads (leads I, II, III, aV_R, aV_L, and aV_F) measure electrical forces in the frontal plane (Figure 38-2). The remaining six leads (V_1 through V_6) measure the electrical forces in the horizontal plane (precordial leads). The 12-lead ECG may show changes that are indicative of structural changes or damage such as ischemia, infarction, enlarged cardiac chambers, electrolyte imbalance, or drug toxicity (Goldsworthy, 2016). Obtaining 12 ECG views of the heart is also helpful in the assessment of dysrhythmias. An example of a normal 12-lead ECG appears in Figure 38-3.

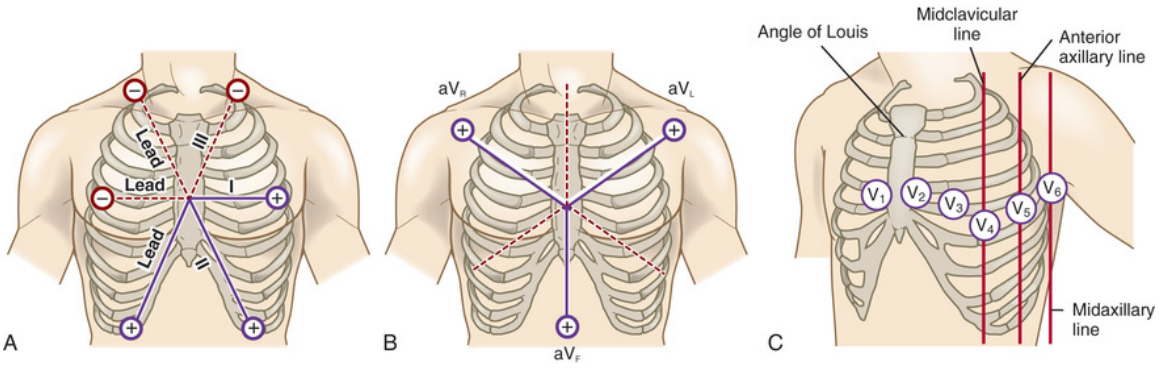

FIGURE 38-2 **A,** Limb leads I, II, and III. These bipolar leads are located on the extremities. Illustrated are the angles from which these leads view the heart. **B,** Limb leads aV_R, aV_L, and aV_F. These unipolar leads use the centre of the heart as their negative electrode. **C,** Placement for the unipolar chest leads: V_1, fourth intercostal space at the right sternal border; V_2, fourth intercostal space at the left sternal border; V_3, halfway between V_2 and V_4; V_4, fifth intercostal space at the left midclavicular line; V_5, fifth intercostal space at the left anterior axillary line; V_6, fifth intercostal space at the left midaxillary line.

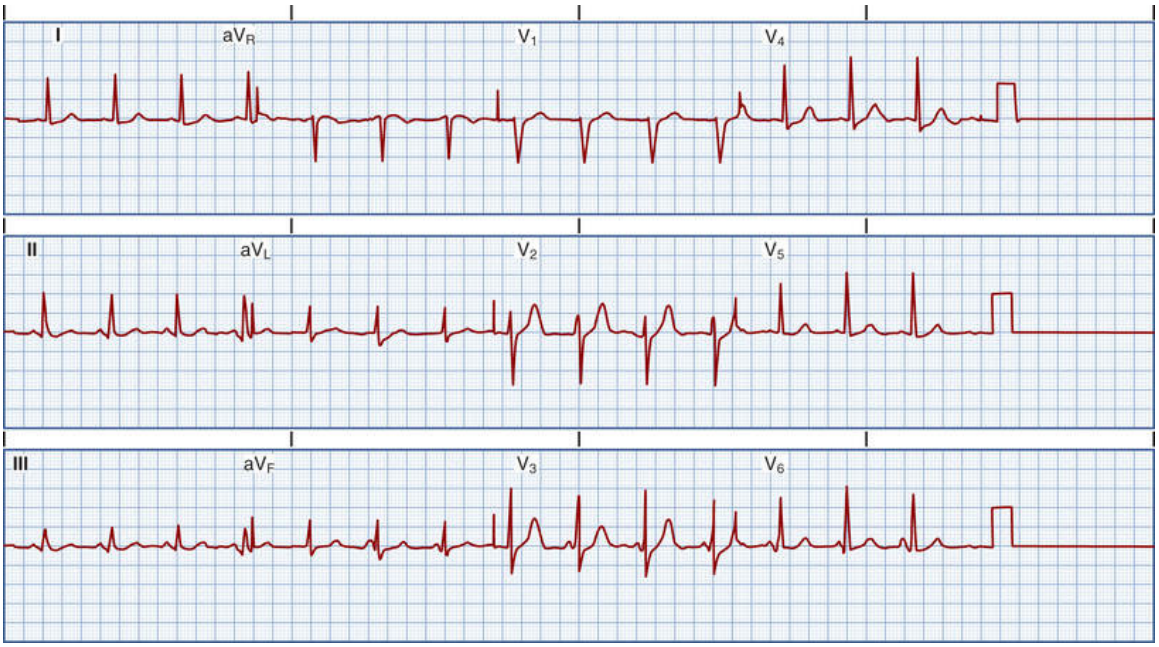

FIGURE 38-3 Twelve-lead electrocardiogram showing a normal sinus rhythm.

When a patient's ECG is being continuously monitored, between 1 and 12 ECG leads may be used. The leads most commonly selected are leads II, V_1, and a modified chest lead—MCL_1—(Figure 38-4), which is similar to V_1 and is used when only three leads are available for monitoring.

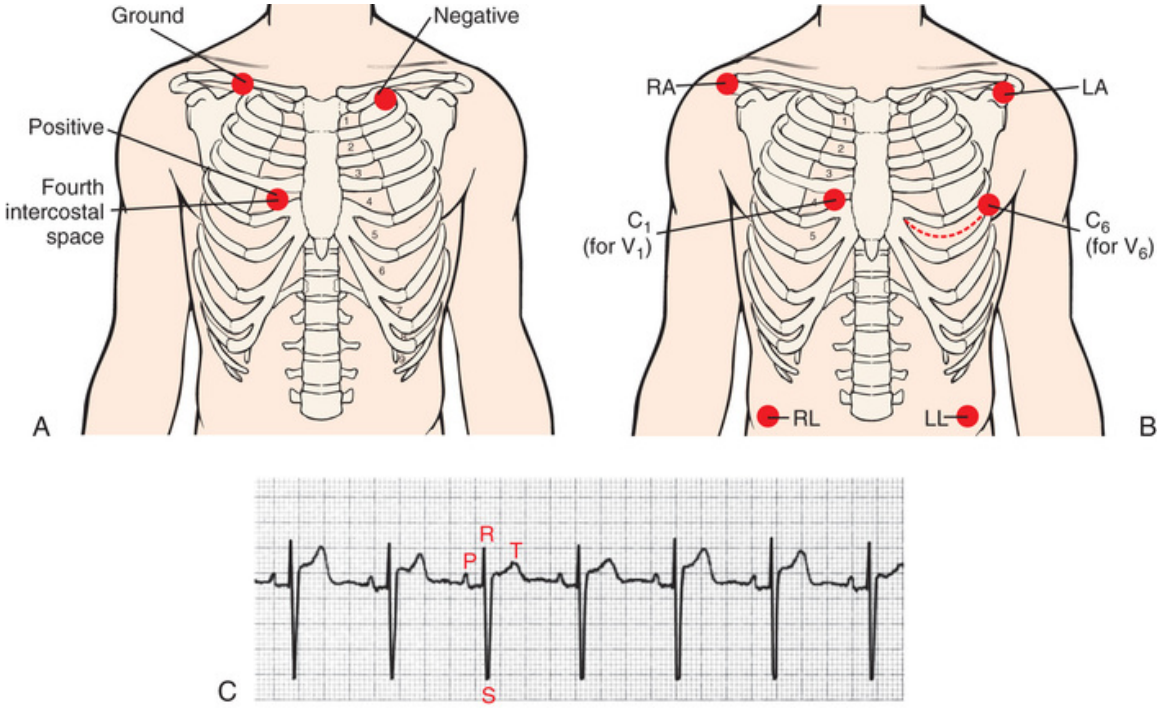

FIGURE 38-4 **A,** Lead placement for MCL_1 when a three-lead system is used. **B,** Lead placement for V_1 or V_6 when a five-lead system is used. **C,** Typical electrocardiographic tracing for lead MCL_1. *C,* chest; *LA,* left arm; *LL,* left leg; *RA,* right arm; *RL,* right leg.

Source: Adapted from Urden, L. D., Stacy, K. M., & Lough, M. E. (2010). *Critical care nursing: Diagnosis and management* (6th ed., p. 370). St. Louis: Mosby.

The ECG can be visualized continuously on a monitor oscilloscope. A recording of the ECG (i.e., rhythm strip) is obtained on ECG paper attached to the monitor. The recording provides documentation of the patient's rhythm. It also allows for measurement of complexes and intervals and for assessment of dysrhythmias.

To correctly interpret an ECG, the nurse must know how to measure time and voltage on the ECG paper. ECG paper consists of large squares (heavy lines) and small squares (light lines; see Figure 38-5). Each large square incorporates 25 smaller squares (five horizontal and five vertical). Each small square represents 0.04 seconds horizontally and 0.1 millivolt

(mV) vertically. This means that the large square represents 0.20 seconds and that 300 large squares represent 1 minute. Vertically, one large square is equal to 0.5 mV. These squares are used to calculate the heart rate (HR) and intervals between different ECG complexes.

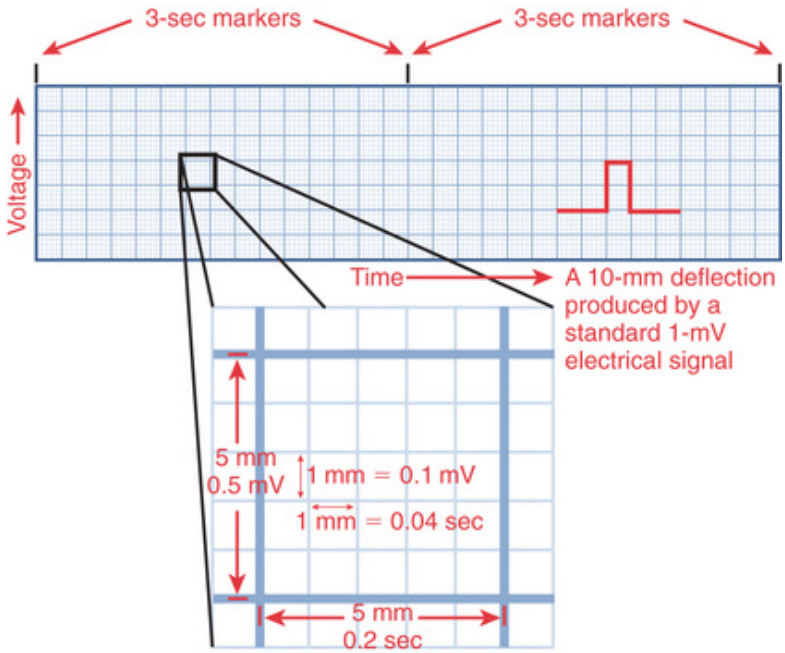

FIGURE 38-5 Time and voltage on the electrocardiogram. Source: Adapted from Wesley, K. (2011). *Huszar's basic dysrhythmias and acute coronary syndromes: Interpretation and management* (4th ed., p. 19). St. Louis: Mosby.

A variety of methods can be used to calculate the HR from an ECG. Probably the most accurate way is to count the number of QRS complexes in 1 minute. However, this method is time consuming. If the rhythm is regular, a simpler process can be used: Every 3 seconds, a marker appears on the ECG paper. An R wave is the first upward (or positive) deflection of the QRS complex. The nurse can count the number of R–R intervals in 6 seconds and multiply that number by 10. This calculation yields the approximate number of beats per minute (Figure 38-6).

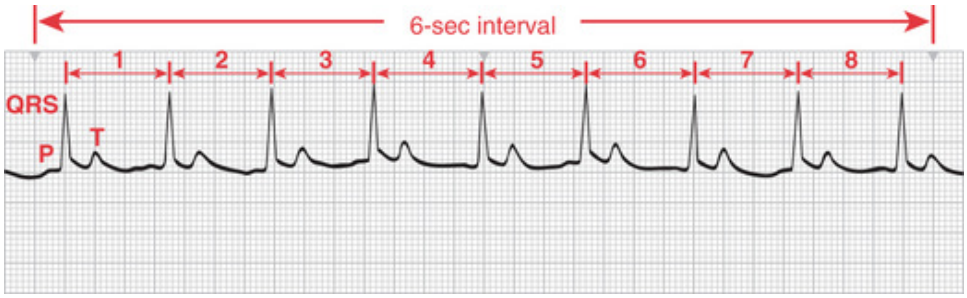

FIGURE 38-6 The heart rate is calculated according to the interval between first upward (or positive) deflection (R wave) of one QRS complex to the R wave of the next. When the rhythm is regular, heart rate can be determined at a glance. The estimated heart rate is 80. The actual heart rate is 86. Source: Adapted from Wesley, K. (2011). *Huszar's basic dysrhythmias and acute coronary syndromes: Interpretation and management* (4th ed., p. 56). St. Louis: Mosby.

Another rapid method for calculating the HR when the rhythm is regular is to count the number of small squares within one R–R interval. Dividing this number by 1 500 yields the HR. The number of large squares within one R–R interval can also be counted and divided by 300 (see Figure 38-6). These methods are accurate only if the rhythm is regular.

An additional way to measure distances on the ECG strip is to use calipers. Calipers are used for fine measurements, especially for points of a specific wave or interval. Many times, a P or R wave does not fall directly on a light or heavy line. The fine points of the calipers can be placed exactly on the components to be measured and then moved to another part of the strip for time measurement.

ECG leads are attached to the patient's chest wall by means of an electrode pad fixed with electrical conductive gel. Before placing these on a patient, the nurse must properly prepare the patient's skin. Excessive hair on the chest wall should be clipped with scissors. The nurse should prepare the skin by rubbing gently with dry gauze until the skin is slightly pink. If the skin is oily, alcohol may be used first. In the case of a diaphoretic patient, a skin protectant should be applied before the electrode is placed. If leads and electrodes are not firmly placed, or if there is muscle activity or electrical interference from an outside source, an artifact may be seen on the monitor. An *artifact* is a distortion of the baseline and waveforms seen on the ECG (Figure 38-7). Accurate interpretation of cardiac rhythm is difficult when an artifact is present. If artifacts occur, the nurse should check for loose connections in the equipment. The electrodes on the patient may need to be removed and

replaced more securely or moved to areas that are less affected by movement (Goldsworthy, 2016).

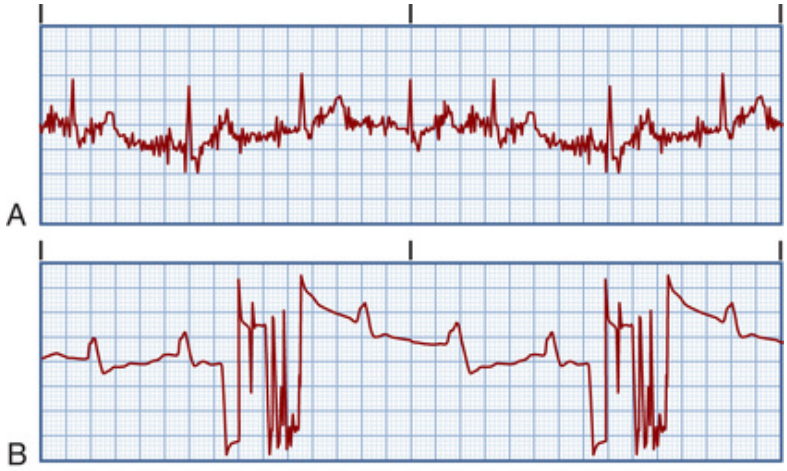

FIGURE 38-7 **A,** Electrocardiogram (ECG) demonstrating muscle tremor. **B,** ECG reflecting loose electrodes.

Telemetry Monitoring.

Telemetry monitoring is the observation of a patient's HR and rhythm to rapidly diagnose dysrhythmias, ischemia, or infarction. Two types of systems are used for telemetry monitoring. The first type, a centralized monitoring system, requires a nurse or telemetry technician to continuously observe all patients' rhythms at a central location. The second system of telemetry monitoring does not require constant surveillance by the nurse or technician. These systems have the capability of detecting and storing data. Sophisticated alarm systems provide different levels of detection of dysrhythmias, ischemia, or infarction, depending on the severity of each. However, computerized monitoring systems are not fail-proof. Frequent nursing assessment is important in caring for monitored patients.

Informatics in Practice

Wireless ECG Monitoring

- Wireless electrocardiogram (ECG) monitoring systems continuously monitor and interpret the findings, sending an alert when patient rhythm or measurements (or both) fall outside of set parameters.
- Early detection of abnormal heart rhythms allows time to assess the patient for signs of hemodynamic instability (e.g., chest pain, hypotension, palpitations, dyspnea) and determine the need to intervene (e.g., call the rapid response team).
- These systems can automatically save the pre-event portion of the ECG while continuing to record the post-event portion and send all of the information to the health care provider.
- Computerized monitoring systems are not fail-proof. The nurse must frequently assess all monitored patients for any signs of hemodynamic instability.

Assessment of Cardiac Rhythm

When assessing the cardiac rhythm, the nurse must make an accurate interpretation and immediately evaluate the consequences of the findings for an individual patient. Assessment of the patient's hemodynamic response to any change in rhythm is essential because this information guides the selection of therapeutic interventions. Determination of the cause of dysrhythmias should be a priority. For example, tachycardias may be the result of fever and may cause a decrease in cardiac output (CO) and hypotension. Certain dysrhythmias may be a result of electrolyte disturbances and may lead to a life-threatening dysrhythmia. At all times, the patient must be assessed and abnormalities treated.

Normal sinus rhythm is a rhythm that originates in the SA node and follows the normal conduction pattern of the cardiac cycle (Figure 38-8). Figure 38-9 shows the normal electrical pattern of the cardiac cycle. Table 38-2 provides a description of ECG waveforms and intervals and possible sources of disturbances in these features. The P wave represents the depolarization of the atria (passage of an electrical impulse through the atria), causing atrial contraction. The PR interval represents the period when the impulse spreads through the atria, the AV node, the bundle of His, and the Purkinje fibres. The QRS complex represents depolarization of the ventricles (ventricular contraction), and the QRS interval represents the time it takes for depolarization. The ST segment represents the time between ventricular depolarization and repolarization. This segment should be flat, or isoelectric, representing the absence of any electrical activity between these two events. The T wave represents repolarization of

the ventricles. The QT interval represents the total time for depolarization and repolarization of the ventricles.

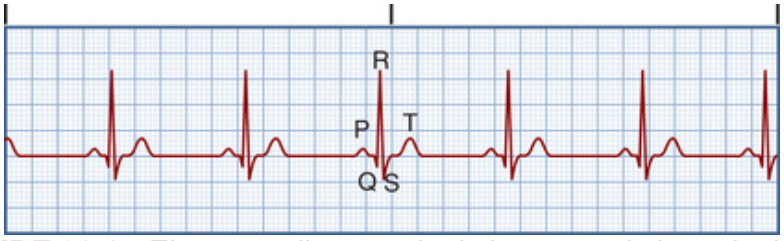

FIGURE 38-8 Electrocardiogram depicting normal sinus rhythm in lead II.

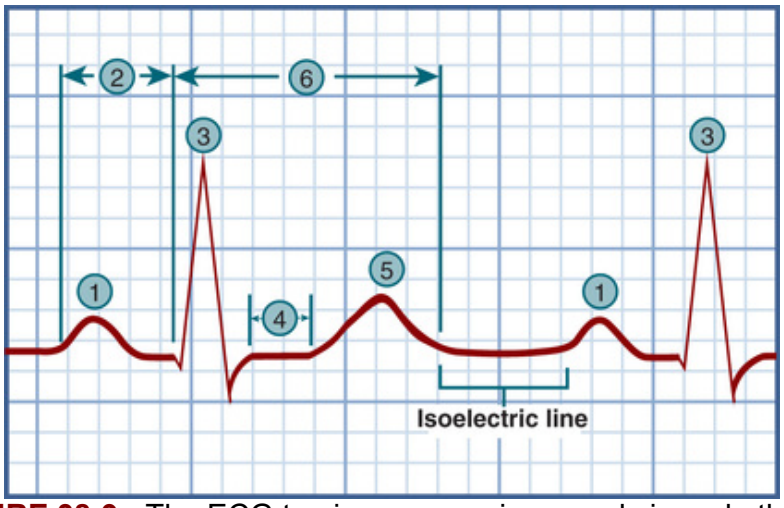

FIGURE 38-9 The ECG tracing as seen in normal sinus rhythm. 1, P wave; 2, PR interval; 3, QRS complex: Q wave, R wave, S wave; 4, ST segment; 5, T wave; 6, QT interval. Isoelectric (flat) line or baseline represents the absence of electrical activity in the heart cells.

TABLE 38-2

DEFINITION AND SOURCES OF VARIATION IN ECG WAVEFORMS AND INTERVALS*

Description	Normal Duration (sec)	Source of Possible Variation
P wave: Represents time for the electrical impulse that causes atrial depolarization (contraction) to pass through the atrium; should be upright	0.06–0.12	Disturbance in conduction within atria
PR interval: Measured from beginning of P wave to beginning of QRS complex; represents time taken for impulse to spread through the atria, the AV node and bundle of His, the bundle branches, and Purkinje fibres to a point immediately before ventricular contraction	0.12–0.20	Disturbance in conduction usually in AV node, bundle of His, or bundle branches but can be in atria as well
QRS interval: Measured from beginning to end of QRS complex; represents time taken for depolarization (contraction) of both ventricles (systole)	0.06–0.10	Disturbance in conduction in bundle branches or in ventricles
ST segment: Measured from the S wave of the QRS complex to the beginning of the T wave; represents the time between ventricular depolarization and repolarization (diastole); should be isoelectric (flat)	N/A	Disturbances usually caused by ischemia, injury, or infarction
T wave: Represents time for ventricular repolarization; should be upright	N/A	Disturbances usually caused by electrolyte imbalances, ischemia, or infarction
QT interval: Measured from beginning of QRS complex to end of T wave; represents time taken for entire electrical depolarization and repolarization of the ventricles	0.34–0.43	Disturbances usually affecting repolarization more than depolarization and caused by drugs, electrolyte imbalances, and changes in heart rate

*Heart rate influences the duration of these intervals, especially those of the PR and QT intervals (e.g., QT interval decreases in duration as heart rate increases).

AV, atrioventricular; *ECG,* electrocardiogram; *N/A,* not applicable.

Electrophysiological Mechanisms of Dysrhythmias

Disorders of impulse formation can cause dysrhythmias. The heart has specialized cells found in the SA node, parts of the atria, the AV node, and the bundle of His and Purkinje fibres (His–Purkinje system) that are able to discharge spontaneously. This situation is termed **automaticity.** Normally, the main pacemaker of the heart is the SA node, which spontaneously discharges 60 to 100 times per minute (Table 38-3). A pacemaker from another site may be discharged in two ways. If the SA node discharges more slowly than a secondary pacemaker, the electrical discharges from the secondary pacemaker may passively "escape." The secondary pacemaker then discharges automatically at its intrinsic rate. These secondary pacemakers may originate from the AV node or the His–Purkinje system at rates of 40 to 60 times per minute and 20 to 40 times per minute, respectively.

TABLE 38-3

Rates of the Conduction System

SA node	60–100 times/min
AV junction	40–60 times/min
Purkinje fibres	20–40 times/min

AV, atrioventricular; *SA*, sinoatrial.

Another way that secondary pacemakers can originate is when they discharge more rapidly than the normal pacemaker of the SA node. Early or late beats may be triggered at an ectopic focus (area outside the normal conduction pathway) in the atria, the AV node, or the ventricles. This may result in a dysrhythmia, which replaces the normal sinus rhythm.

The impulse started by the SA node or an ectopic focus must be conducted to the entire heart chamber. The property of myocardial tissue that allows it to be depolarized by a stimulus is called *excitability*. This is an important part of the transmission of the impulse from one fibre to another. The level of excitability is determined by the length of time after depolarization that the tissues can be reactivated. The recovery period after stimulation is called the *refractory phase* or *refractory period*. The absolute refractory phase or period occurs when excitability is zero and heart tissue cannot be stimulated. The relative refractory period occurs slightly later in the cycle, and excitability is more likely to occur. In states of full excitability, the heart is completely recovered. Figure 38-10 shows the relationship between the refractory period and the ECG.

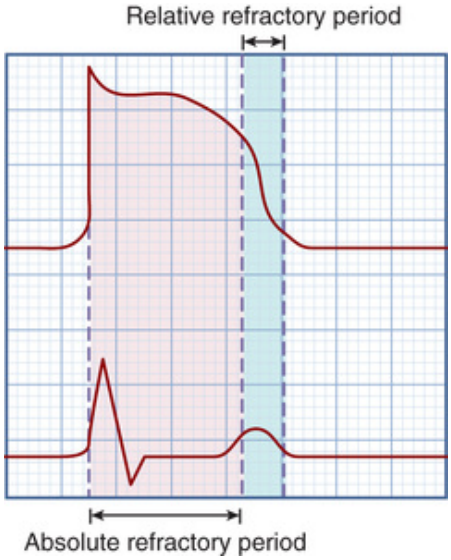

FIGURE 38-10 Diagram of absolute and relative refractory periods correlated with the cardiac muscle's action potential and with an ECG tracing. Source: Adapted from Urden, L. D., Stacy, K. M., & Lough, M. E. (2010). *Critical care nursing: Diagnosis and management* (6th ed., p. 368). St. Louis: Mosby.

If conduction is depressed, and if some areas of the heart are blocked (e.g., by necrosis), the unblocked areas are activated earlier than the blocked areas. When the block is unidirectional, this uneven conduction may allow the initial impulse to re-enter areas that were previously not excitable but have recovered. The re-entering impulse may be able to depolarize the atria and ventricles, causing a premature beat. If the re-entrant excitation continues, tachycardia occurs (Aehlert, 2013).

Evaluation of Dysrhythmias

Dysrhythmias occur as the result of various abnormalities and disease states (Aehlert, 2013). The cause of a dysrhythmia influences the treatment of the patient. Common causes of dysrhythmias are listed in Table 38-4. In Table 38-5, a systematic approach to assessing a cardiac rhythm is presented.

TABLE 38-4
Common Causes of Dysrhythmias

Cardiac Conditions	Other Conditions
• Accessory pathways • Conduction defects • Heart failure • Hypertrophy of cardiac muscle • Myocardial cell degeneration • Myocardial infarction	• Acid–base imbalances • Alcohol • Coffee, tea, tobacco • Connective tissue disorders • Drug effects or toxicity • Electric shock • Electrolyte imbalances • Emotional crisis • Hypoxia, shock • Metabolic conditions (e.g., thyroid dysfunction) • Near-drowning • Poisoning

TABLE 38-5
SYSTEMATIC APPROACH TO ASSESSING CARDIAC RHYTHMS

When assessing a cardiac rhythm, always assess the patient first, and then proceed with a systematic approach to interpreting the rhythm. A recommended approach is as follows:
1. Evaluate the rhythm (ventricular and atrial). 2. Determine the rate (ventricular and atrial). 3. Assess the presence and configuration of P waves. 4. Calculate the duration of the PR interval. 5. Calculate the QRS duration. 6. Calculate the QT interval. 7. Assess for changes in ST segment, T wave, or both. 8. Interpret the rhythm (e.g., atrial fibrillation). 9. Determine the clinical significance of this rhythm. Is the patient stable or unstable? 10. Determine the treatment for the rhythm.

Dysrhythmias occurring in out-of-hospital settings present problems of management. Determination of the rhythm by cardiac monitoring is a high priority. If indicated, the emergency medical services (EMS) system is contacted after the patient has been assessed. Emergency care of the patient with a dysrhythmia is outlined in Table 38-6.

TABLE 38-6

Emergency Management Dysrhythmias

Etiology	Assessment Findings	Interventions
See Table 38-4	• Chest, neck, shoulder, or arm pain • Cold, clammy skin • Decreased blood pressure • Decreased level of consciousness • Decreased O_2 saturation • Diaphoresis • Dizziness, syncope • Dyspnea • Extreme restlessness • Feeling of impending doom • Irregular rate and rhythm, palpitations • Nausea and vomiting • Numbness, tingling of arms • Pallor • Weakness and fatigue	**Initial** • Ensure patent airway • Administer O_2 via nasal cannula • Establish IV access • Apply cardiac monitoring electrodes • Identify underlying rhythm • Identify ectopic beats **Ongoing Monitoring** • Monitor vital signs, level of consciousness, O_2 saturation, and cardiac rhythm • Anticipate need for intubation if respiratory distress is evident • Prepare to initiate CPR or defibrillation, or both

CPR, cardiopulmonary resuscitation; *IV*, intravenous.

In addition to continuous ECG monitoring during hospitalization, several other methods are used to evaluate cardiac dysrhythmias and the effectiveness of antidysrhythmia drug therapy. An electrophysiological test (an invasive method) and Holter monitoring, event recorder monitoring, exercise treadmill testing, and signal-averaged ECG (all noninvasive methods) can be performed on both an inpatient and an outpatient basis.

An electrophysiological study (EPS) is performed to identify different mechanisms of tachydysrhythmias (dysrhythmias with rates >100), as well as heart blocks, bradydysrhythmias (dysrhythmias with rates <100), and causes of syncope. It can also be used to identify locations of accessory pathways and to determine the effectiveness of antidysrhythmia drugs. It involves introducing several electrode catheters transvenously through the femoral vein to the right side of the heart with fluoroscopic guidance. Electrical stimulation to various areas of the atrium and the ventricle is performed to induce the dysrhythmia. Immediate cardioversion or defibrillation may be required because serious dysrhythmias can be provoked during the procedure.

Preprocedure anxiety is common for patients undergoing EPS. Emotional support from the nurse is important. Patients should be told that they will be sedated but conscious during the procedure. Nursing care

before and after the procedure is similar to that for cardiac catheterization (see Chapter 34). (EPS is also discussed in Chapter 34.)

The Holter monitor is a device that records the ECG while the patient is ambulatory. The device can record heart rhythm for 24 to 48 hours while the patient performs daily activities. The patient maintains a diary in which activities and any symptoms are recorded. Events in the diary can later be correlated with any dysrhythmias observed on the recording. The monitor is generally a useful device for detecting significant dysrhythmias and evaluating the effects of drugs during a patient's normal activities. It can also be used for detecting ischemia by analyzing ST segments. A limitation of the device is that patients who have frequent ventricular dysrhythmias, some of which may be lethal, may not have these dysrhythmias during the monitored time. (Holter monitoring is also discussed in Chapter 34.)

Use of event monitors has greatly improved the evaluation of outpatient dysrhythmias. Event monitors are recorders that are activated by the patient and can be used only at the time the patient experiences symptoms. The recorder is placed over the patient's chest during symptoms. The patient then transmits the rhythm to a central monitoring company via telephone. This is an easier method of documenting a dysrhythmia than the 24-hour monitor, especially if symptoms are not occurring daily. (Ambulatory ECG monitoring is discussed in Chapter 34.)

Exercise treadmill testing is used for evaluation of cardiac rhythm response to exercise. Exercise-induced dysrhythmias can be reproduced and analyzed, and drug therapy can be evaluated. These tests are performed with routine treadmill testing protocols. Diagnostic procedures for assessment of the cardiovascular system are presented in Chapter 34, Table 34-6.

Types of Dysrhythmias

Examples of the ECG tracings of common dysrhythmias are presented in Figures 38-11 through 38-19. Descriptive characteristics of common dysrhythmias are presented in Table 38-7.

TABLE 38-7
Characteristics of Common Dysrhythmias

Pattern	Rate and Rhythm	P Wave	PR Interval	QRS Complex
Normal sinus rhythm	60–100 beats/min and regular	Normal	Normal	Normal
Sinus bradycardia	<60 beats/min and regular	Normal	Normal	Normal
Sinus tachycardia	>100 beats/min and regular	Normal	Normal	Normal
Premature atrial contraction	Usually 60–100 beats/min and irregular	Abnormal shape	Normal or variable	Normal (usually)
Paroxysmal supraventricular tachycardia	150–250 beats/min and regular	Abnormal shape, may be hidden	Variable	Normal (usually)
Atrial flutter	*Atrial:* 250–350 beats/min and regular *Ventricular:* >100 beats/min and irregular	Sawtooth shape	Variable	Normal (usually)
Atrial fibrillation	*Atrial:* 350–600 beats/min and irregular *Ventricular:* >100 beats/min and irregular or possibly any rate	Chaotic, fibrillatory	Not present	Normal (usually)
Junctional rhythms	40–140 beats/min and regular	Inverted (may be hidden)	Variable	Normal (usually)
First-degree AV heart block	Normal and regular	Normal	>0.20 sec, constant	Normal
Second-degree AV heart block				
Type I (Mobitz I, Wenckebach's)	*Atrial:* Normal and regular *Ventricular:* Slower and irregular	Normal	Progressively lengthened	Normal width, with pattern of one nonconducted QRS complex
Type II (Mobitz II)	*Atrial:* Usually normal and regular or irregular *Ventricular:* Slower and regular or irregular	More P waves than QRS complexes	Normal or prolonged	Widened, preceded by two or more P waves
Third-degree AV heart block	Ventricular rate 20–40 beats/min and regular	Normal, but no connection with QRS complex	None; PR interval not related to QRS complex; more P waves than QRS complexes	Normal or widened; no connection with P waves
Premature ventricular contraction	60–100 beats/min and irregular	None	Not present	Wide and distorted
Ventricular tachycardia	100–250 beats/min and regular or irregular	None	None	Wide and distorted
Ventricular fibrillation	Not measurable and irregular	Absent	Not present	Not measurable

AV, atrioventricular.

Sinus Bradycardia.

In sinus bradycardia, the conduction pathway is the same as that in sinus rhythm, but the SA node fires at a rate less than 60 beats/minute. This is referred to as *absolute bradycardia* (Figure 38-11, *A*). Relative bradycardia is an HR that is less than expected for the patient's condition, causing symptoms (Aehlert, 2013).

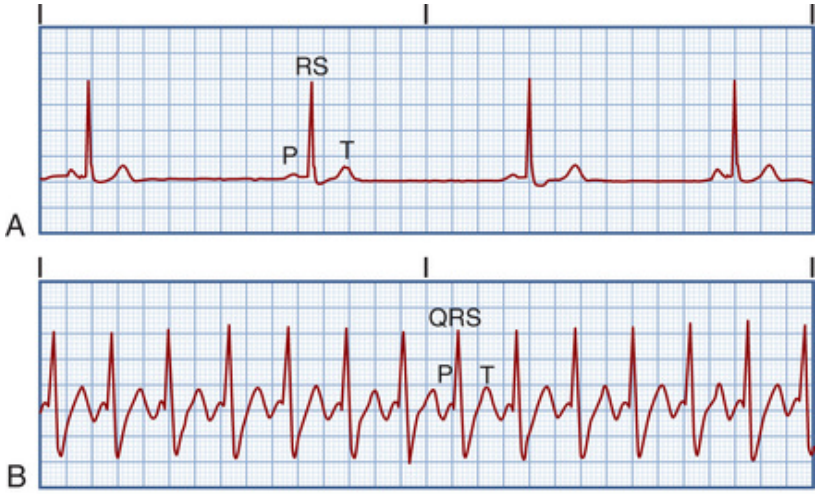

FIGURE 38-11 **A,** ECG demonstrating sinus bradycardia. **B,** ECG demonstrating sinus tachycardia.

Clinical Associations.

Sinus bradycardia may be a normal sinus rhythm in aerobically trained athletes and in other individuals during sleep. It also occurs in response to carotid sinus massage, the Valsalva manoeuvre, hypothermia, increased intraocular pressure, increased vagal tone, and administration of parasympathomimetic drugs (e.g., bethanechol [Duvoid]). Disease states associated with sinus bradycardia are hypothyroidism, increased intracranial pressure, obstructive jaundice, and inferior wall myocardial infarction (MI).

Electrocardiographic Characteristics.

In sinus bradycardia, the HR is less than 60 beats/minute, and the rhythm is regular. The P wave precedes each QRS complex and has a normal

shape and duration. The PR interval is normal, and the QRS complex has a normal shape and duration.

Clinical Significance.

The clinical significance of sinus bradycardia depends on how the patient tolerates it hemodynamically. Signs of symptomatic bradycardia can include pale, cool skin; hypotension; weakness; angina; dizziness or syncope; confusion or disorientation; and shortness of breath.

Treatment.

Treatment of sinus bradycardia consists of administration of atropine (an anticholinergic drug) for the patient with symptoms. Pacemaker therapy may be required.

Sinus Tachycardia.

The conduction pathway is the same in sinus tachycardia as that in normal sinus rhythm. The discharge rate from the sinus node is increased as a result of vagal inhibition or sympathetic stimulation. The sinus rate is greater than 100 beats/minute (see Figure 38-11, *B*).

Clinical Associations.

Sinus tachycardia is associated with physiological and psychological stressors such as exercise, fever, pain, hypotension, hypovolemia, anemia, hypoxia, hypoglycemia, myocardial ischemia, heart failure (HF), hyperthyroidism, anxiety, and fear. It can also be an effect of drugs such as epinephrine (EpiPen), norepinephrine (Levophed), atropine, caffeine, theophylline, nifedipine, or hydralazine (Apresoline). In addition, many over-the-counter cold remedies have active ingredients (e.g., pseudoephedrine [Sudafed]) that can cause tachycardia.

Electrocardiographic Characteristics.

In sinus tachycardia, the HR is greater than 100 beats/minute and the rhythm is regular. The P wave is normal, precedes each QRS complex, and has a normal shape and duration. The PR interval is normal, and the QRS complex has a normal shape and duration.

Clinical Significance.

The clinical significance of sinus tachycardia depends on the patient's tolerance of the increased HR. The patient may have symptoms of

dizziness, dyspnea, and hypotension. Increased myocardial oxygen consumption is associated with an increased HR. Angina or an increase in infarction size may accompany persistent sinus tachycardia in patients with an acute MI.

Treatment.

Treatment is based on the underlying cause. For instance, if the patient is experiencing tachycardia from pain, tachycardia should resolve with effective pain management.

Premature Atrial Contraction.

A **premature atrial contraction (PAC)** is a contraction originating from an ectopic focus in one atrium in a location other than the sinus node. The ectopic signal originates in the left or the right atrium and travels across both atria by an abnormal pathway, causing the P wave to be distorted (Figure 38-12). At the AV node, it may be stopped (nonconducted PAC), delayed (lengthened PR interval), or conducted normally. If the signal moves through the AV node, in most cases it is conducted normally through the ventricles.

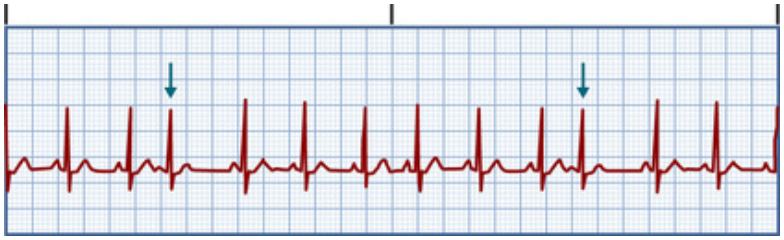

FIGURE 38-12 ECG demonstrating premature atrial contractions *(arrows)*.

Clinical Associations.

In a normal heart, a PAC can result from emotional stress, physical fatigue, or the use of caffeine, tobacco, or alcohol. A PAC can also result from hypoxia, electrolyte imbalances, and disease states such as hyperthyroidism, chronic obstructive pulmonary disease (COPD), and heart disease, including coronary artery disease (CAD) and valvular disease.

Electrocardiographic Characteristics.

Heart rate varies with the underlying rate and frequency of the PAC, and the rhythm is irregular. The P wave has a different shape from that of the P wave originating from the SA node. It may be notched or have downward (or negative) deflection, or it may be hidden in the preceding T wave. The PR interval may be shorter or longer than the PR interval originating from the SA node, but its length is within normal limits. The QRS complex is usually normal. If the QRS interval is 0.12 seconds or longer, conduction through the ventricles is abnormal.

Clinical Significance.

In people with healthy hearts, isolated PACs are not significant. In people with heart disease, frequent PACs may indicate enhanced automaticity of the atria or a re-entry mechanism. Such PACs may warn of or initiate more serious dysrhythmias (e.g., supraventricular tachycardia).

Treatment.

Treatment of PAC depends on the patient's symptoms. Withdrawal of sources of stimulation such as caffeine or sympathomimetic drugs may be warranted.

Paroxysmal Supraventricular Tachycardia.

Paroxysmal supraventricular tachycardia (PSVT) is a dysrhythmia originating in an ectopic focus anywhere above the bifurcation of the bundle of His (Figure 38-13). Identification of the ectopic focus is often difficult even with 12-lead ECG because the dysrhythmia must be recorded as it is initiated.

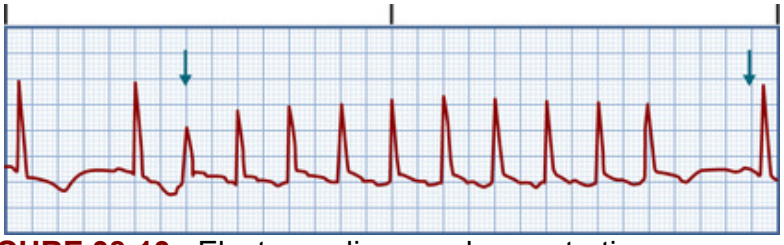

FIGURE 38-13 Electrocardiogram demonstrating paroxysmal supraventricular tachycardia (PSVT). Arrows indicate beginning and ending of PSVT.

PSVT occurs because of a re-entrant phenomenon (re-excitation of the atria when there is a one-way block). Usually, a PAC triggers a run of

repeated premature beats. *Paroxysmal* refers to an abrupt onset and termination. The termination is sometimes followed by a brief period of asystole. Some degree of AV block may be present. PSVT can occur in the presence of Wolff–Parkinson–White (WPW) syndrome, or "pre-excitation." In this syndrome, extra conduction pathways or accessory pathways are present.

Clinical Associations.

In the normal heart, PSVT is associated with overexertion, emotional stress, deep inspiration, and stimulants such as caffeine and tobacco. PSVT is also associated with rheumatic heart disease, digitalis toxicity, CAD, and cor pulmonale.

Electrocardiographic Characteristics.

In PSVT, the HR is 100 to 300 beats/minute, and rhythm is regular or slightly irregular. The P wave is often hidden in the preceding T wave, but if seen, it may have an abnormal shape. The PR interval may be shortened or normal, and the QRS complex is usually normal.

Clinical Significance.

The clinical significance of PSVT depends on symptoms and HR. A prolonged episode and heart rate greater than 180 beats/minute may precipitate a decrease in CO, resulting in hypotension, dyspnea, and angina.

Treatment.

Treatment for PSVT includes vagal stimulation and drug therapy. Common vagal manoeuvres include Valsalva manoeuvres and coughing. Intravenous (IV) adenosine is the drug of first choice to convert PSVT to a normal sinus rhythm. This drug has a short half-life (1.5–10 seconds) and is well tolerated by most patients (Lehne, 2016). IV β-adrenergic blockers, calcium channel blockers (e.g., diltiazem [Cardizem]), and amiodarone can also be used. For a patient with WPW syndrome, amiodarone should be used. If vagal stimulation and drug therapy are ineffective and the patient becomes hemodynamically unstable, direct-current (DC) cardioversion may be used. (Cardioversion is discussed on p. 881.) If PSVT recurs in patients with WPW syndrome, they may ultimately be treated with radiofrequency ablation of the accessory pathway. (Radiofrequency ablation therapy is discussed on p. 884.)

Drug Alert

Adenosine (Adenocard)

- Injection site should be as close to the heart as possible (e.g., antecubital area).
- IV dose should be given rapidly (over 1–2 seconds) and followed with a rapid 20-mL normal saline flush.
- Patient's ECG must be monitored continuously. Brief period of asystole can occur.
- Patient should be observed for flushing, dizziness, chest pain, or palpitations.

Atrial Flutter.

Atrial flutter is an atrial tachydysrhythmia identified by recurring, regular, sawtooth-shaped flutter (F) waves that originate from a single ectopic focus in the right atrium (Figure 38-14, *A*).

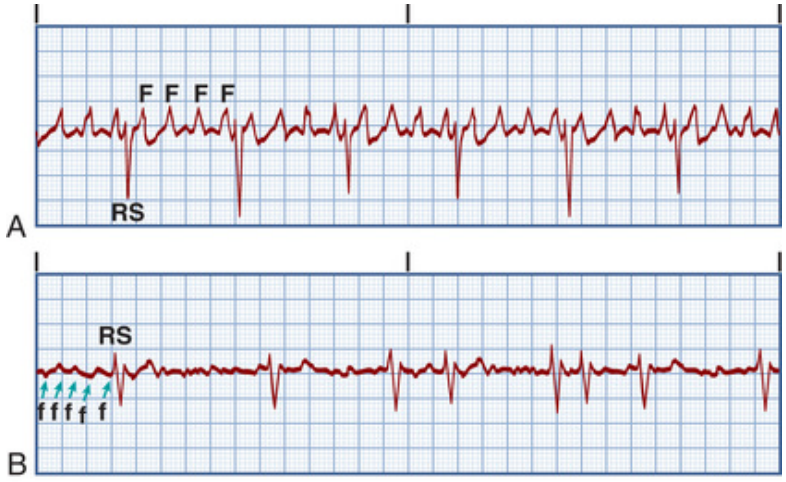

FIGURE 38-14 **A,** Atrial flutter with a 4 : 1 conduction (four flutter *[F]* waves to each QRS complex). **B,** Atrial fibrillation with a controlled ventricular response. Note the chaotic fibrillatory *(f)* waves *(arrows)* between the RS complexes. NOTE: Recorded from lead V_1.

Clinical Associations.

Atrial flutter rarely occurs in a normal heart. It is associated with disease states such as CAD, hypertension, mitral valve disorders, pulmonary embolus, chronic lung disease, cor pulmonale, cardiomyopathy, and hyperthyroidism and with the use of drugs such as digoxin, quinidine, and epinephrine.

Electrocardiographic Characteristics.

In atrial flutter, atrial rate is 250 to 350 beats/minute. The ventricular rate varies according to the conduction ratio. In 2 : 1 conduction, the ventricular rate is typically found to be approximately 150 beats/minute. Atrial rhythm is regular, and ventricular rhythm is usually regular. The atrial flutter waves represent atrial depolarization followed by repolarization. The PR interval is variable and cannot be measured. The QRS complex is usually normal. Because of the ability of the AV node to delay signals from the atria, there is usually some AV block in a fixed ratio of flutter waves to QRS complexes (e.g., 2 : 1, 3 : 1).

Clinical Significance.

The high ventricular rates (>100 beats/minute) and loss of the atrial "kick" (atrial contraction reflected by a sinus P wave) that are associated with atrial flutter can decrease CO and cause serious consequences such as HF, especially in the patient with underlying heart disease. Patients with atrial flutter are at increased risk for stroke because of the risk for thrombus formation in the atria from the stasis of blood. Warfarin (Coumadin) is used to prevent stroke in patients with atrial flutter of longer than 48 hours' duration (American Heart Association [AHA], 2015).

Treatment.

The primary goal in treatment of atrial flutter is to slow the ventricular response by increasing AV block. Drugs used to control ventricular rate include calcium channel blockers and β-adrenergic blockers. Electrical cardioversion may be used to convert the atrial flutter to sinus rhythm in an emergency situation (i.e., the patient is hemodynamically unstable) and electively. Antidysrhythmia drugs used to convert atrial flutter to sinus rhythm or to maintain sinus rhythm include amiodarone, propafenone (Rythmol), and ibutilide (Corvert) (Lehne, 2016).

Radiofrequency ablation is increasingly being used as curative therapy for atrial flutter. The procedure is performed in the electrophysiology laboratory and involves positioning a catheter in the right atrium between

the inferior vena cava and the tricuspid valve. With the use of a low-voltage, high-frequency form of electrical energy, the tissue is ablated (or destroyed), the dysrhythmia is terminated, and normal sinus rhythm is restored in most cases (Greenberg & Chandrakantan, 2015). (Radiofrequency ablation in discussed on p. 884.)

Atrial Fibrillation.

Atrial fibrillation is characterized by a total disorganization of atrial electrical activity caused by multiple ectopic foci, resulting in loss of effective atrial contraction (see Figure 38-14, *B*). Atrial fibrillation is the most common dysrhythmia encountered in the emergency department, and the focus of treatment is the rapid assessment of potential hemodynamic instability and identification and treatment of the underlying cause (Stiell & Macle, 2011). The dysrhythmia may be chronic or intermittent. Atrial fibrillation is the most common dysrhythmia in Canada, affecting approximately 350 000 people (Heart and Stroke Foundation, 2017). Its prevalence increases with age.

Clinical Associations.

Atrial fibrillation usually occurs in patients with underlying heart disease, such as CAD, rheumatic heart disease, cardiomyopathy, hypertensive heart disease, HF, and pericarditis. It is often acutely caused by factors such as thyrotoxicosis, alcohol intoxication, caffeine use, electrolyte disturbances, stress, and cardiac surgery.

Electrocardiographic Characteristics.

During atrial fibrillation, the atrial rate may be as high as 600 beats/minute. Ventricular rate can vary from as low as 50 beats/minute to as high as 180 beats/minute. Atrial fibrillation with ventricular rates greater than 100 are described as atrial fibrillation with a rapid ventricular response. When ventricular rates are less than 100, the condition is described as atrial fibrillation with a slow or controlled ventricular response. P waves are replaced by chaotic, fibrillatory waves in atrial fibrillation. The ventricular rhythm is usually irregular. The PR interval is not measurable, but the QRS complex usually has a normal shape and duration. At times, atrial flutter and atrial fibrillation may coexist.

Clinical Significance.

Atrial fibrillation can often result in a decrease in CO because of ineffective atrial contractions or loss of atrial kick, a rapid ventricular response, or both. Thrombi may form in the atria as a result of blood stasis. An embolized clot may develop and travel to the brain, causing a stroke. Overall risk for stroke is increased three to five times with atrial fibrillation (Heart and Stroke Foundation, 2017).

Treatment.

The goals of treatment for atrial fibrillation include a decrease in ventricular response (to <100/minute) and prevention of cerebral embolic events (Stiell & Macle, 2011). Ventricular rate control is a priority for patients with atrial fibrillation. Drugs used for rate control include calcium channel blockers (e.g., diltiazem) and β-adrenergic blockers (e.g., metoprolol).

For some patients, conversion of atrial fibrillation to a normal sinus rhythm may be a consideration (e.g., reduced exercise tolerance with rate control drugs, contraindications to warfarin). Antidysrhythmia drugs used for conversion to and maintenance of sinus rhythm include medications such as amiodarone in the stable patient (AHA, 2015). In unstable patients with severe left ventricular dysfunction or HF, amiodarone or DC cardioversion should be used (AHA, 2015).

Cardioversion may be used to convert atrial fibrillation to a normal sinus rhythm. Before proceeding to cardioversion, in the absence of systemic anticoagulation, the nurse must determine that the patient has had atrial fibrillation or atrial flutter for less than 48 hours (Stiell & Macle, 2011). The cardioversion procedure can cause clots to dislodge, which increases the patient's risk for stroke. If clots are present, the procedure is contraindicated.

If drugs or cardioversion do not convert atrial fibrillation to normal sinus rhythm, long-term anticoagulation therapy is required. Long-term follow-up with patients experiencing atrial fibrillation or flutter is recommended to assess the need for long-term antithrombotic therapy or antiarrhythmic therapy. (See Chapter 40 for discussion of anticoagulation therapy.)

Other treatment strategies exist for drug-refractory atrial fibrillation and for patients who cannot or choose not to have long-term anticoagulation. These include the use of radiofrequency ablation, which is similar to the procedure for atrial flutter (Canadian Cardiovascular Society, 2011).

Evidence-Informed Practice

Translating Research Into Practice

Geena Dodd is an 82-year-old woman with a new onset of atrial fibrillation and a history of mitral stenosis (high-risk factor). Her physician has ordered warfarin (Coumadin) to be started. The nurse begins to teach her about the purpose and adverse effects of warfarin. She stops the nurse and states that she will not take the medicine—she has heard too many stories about people bleeding from this medication. Furthermore, she says that she does not want to deal with the blood tests that are needed nor worry about what she eats. She states that she will continue to take her aspirin once a day as usual.

Best Available Evidence	Clinician Expertise	Patient Preferences and Values
Warfarin (Coumadin) is the drug of choice to treat patients with atrial fibrillation who have one or more high-risk factors, in order to prevent stroke. For patients for whom oral anticoagulation with warfarin is considered unsuitable (e.g., patient preference), the addition of clopidogrel (Plavix) to ASA (Aspirin) reduces the risk for major vascular events (especially stroke) but increases the risk for major hemorrhage.	Bleeding is a potential and serious adverse effect of warfarin and of dual antiplatelet therapy (ASA; Aspirin and clopidogrel). When taking warfarin, INR blood levels need to be checked on a regular basis. Patients should avoid drastic changes in diet, especially foods high in vitamin K (interfere with the action of warfarin).	Mrs. Dodd does not want to take warfarin or clopidogrel because she is afraid of bleeding. In addition, she does not want to change her lifestyle to accommodate the changes that would be needed to use warfarin.

Decision and Action

The nurse explains the risks of not taking the prescribed medicine (warfarin) or adequate medication (adding clopidogrel to her ASA [Aspirin] therapy). She tells the nurse that she understands completely. The nurse supports her choice and informs the physician of Mrs. Dodd's decision.

ASA, Acetylsalicylic acid; *INR,* international normalized ratio.

Junctional Dysrhythmias.

Junctional dysrhythmias are dysrhythmias that originate in the area of the AV node, primarily because the SA node has failed to fire or the signal has been blocked. In this situation, the AV node becomes the pacemaker of the heart. The impulse from the AV node usually moves in a retrograde (backward) manner that produces an abnormal P wave occurring just before or after the QRS complex or that is hidden in the QRS complex. The impulse usually moves normally through the ventricles. Junctional premature beats may occur, and they are treated in a manner similar to that for PACs. Other junctional dysrhythmias include junctional escape rhythm (Figure 38-15), accelerated junctional rhythm, and junctional tachycardia. These dysrhythmias are treated according to the patient's tolerance of the rhythm and the patient's clinical condition.

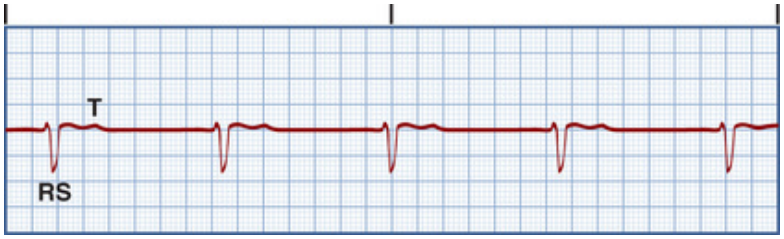

FIGURE 38-15 Electrocardiogram demonstrating junctional escape rhythm. The P wave is hidden in the QRS complex. NOTE: Recorded from lead V_1.

Clinical Associations.

Junctional dysrhythmias are often associated with CAD, HF, cardiomyopathy, electrolyte imbalances, inferior MI, and rheumatic heart disease. Certain drugs (e.g., digoxin, amphetamines, caffeine, nicotine) can also cause junctional dysrhythmias (Aehlert, 2013).

Electrocardiographic Characteristics.

In junctional escape rhythm, the HR is 40 to 60 beats/minute; in accelerated junctional rhythm, it is 61 to 100 beats/minute; and in junctional tachycardia, it is 101 to 150 beats/minute. Rhythm is regular. The P wave is abnormal in shape and inverted, or it may be hidden in the QRS complex (see Figure 38-15). The PR interval is less than 0.12 seconds when the P wave precedes the QRS complex. The QRS complex is usually normal.

Clinical Significance.

Junctional escape rhythms serve as a safety mechanism for when the SA node has not been effective in firing. Escape rhythms such as this should not be suppressed. Accelerated junctional rhythm and junctional tachycardia, however, indicate a more serious problem with the sinoatrial node. These rhythms may result in a reduction of CO, causing the patient to become hemodynamically unstable (e.g., hypotensive).

Treatment.

Treatment varies according to the type of junctional dysrhythmia. If a patient has symptoms with an escape junctional rhythm, atropine can be administered. In accelerated junctional rhythm and junctional tachycardia caused by digoxin toxicity, the digoxin is withheld. In the absence of digoxin toxicity, β-adrenergic blockers, calcium channel blockers, and amiodarone are used for rate control.

First-Degree Atrioventricular Block.

First-degree atrioventricular (AV) block is a type of AV block in which every impulse is conducted to the ventricles but the duration of AV conduction is prolonged (Figure 38-16, *A*). After the impulse moves through the AV node, it is usually conducted normally through the ventricles.

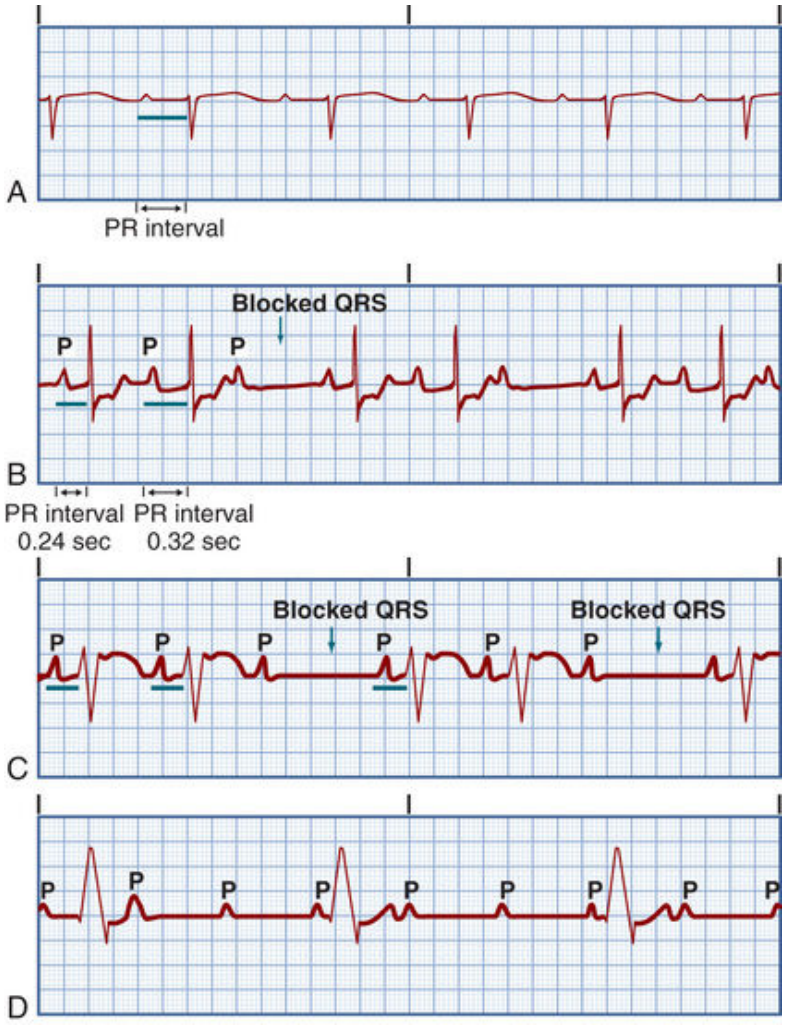

FIGURE 38-16 Heart block. **A,** First-degree atrioventricular (AV) block with a PR interval of 0.40 seconds. **B,** Second-degree AV block, type I, with progressive lengthening of the PR interval until a QRS complex is blocked. **C,** Second-degree AV block, type II, with constant PR intervals and variable blocked QRS complexes. **D,** Third-degree AV block. Note that there is no relationship between P waves and QRS complexes.

Clinical Associations.

First-degree AV block is associated with MI, CAD, rheumatic fever, hyperthyroidism, vagal stimulation, and drugs such as digoxin, β-adrenergic blockers, calcium channel blockers, and flecainide.

Electrocardiographic Characteristics.

In first-degree AV block, the HR is normal, and the rhythm is regular. The P wave is normal, the PR interval is prolonged to more than 0.20 seconds,

and the QRS complex usually has a normal shape and duration.

Clinical Significance.

First-degree AV block is usually not serious but can be a precursor of higher degrees of AV block. Patients with first-degree AV block have no symptoms.

Treatment.

There is no treatment for first-degree AV block. Modifications to causative medications may be considered. Patients should continue to be monitored for any new changes in heart rhythm.

Second-Degree Atrioventricular Block, Type I.

Type I second-degree AV block (Mobitz I or *Wenckebach's heart block)* includes a gradual lengthening of the PR interval. It occurs because of a prolonged AV conduction time until an atrial impulse is not conducted and a QRS complex is blocked (missing) (see Figure 38-16, *B*). Type I AV block most commonly occurs in the AV node, but it can also occur in the His–Purkinje system.

Clinical Associations.

Type I AV block may result from the use of drugs such as digoxin or β-adrenergic blockers. It may also be associated with CAD and other diseases that can slow AV conduction.

Electrocardiographic Characteristics.

The atrial rate is normal, but the ventricular rate may be slower as a result of nonconducted atrial impulses or blocked QRS complexes. Once a ventricular beat is blocked, the cycle repeats itself with progressive lengthening of the PR intervals, until another QRS complex is blocked. The rhythm appears on the ECG in a pattern of grouped beats. Ventricular rhythm is irregular. The P wave has a normal shape. The QRS complex has a normal shape and duration.

Clinical Significance.

Type I AV block is usually a result of myocardial ischemia or infarction. It is almost always transient and is usually well tolerated. However, in some patients (e.g., after an MI), it may be a warning signal of a more serious AV conduction disturbance.

Treatment.

If the patient has symptoms, atropine is used to increase the HR, or a temporary pacemaker may be needed, especially if the patient has experienced an MI. If the patient has no symptoms, the rhythm should be closely observed with a transcutaneous pacemaker on standby. Bradycardia is more likely to become symptomatic when one or more of the following are present: (a) hypotension, (b) HF, or (c) shock.

Second-Degree Atrioventricular Block, Type II.

In *type II second-degree AV block (Mobitz II heart block),* a P wave is not conducted without progressive antecedent PR lengthening. This almost always occurs when a block in one of the bundle branches is present (see Figure 38-16, *C*). On conducted beats, the PR interval is constant. Type II second-degree AV block is a more serious type of block, in which a certain number of impulses from the SA node are not conducted to the ventricles. This occurs in ratios of 2 : 1, 3 : 1, and so on (i.e., two P waves to one QRS complex, three P waves to one QRS complex). It may occur with varying ratios. Type II AV block almost always originates in the His–Purkinje system.

Clinical Associations.

Type II AV block is associated with rheumatic heart disease, CAD, anterior MI, and digitalis toxicity.

Electrocardiographic Characteristics.

The atrial rate is usually normal. The ventricular rate depends on the intrinsic rate and the degree of AV block. The atrial rhythm is regular, but the ventricular rhythm may be irregular. The P wave has a normal shape. The PR interval may be normal or prolonged in duration and remains constant on conducted beats. The QRS complex is usually more than 0.12 seconds because of bundle-branch block.

Clinical Significance.

Type II AV block often progresses to third-degree AV block and is associated with a poor prognosis. The reduced HR often results in decreased CO with subsequent hypotension and myocardial ischemia. Type II AV block is an indication for therapy with a permanent pacemaker.

Treatment.

Temporary treatment before the insertion of a permanent pacemaker may be necessary if the condition becomes symptomatic (e.g., hypotension, angina). Such treatment involves the use of a temporary transvenous or transcutaneous pacemaker (Aehlert, 2013).

Third-Degree Atrioventricular Block.

Third-degree AV block, or **complete heart block,** constitutes one form of AV dissociation, in which no impulses from the atria are conducted to the ventricles (see Figure 38-16, *D*). The atria are stimulated and contract independently of the ventricles. The ventricular rhythm is an escape rhythm, and the ectopic pacemaker may be above or below the bifurcation of the bundle of His.

Clinical Associations.

Third-degree AV block is associated with severe heart disease, including CAD, MI, myocarditis, cardiomyopathy, and some systemic diseases such as amyloidosis and progressive systemic sclerosis (scleroderma). Some medications can also cause third-degree AV block, such as digoxin, β-adrenergic blockers, and calcium channel blockers.

Electrocardiographic Characteristics.

The atrial rate with third-degree AV block is usually a sinus rate of 60 to 100 beats/minute. The ventricular rate depends on the site of the block. If it is in the AV node, the rate is 40 to 60 beats/minute, and if it is in the His–Purkinje system, it is 20 to 40 beats/minute. Atrial and ventricular rhythms are regular but unrelated to each other. The P wave has a normal shape. The PR interval is variable, and there is no time relationship between the P wave and the QRS complex. The QRS complex is normal if an escape rhythm is initiated at the bundle of His or above. It is widened if an escape rhythm is initiated below the bundle of His.

Clinical Significance.

Third-degree AV block almost always results in reduced CO with subsequent ischemia, HF, and shock. Syncope from third-degree AV block may result from severe bradycardia or even periods of asystole.

Treatment.

When patients are unstable in the presence of a bradycardia, a transcutaneous pacemaker is typically used as first-line treatment (AHA,

2015). The use of drugs such as atropine, epinephrine, isoproterenol, and dopamine is a temporary measure to increase the HR and support blood pressure (BP) until temporary pacing is initiated. Patients need a permanent pacemaker implanted as soon as possible.

Premature Ventricular Contractions.

A **premature ventricular contraction (PVC)** is a contraction originating in an ectopic focus in the ventricles. It is the premature occurrence of a QRS complex, which is wide and whose shape is distorted in comparison with a QRS complex initiated from the normal conduction pathway (Figure 38-17). PVCs that are initiated from different foci appear different in shape from each other and are called *multifocal* PVCs. PVCs that appear to have the same shape are called *unifocal* PVCs. When every other beat is a PVC, it is called *ventricular bigeminy.* When every third beat is a PVC, it is called *ventricular trigeminy.* Two consecutive PVCs are called a *couplet.* When three or more consecutive PVCs occur, it is called *ventricular tachycardia.* A PVC that falls on the T wave of a preceding beat is called the *R-on-T phenomenon*. This phenomenon is considered especially dangerous because the PVC is occurring during the relative refractory phase of ventricular repolarization. Excitability of the cardiac cells is increased during this time, and the risk for the PVC to initiate ventricular tachycardia or ventricular fibrillation is high.

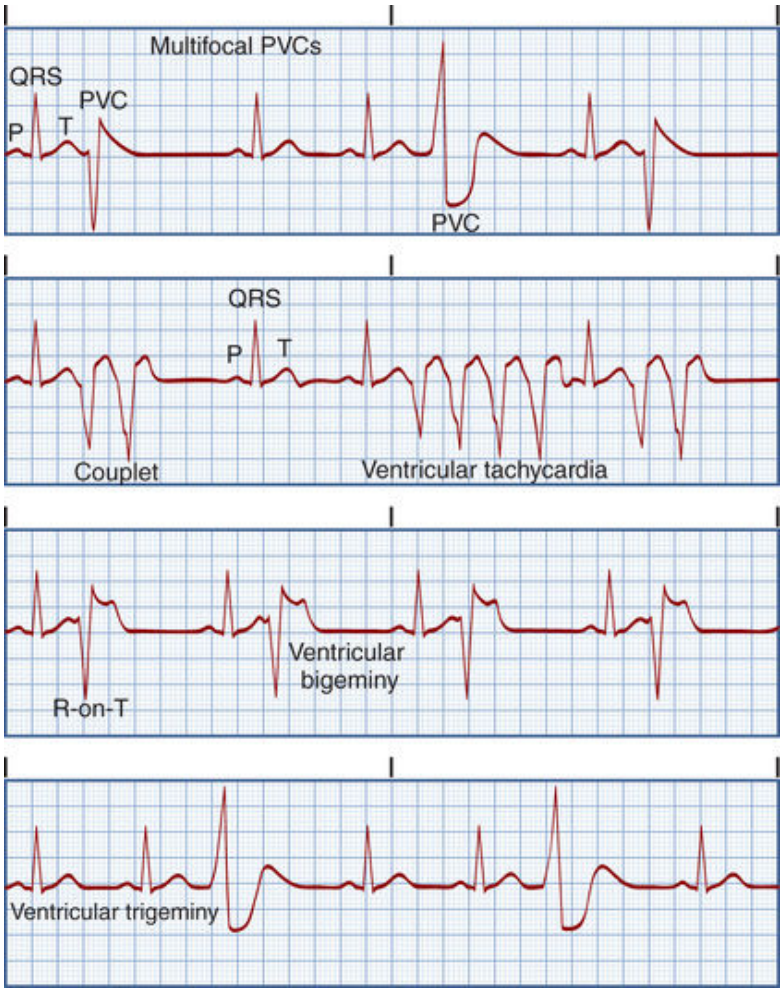

FIGURE 38-17 Various forms of premature ventricular contractions (PVCs).

Clinical Associations.

PVCs are associated with stimulants such as caffeine, alcohol, nicotine, aminophylline, epinephrine, isoproterenol, and digoxin. They are also associated with electrolyte imbalances, hypoxia, fever, exercise, and emotional stress. Disease states associated with PVCs include MI, mitral valve prolapse, HF, and CAD.

Electrocardiographic Characteristics.

HR varies according to intrinsic rate and number of PVCs. The rhythm is irregular because of premature beats. The P wave is absent in a PVC. The QRS complex is wide and distorted in shape, lasting more than 0.12 seconds. The T wave is generally large and opposite in direction to the major direction of the QRS complex.

Clinical Significance.

PVCs are usually a benign finding in the patient with a normal heart. In heart disease, depending on frequency, PVCs may reduce the CO and precipitate angina and HF if they are frequently occurring (>10/minute). Because PVCs in CAD or acute MI represent ventricular irritability, the patient's physiological response to PVCs must be monitored.

Treatment.

Treatment is often based on the cause of the PVCs (e.g., oxygen therapy for hypoxia, electrolyte replacement); however, infrequent PVCs are not typically treated. Assessment of the patient's hemodynamic status is important to guide treatment. Most importantly, the patient must be assessed for signs of decreased CO and whether the PVCs are causing the patient to be symptomatic (e.g., chest pain, dizziness) to determine whether treatment is indicated.

Ventricular Tachycardia.

The diagnosis of **ventricular tachycardia (VT)** is made when a run of three or more PVCs occurs. It occurs when an ectopic focus or foci fire repetitively and the ventricle takes control as the pacemaker. VT appears in different forms, depending on the QRS configuration. Monomorphic VT (Figure 38-18, *A*) has QRS complexes that are the same in shape, size, and direction. In polymorphic VT, the QRS complexes gradually change back and forth from one shape, size, and direction to another over a series of beats. *Torsades de pointes* (French, "twisting of the points") is polymorphic VT associated with a prolonged QT interval of the underlying rhythm (see Figure 38-18, *B*).

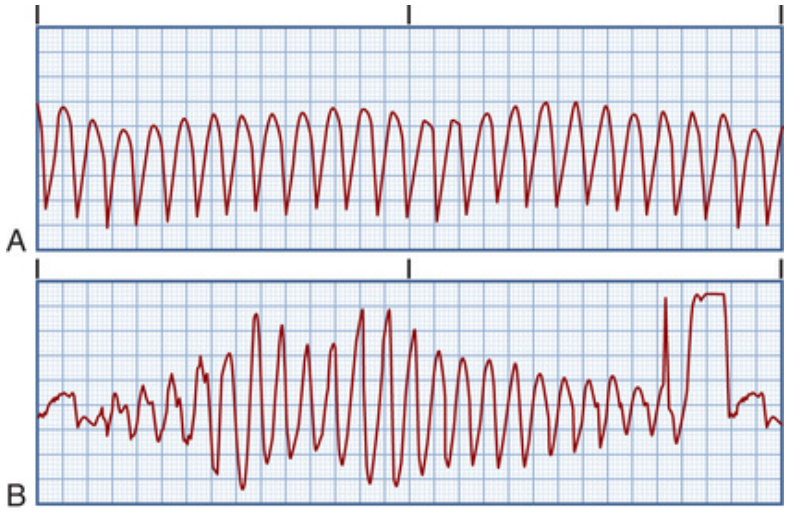

FIGURE 38-18 ECGs demonstrating ventricular tachycardia. **A,** Monomorphic. **B,** Torsades de pointes (polymorphic).

Ventricular tachycardia may be sustained or nonsustained. Sustained VT lasts for more than 30 seconds. Nonsustained VT lasts for 30 seconds or less. The development of VT is an ominous sign. It is considered to be a life-threatening dysrhythmia because of decreased CO and the possibility of deterioration to ventricular fibrillation, which is a lethal dysrhythmia.

Clinical Associations.

Ventricular tachycardia is associated with MI, CAD, significant electrolyte imbalances, cardiomyopathy, mitral valve prolapse, long QT syndrome, digitalis toxicity, and central nervous system disorders. This dysrhythmia has also been observed in patients who have no evidence of cardiac disease.

Electrocardiographic Characteristics.

The ventricular rate in VT is 150 to 250 beats/minute. The rhythm is regular.

The QRS complex is distorted in appearance, with a duration exceeding 0.12 seconds and with the ST–T wave in the opposite direction to that of the QRS complex (see Figure 38-18). The R–R interval may be irregular or regular.

Clinical Significance.

Ventricular tachycardia can be stable (patient has a pulse) or unstable (patient is pulseless). Sustained VT causes a severe decrease in CO as a result of decreased ventricular diastolic filling times and loss of atrial

contraction. Results include hypotension, pulmonary edema, decreased cerebral blood flow, and cardiopulmonary arrest. The dysrhythmia must be treated quickly, even if it occurs only briefly and stops abruptly, because episodes may recur if prophylactic treatment is not begun. Ventricular fibrillation may also develop.

Treatment.

Precipitating causes of VT must be identified and treated (e.g., electrolyte imbalances, ischemia). If the VT is monomorphic and the patient is hemodynamically stable (e.g., pulse is present) and has preserved left ventricular function, IV amiodarone is typically used. If the patient becomes hemodynamically unstable or has poor left ventricular function, IV amiodarone is given, followed by cardioversion if the original drug therapy alone is ineffective.

If the VT is polymorphic with a normal baseline QT interval, any one of the following medications is used: β-adrenergic blockers, amiodarone, or sotalol. Cardioversion is performed if drug therapy is ineffective.

If the VT is polymorphic with a prolonged baseline QT interval, therapies include IV magnesium and antitachycardia pacing (discussed later in this chapter). Drugs that prolong the QT interval should be discontinued. If the rhythm is not converted, cardioversion may be needed.

VT without a pulse is a life-threatening situation and is treated in the same manner as ventricular fibrillation—cardiopulmonary resuscitation (CPR) and rapid defibrillation are the first lines of treatment, followed by the administration of epinephrine if defibrillation is unsuccessful (AHA, 2015).

An *accelerated idioventricular rhythm* (AIVR) can develop when the intrinsic pacemaker rate (SA node or AV node) becomes lower than that of a ventricular ectopic pacemaker; the rate is between 40 and 100 beats/minute. It is most commonly associated with acute MI and reperfusion of the myocardium after fibrinolytic therapy or angioplasty of coronary arteries. It can also occur with digitalis toxicity. In the setting of acute MI, AIVR is usually self-limiting and well tolerated and necessitates no treatment. If it becomes symptomatic (e.g., hypotension, angina), atropine can be considered. Temporary pacing may be required. Drugs that suppress ventricular rhythms (e.g., lidocaine) should not be used because they can terminate the ventricular rhythm and further reduce the HR.

Ventricular Fibrillation.

Ventricular fibrillation is a severe derangement of the heart rhythm, characterized by irregular undulations of varying shapes and amplitude on the ECG (Figure 38-19). This presentation represents the firing of multiple ectopic foci in the ventricle. Mechanically, the ventricle is simply "quivering," and no effective contraction—and consequently no cardiac output—occurs.

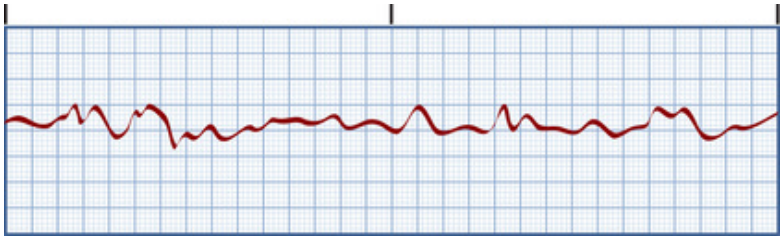

FIGURE 38-19 ECG demonstrating ventricular fibrillation.

Clinical Associations.

Ventricular fibrillation occurs in acute MI and myocardial ischemia and in chronic diseases such as CAD and cardiomyopathy. It may occur during cardiac pacing or cardiac catheterization procedures as a result of catheter stimulation of the ventricle. It may also occur with coronary reperfusion after fibrinolytic therapy. Other clinical associations are accidental electric shock, hyperkalemia, hypoxemia, acidosis, and drug toxicity.

Electrocardiographic Characteristics.

In ventricular fibrillation, the HR is not measurable. The rhythm is irregular and chaotic. The P wave is not detectable, and the PR and the QRS intervals are not measurable.

Clinical Significance.

Ventricular fibrillation results in an unresponsive, pulseless, and apneic state. If it is not rapidly treated, the patient will die.

Treatment.

Treatment consists of assessment of circulation, airway, and breathing (CAB), and if no pulse is found, high quality CPR and advanced cardiac life support (ACLS) measures are initiated immediately with the use of

defibrillation and definitive drug therapy. If a defibrillator is immediately available, it must be used without delay (AHA, 2015).

Asystole.

Asystole represents the total absence of ventricular electrical activity. On occasion, P waves are detected. No ventricular contraction occurs because depolarization does not occur. Patients are unresponsive, pulseless, and apneic. This is a lethal dysrhythmia that necessitates immediate treatment. Ventricular fibrillation may masquerade as asystole; thus the rhythm should be assessed in more than one lead. The prognosis of a patient with asystole is extremely poor.

Clinical Associations.

Asystole is usually a result of advanced cardiac disease, a severe cardiac conduction system disturbance, or end-stage HF.

Clinical Significance.

In general, patients with asystole have end-stage cardiac disease or have a prolonged cardiac arrest and cannot be resuscitated.

Treatment.

Treatment consists of high quality CPR with initiation of ACLS measures, which include: IV/IO access, epinephrine 1 mg every 3 to 5 minutes, consider advanced airway, and capnography (AHA, 2015).

Pulseless Electrical Activity.

Pulseless electrical activity (PEA) is a situation in which electrical activity can be observed on the ECG, but there is no mechanical activity of the ventricles and the patient has no pulse. The prognosis is poor unless the underlying cause can be identified and quickly corrected. The most frequent causes of PEA include hypovolemia, hypoxia, metabolic acidosis, hyperkalemia or hypokalemia, hypothermia, drug overdose, cardiac tamponade, MI, tension pneumothorax, and pulmonary embolus. Treatment begins with assessment of CAB and if no pulse is detected, high quality CPR is initiated and followed by IV/IO access, epinephrine 1 mg every 3 to 5 minutes, consider advanced airway, and capnography. Treatment is aimed at potential treatable causes (e.g., hypovolemia) (AHA, 2015).

Sudden Cardiac Death.

The term *sudden cardiac death (SCD)* refers to death from a cardiac cause. The majority of SCDs result from ventricular dysrhythmias, specifically VT or ventricular fibrillation. (SCD is discussed further in Chapter 36.)

Antidysrhythmia Drugs

An increasing number of antidysrhythmia drugs have become available. Table 38-8 categorizes major drug classes by primary effects on the cardiac cells.

TABLE 38-8

DRUG THERAPY
Antidysrhythmia Drugs: Classifications, Actions, and Effects on ECG

Classification	Actions	Effects on ECG
Class I: Sodium channel blockers	Decrease conduction velocity in the atria, ventricles, and His–Purkinje system	—
Class IA • Procainamide (Procan) • Quinidine	Delay repolarization	Widened QRS and prolonged QT interval
Class IB • Lidocaine (Xylocaine) • Mexiletine • Phenytoin (Dilantin)	Accelerate repolarization	Little or none
Class IC • Flecainide (Tambocor) • Propafenone (Rythmol)	Decrease impulse conduction	Pronounced prodysrhythmic actions, widened QRS, prolonged QT interval
Class II: β-Adrenergic blockers • Atenolol (Tenormin) • Carvedilol • Esmolol (Brevibloc) • Metoprolol (Lopressor) • Sotalol*	Decrease automaticity of the SA node; decrease conduction velocity in AV node; reduce atrial and ventricular contractility	Bradycardia, prolonged PR interval, AV block
Class III: Potassium channel blockers • Amiodarone • Ibutilide (Corvert) • Sotalol*	Delay repolarization, which results in prolonged duration of action potential and prolonged refractory period	Prolonged PR and QT intervals, widened QRS, bradycardia
Class IV: Calcium channel blockers • Diltiazem (Cardizem) • Verapamil	Decrease automaticity of SA node; delay AV node conduction; reduce myocardial contractility	Bradycardia, prolonged PR interval, AV block
Other antidysrhythmia drugs • Adenosine (Adenocard) • Digoxin • Magnesium	Decrease conduction through AV node; reduce automaticity of SA node	Prolonged PR interval, AV block

*Sotalol has both class II and class III properties.

AV, atrioventricular; *ECG,* electrocardiogram; *SA,* sinoatrial.

Defibrillation

Defibrillation is the most effective method of terminating ventricular fibrillation and pulseless VT. It is most effective when the myocardial cells are not anoxic or acidotic, making rapid defibrillation crucial for a successful patient outcome. Defibrillation is accomplished by the passage of a DC electric shock through the heart that is sufficient to depolarize the cells of the myocardium. The intent is that subsequent repolarization of myocardial cells allows the SA node to resume the role of pacemaker (AHA, 2015).

Research has shown that biphasic defibrillators are preferred over monophasic defibrillators and deliver successful shocks at lower energies and with fewer post-shock ECG abnormalities than monophasic defibrillators (Figure 38-20) (AHA, 2015).

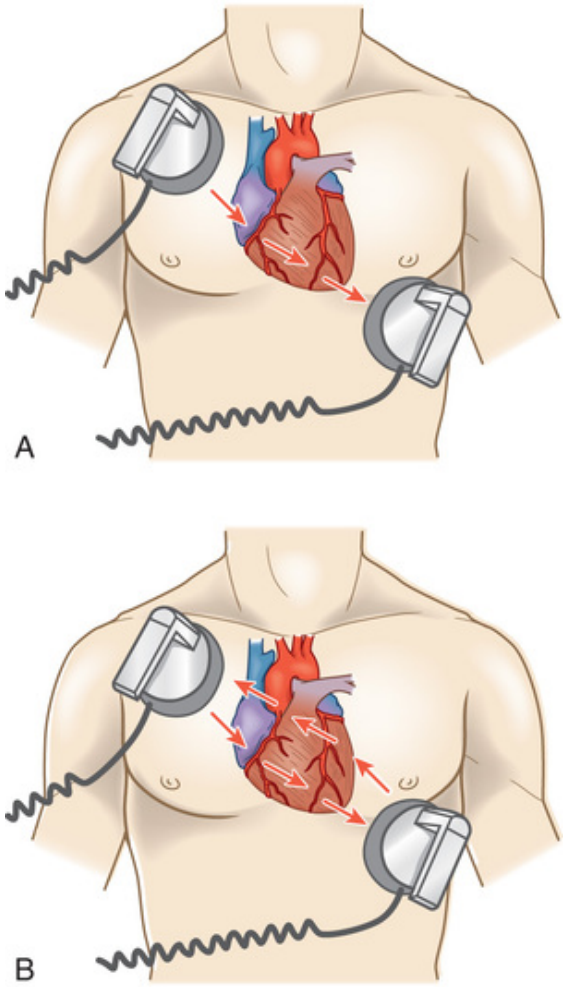

FIGURE 38-20 Paddle placement and current flow in monophasic defibrillation **(A)** and biphasic defibrillation **(B).**

The output of a defibrillator is measured in joules (J), or watts per second. The recommended energy for initial shocks in defibrillation depends on the type of defibrillator. Biphasic defibrillators deliver all shocks of 150 to 200 J. After the initial shock, CPR should be started immediately, beginning with chest compressions.

Rapid defibrillation can be performed with a manual or automatic device (Figure 38-21). Manual defibrillators require health care providers to interpret cardiac rhythms, determine the need for a shock, and deliver a shock. **Automatic external defibrillators (AEDs)** are defibrillators that have rhythm detection capability and the ability to advise the operator to deliver a shock with hands-free defibrillator pads. Proficiency in use of the AED is incorporated in the basic life support course for health care providers (AHA, 2015). The nurse should be familiar with the operation of the type of defibrillator that is used in the clinical setting and must be

certified to use this equipment. The Heart and Stroke Foundation of Ontario has implemented a public access defibrillation (PAD) program in communities in order to enhance the provision of early advanced cardiac care to save lives (Heart and Stroke Foundation, 2012). Through this program, AEDs are placed in public places such as arenas, pools, and community centres.

FIGURE 38-21 The LifePak device contains a monitor, a defibrillator, and a transcutaneous pacemaker. Source: Science History Images/Alamy Stock Photo.

Upon defibrillation, the operator calls, "All clear" and looks to see that personnel are not touching the patient or the bed at the time of defibrillator discharge. It is essential that the operator ensures that all personnel are clear before the defibrillator is discharged.

Synchronized Cardioversion.

Synchronized cardioversion is the therapy of choice for patients with hemodynamically unstable ventricular or supraventricular tachydysrhythmias. A synchronized circuit in the defibrillator is used to deliver a countershock that is programmed to occur on the R wave of the QRS complex. The synchronizer switch must be turned on when cardioversion is planned.

The procedure for synchronized cardioversion is the same as for defibrillation, with the following exceptions. If synchronized cardioversion is performed on a nonemergency basis (i.e., the patient is awake and hemodynamically stable), the patient is sedated (e.g., IV midazolam)

before the procedure. Strict attention to maintenance of a patent airway is important in this situation. When a patient with supraventricular tachycardia or VT with a pulse is hemodynamically unstable, synchronized cardioversion is performed as quickly as possible. In addition, the energy needed for synchronized cardioversion is generally less than the energy needed for defibrillation. Energy levels are started at 50 J on a defibrillator and increased (e.g., 100 J, 200 J) if needed.

Implantable Cardioverter–Defibrillator.

The implantable cardioverter–defibrillator (ICD) is important technology for patients who (a) have survived SCD, (b) have spontaneous sustained VT, (c) demonstrate syncope with inducible VT or fibrillation during EPS, and (d) are at high risk for future life-threatening dysrhythmias (e.g., have cardiomyopathy). Use of the ICD has significantly decreased cardiac mortality rates among such patients and has added a new dimension to the management of life-threatening dysrhythmias and the prevention of SCD (AHA, 2015).

The ICD consists of a lead system placed via a subclavian vein to the endocardium. A battery-powered pulse generator is implanted subcutaneously, usually over the pectoral muscle on the patient's nondominant side. The pulse generator is similar in size to a cardiac pacemaker. The newest systems are single-lead systems instead of earlier multi-lead or patch systems (Figure 38-22). The ICD sensing system monitors the HR and the rhythm and identifies VT or ventricular fibrillation. Approximately 25 seconds after the sensing system detects a lethal dysrhythmia, the defibrillating mechanism delivers a 25-J or milder shock to the patient's heart. If the first shock is unsuccessful, the generator recycles and can continue to deliver shocks.

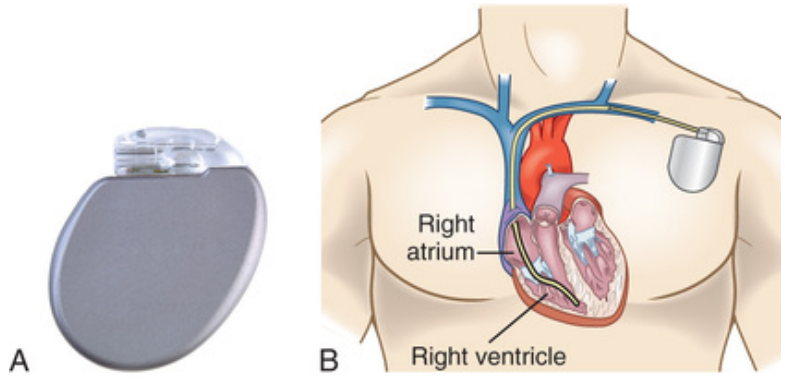

FIGURE 38-22 **A,** The implantable cardioverter–defibrillator (ICD) pulse generator. **B,** The ICD is placed in a subcutaneous pocket over the pectoral muscle. A single-lead system is placed transvenously from the pulse generator to the endocardium. The single lead detects dysrhythmias and delivers an electric shock to the heart muscle. Source: *A,* © Can Stock Photo/CarolinaSmith.

In addition to defibrillation capabilities, ICDs are equipped with antitachycardia and antibradycardia pacemakers. These sophisticated devices use dysrhythmia algorithms that detect dysrhythmias and determine the appropriate programmed response. These devices can initiate overdrive pacing of supraventricular and ventricular tachycardias, sparing the patient painful defibrillator shocks. They also provide backup pacing for bradydysrhythmias that may occur after defibrillation discharges. Preprocedure and post-procedure nursing care of patients undergoing ICD placement is similar to the care of patients undergoing permanent pacemaker implantation (see pp. 883 to 884).

Education of patients who receive an ICD is of extreme importance. Patients experience a variety of emotions, including fear of body image change, fear of recurrent dysrhythmias, expectation of pain with ICD discharge (described as a feeling of a blow to the chest), and anxiety about going home. Table 38-9 describes the teaching guidelines for the patient with an ICD and the patient's caregivers. Participation in an ICD support group should be encouraged. Online resources for patients with an ICD include support groups and the Sudden Cardiac Arrest Network (see the Resources at the end of Chapter 36.)

TABLE 38-9

PATIENT & CAREGIVER TEACHING GUIDE
Implantable Cardioverter–Defibrillator

The following guidelines should be included when teaching the patient and caregiver after undergoing insertion of an implantable cardioverter–defibrillator (ICD):

1. Maintain close follow-up with the physician for testing of ICD function and for inspection of ICD insertion site.
2. Watch for signs of infection at incision site (e.g., redness, swelling, drainage).
3. Keep the incision dry for 1 wk after ICD insertion.
4. Avoid lifting the operative-side arm above the shoulder for 1 wk.
5. Avoid direct blows to ICD site.
6. When travelling by airplane, inform airport security of the presence of the ICD because it may set off the metal detector. If a handheld screening wand is used, it should not be placed directly over the ICD.
7. When the ICD fires:
    - Lie down.
    - If you lose consciousness or if there is repetitive firing, someone should call 911.
    - If you are feeling well and there is repetitive firing, contact your physician's office for ICD interrogation, including battery checks and safety and diagnostic checks.
8. Ensure routine ICD check with interrogator–programmer device, which is needed every 2 to 3 months.
9. Wear a medical alert bracelet at all times.
10. Make sure an information card about the ICD is easily accessible in your wallet.
11. Ensure that your family members learn CPR.
12. Speak with your nurse, who should assist you with the development of positive coping strategies to reduce stress.
13. Avoid large electromagnetic and vibratory forces because they may turn off the device.
14. In general, do not drive until cleared by your physician. The approval to drive is based on the presence of dysrhythmias, the frequency of ICD firings, your overall health, and provincial or territorial laws regarding drivers with ICDs.

CPR, cardiopulmonary resuscitation; *ICD*, implantable cardioverter–defibrillator.

Pacemakers

The artificial **cardiac pacemaker** is an electronic device used to pace the heart when the normal conduction pathway is damaged or diseased. The basic pacing circuit consists of a power source (battery-powered pulse generator), one or more conducting leads (pacing leads), and the myocardium. The electrical signal (stimulus) travels from the pacemaker, through the leads, to the wall of the myocardium. The myocardium is "captured" and stimulated to contract (Figure 38-23).

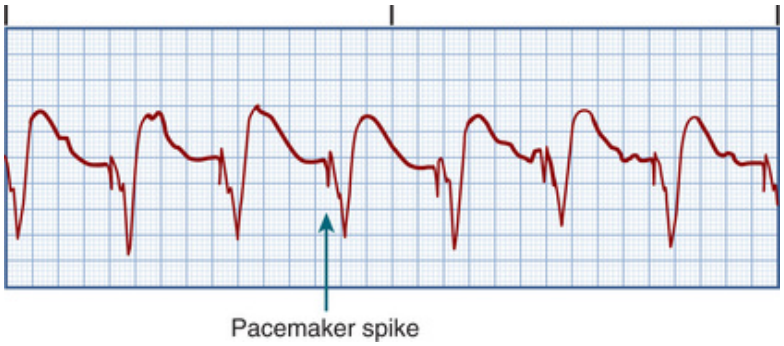

FIGURE 38-23 ECG demonstrating ventricular capture (depolarization) secondary to signal (pacemaker spike) from pacemaker lead in the right ventricle.

Advances in technology have been applied extensively to pacemakers. This advancement has resulted in sophisticated, noninvasive, programmable single- and dual-chambered pacemakers with specialized circuits. The newer pacemakers are more physiologically accurate, pacing the atrium and one or both of the ventricles (Aehlert, 2013). Pacemakers were initially indicated for symptomatic bradydysrhythmias. However, advances now include pacing for antitachycardia and overdrive pacing. Antitachycardia pacing involves the delivery of a stimulus to the ventricle to terminate tachydysrhythmias (e.g., VT). Overdrive pacing involves pacing the atrium at rates of 200 to 500 impulses per minute in an attempt to terminate atrial tachycardias (e.g., atrial flutter, atrial fibrillation). Multiple other indications for pacemakers have evolved. A permanent pacemaker is one that is implanted totally within the body (Figure 38-24). The permanent pacemaker power source is implanted subcutaneously, usually over the pectoral muscle on the patient's nondominant side. It is attached to pacing leads, which are threaded transvenously to the right atrium and one or both ventricles. Indications for insertion of permanent pacemakers are listed in Table 38-10.

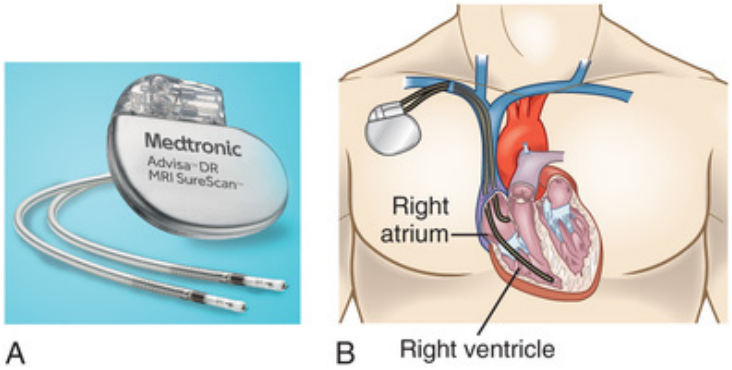

FIGURE 38-24 **A,** A dual-chamber rate-responsive pacemaker from Medtronic, Inc., is designed to treat patients with chronic heart problems in which the heart beats too slowly to adequately support the body's circulation needs. **B,** Pacing leads in both the atrium and the ventricle enable a dual-chamber pacemaker to sense and pace in both heart chambers. Source: *A,* © 2017 Medtronic.

TABLE 38-10
INDICATIONS FOR PERMANENT PACEMAKER THERAPY

• Chronic atrial fibrillation with slow ventricular response
• Fibrosis or sclerotic changes of cardiac conduction system
• Hypersensitive carotid sinus syndrome
• Sick sinus syndrome
• Sinus node dysfunction
• Tachydysrhythmias
• Third-degree AV block

A specialized type of cardiac pacing has been developed for the management of HF. More than 50% of patients with HF have intraventricular conduction delays that cause abnormal ventricular activation and contraction and subsequent asynchrony between the right and left ventricles. This asynchrony can result in reduced systolic function, pump inefficiency, and worsened HF. Cardiac resynchronization therapy (CRT) is a pacing technique that resynchronizes the cardiac cycle by pacing both ventricles, thus promoting improvement in ventricular function. Several devices are available in which CRT is combined with an ICD for maximum therapy. (HF is discussed in Chapter 37.)

Temporary Pacemaker.

A temporary pacemaker is one whose power source is outside the body (Figure 38-25). There are three types of temporary pacemakers:

transvenous, epicardial, and transcutaneous. Indications for temporary pacing are listed in Table 38-11.

FIGURE 38-25 Temporary external, dual-chamber demand pacemaker. Source: © 2017 Medtronic.

TABLE 38-11
INDICATIONS FOR TEMPORARY PACING

- Maintenance of adequate HR and rhythm during special circumstances such as surgery and postoperative recovery, cardiac catheterization, or coronary angioplasty; during drug therapy that may cause bradycardia; and before implantation of a permanent pacemaker
- As prophylaxis after open-heart surgery
- Acute anterior MI with second- or third-degree AV block or bundle-branch block
- Acute inferior MI with symptomatic bradycardia and AV block
- Termination of AV nodal re-entry or reciprocating tachycardia associated with WPW syndrome, atrial flutter, or ventricular tachycardia
- Suppression of ectopic atrial or ventricular rhythm
- EPS to evaluate patient with bradydysrhythmias and tachydysrhythmias

AV, atrioventricular; *EPS,* electrophysiology study; *MI,* myocardial infarction; *WPW,* Wolff–Parkinson–White.

A transvenous pacemaker consists of a lead or leads that are threaded transvenously to the right atrium, the right ventricle, or both and attached to the external power source (Figure 38-26). Most temporary transvenous pacemakers are inserted in critical care units in emergency situations. They are used until a permanent pacemaker can be inserted or the underlying cause of the dysrhythmia has been resolved.

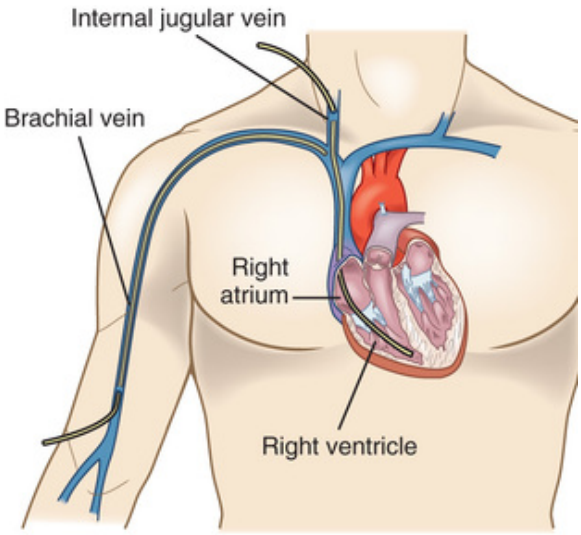

FIGURE 38-26 Temporary transvenous pacemaker catheter insertion. A single lead is positioned in the right ventricle through the brachial, subclavian, jugular, or femoral vein.

To achieve epicardial pacing, an atrial pacing lead and a ventricular pacing lead are attached to the epicardium during heart surgery. The leads are passed through the chest wall and attached to the external power source. Epicardial pacing leads are placed prophylactically in case any bradydysrhythmias or tachydysrhythmias occur postoperatively.

A transcutaneous pacemaker (TCP) is used to maintain adequate HR and rhythm in an emergency situation. Placement of the transcutaneous pacemaker is a noninvasive procedure, and this pacemaker is used temporarily until a transvenous pacemaker can be inserted or until more definitive therapy is available.

The TCP consists of a power source and a rate- and voltage-control device that is attached to two large, multifunction electrode pads. One pad is positioned on the anterior part of the chest, usually at the V_2 or V_5 lead position, and the other pad is placed on the back between the spine and the left scapula at the level of the heart (Figure 38-27).

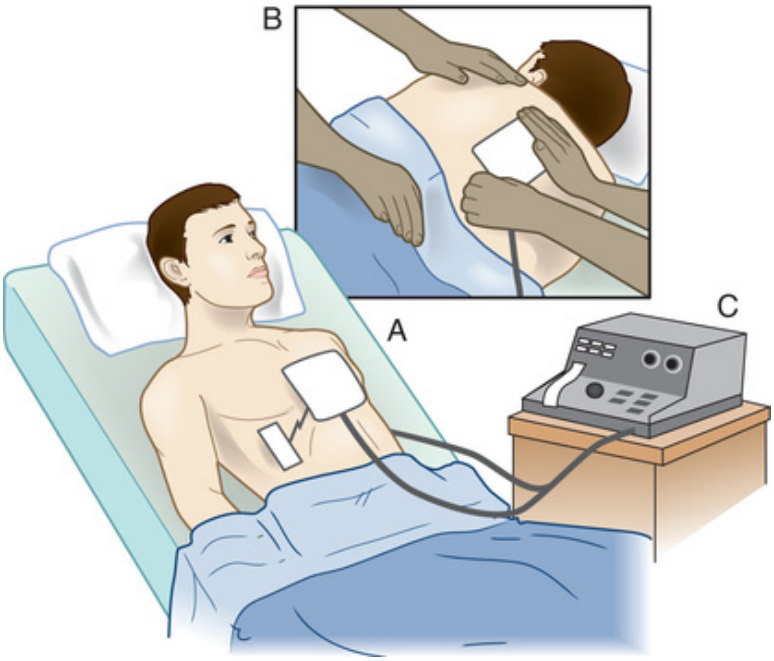

FIGURE 38-27 Transcutaneous pacemaker. Pacing electrodes are placed on the patient's anterior **(A)** and posterior **(B)** chest walls and attached to an external pacing unit **(C)**.

Before TCP therapy is initiated, the patient must be told what to expect. The uncomfortable muscle contractions that the pacemaker creates when the current passes through the chest wall should be explained. The patient should be reassured that the therapy is temporary and that the TCP will be replaced with a transvenous pacemaker as soon as possible. Whenever possible, an analgesic, sedative, or both should be provided.

Patient Monitoring.

Patients with temporary or permanent pacemakers are monitored by ECG to evaluate the status of the pacemaker. Pacemaker malfunction is manifested primarily by a failure to sense or a failure to capture. *Failure to sense* is the situation in which the pacemaker fails to recognize spontaneous atrial or ventricular activity, and it fires inappropriately. Failure to sense may be caused by pacer lead damage, battery failure, or dislodgement of the electrode. *Failure to capture* is the situation in which the electrical charge to the myocardium is insufficient to produce atrial or ventricular contraction. Failure to capture may also be caused by pacer lead damage, battery failure, or dislodgement of the electrode, as well as by fibrosis at the electrode tip.

Complications of invasive temporary (i.e., transvenous) or permanent pacemaker insertion include infection and hematoma formation at the site of insertion of the pacemaker power source or leads; pneumothorax; failure to sense or capture with possible symptomatic bradycardia; perforation of the atrial or the ventricular septum by the pacing lead; and appearance of “end-of-life” battery parameters when the pacemaker is tested.

Several measures are taken to prevent or assess for complications, including prophylactic IV antibiotic therapy before and after insertion, post-insertion chest radiographic study to check lead placement and to rule out the presence of a pneumothorax; careful observation of insertion site; and continuous ECG monitoring of the patient's rhythm. After pacemaker insertion, the patient is permitted out of bed once the HR and rhythm are stable. Arm and shoulder activity is limited to prevent dislodgement of the newly implanted pacing leads. The nurse observes the insertion site for signs of bleeding and to check that the incision is intact. Any temperature elevation should be noted, and pain at the insertion site should be treated. Most patients are discharged the next day if the HR and rhythm are stable.

The nurse must provide patient teaching in addition to observing for complications after pacemaker insertion. The patient with a newly implanted pacemaker may have questions about activity restrictions and concerns about body image after the procedure. The goal of pacemaker therapy should be to enhance physiological functioning and the quality of life. This should be emphasized to the patient, and the nurse should give specific advice about activity restrictions. Patient and caregiver teaching for the patient with a pacemaker is outlined in Table 38-12.

TABLE 38-12

PATIENT & CAREGIVER TEACHING GUIDE
Pacemaker

The following guidelines should be included when teaching the patient and caregiver after undergoing insertion of a pacemaker:

1. Maintain follow-up care plan with a physician to check the pacemaker site and begin regular pacemaker function checks with interrogator or programmer device.
2. Watch for signs of infection at incision site, for example, redness, swelling, or drainage.
3. Keep the incision dry for 1 wk after pacemaker implantation.
4. Avoid lifting operative-side arm above shoulder level for 1 wk.
5. Avoid direct blows to generator site.
6. Avoid close proximity to high-output electrical generators or large magnets such as an MRI scanner. These devices can reprogram a pacemaker.
7. Don't be concerned about microwave ovens, which are safe to use and do not threaten pacemaker function.
8. Be aware that you may travel without restrictions. The small metal case of an implanted pacemaker rarely sets off an airport security alarm.
9. Ensure that you are taught how to take your pulse.
10. Carry a pacemaker information card at all times.
11. Watch for return of preimplantation symptoms (i.e., chest pain, excessive sweating, dizziness).

MRI, magnetic resonance imaging.

After discharge, pacemaker function should be checked regularly during outpatient visits to a pacemaker interrogator or programmer or by home monitoring using telephone transmitter devices. Another method to evaluate pacemaker performance is noninvasive program stimulation, which is done on an outpatient basis in the electrophysiology laboratory.

Radiofrequency Ablation Therapy

Radiofrequency ablation (RFA) therapy is a relatively new development in the area of antidysrhythmia therapy. Radiofrequency energy (produced by a low-voltage, high-frequency form of electrical energy) is used to "burn" or ablate areas of the conduction system as definitive treatment of tachydysrhythmias.

Ablation therapy is performed after EPS has identified the source of the dysrhythmia. An electrode-tipped ablation catheter is used to ablate accessory pathways or ectopic sites in the atria, the AV node, and the ventricles. Catheter ablation is considered the nonpharmacological treatment of choice for AV nodal re-entrant tachycardia or for re-entrant tachycardia related to accessory bypass tracts, and to control the ventricular response of certain tachydysrhythmias. In some cases of uncontrolled ventricular response in atrial fibrillation or of atrial flutter that is unresponsive to medical therapy, the AV node or bundle of His may be ablated completely. If this is done, the patient must have a permanent pacemaker inserted at the same time. The ablation procedure is a

successful therapy with a low complication rate. Care of the patient undergoing ablation therapy is similar to that of a patient undergoing cardiac catheterization (see Chapter 34).

Electrocardiographic Changes Associated With Acute Coronary Syndrome

The 12-lead ECG is the primary diagnostic tool used to evaluate patients receiving care for acute coronary syndrome (ACS). Many treatment decisions are directed by the ECG changes that occur with ACS. These definitive changes are in response to ischemia, injury, or infarction of myocardial cells and are detected in the leads that face the area of involvement (Figure 38-28). Reciprocal (opposite) ECG changes are often detected in the leads facing opposite the area involved in ACS. In addition, the pattern of ECG changes provides information on the coronary artery involved in ACS (Table 38-13).

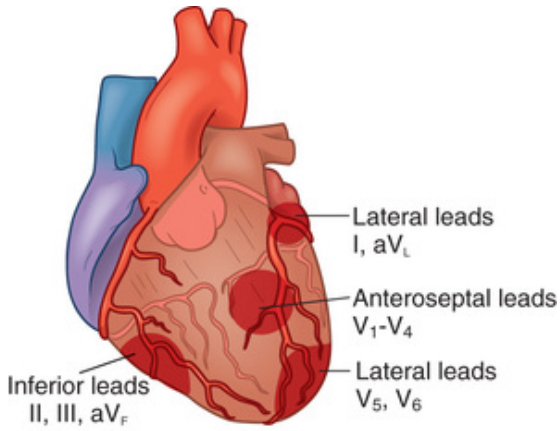

FIGURE 38-28 Diagram showing where leads detect ECG changes. Definitive ECG changes occur in leads that face the area of ischemia, injury, or infarction. Reciprocal changes may occur in leads facing opposite the area of ischemia, injury, or infarction.

TABLE 38-13

ECG EVIDENCE AND ASSOCIATED CORONARY ARTERY IN ACUTE CORONARY SYNDROME

Area of Involvement of Left Ventricle	ECG Evidence		
	Leads Facing Area	Leads Opposite Area	Associated Coronary Artery
Septal wall	V_1, V_2	II, III, aV_F	Left anterior descending
Anterior wall	V_2, V_3, V_4	II, III, aV_F	Left anterior descending
Lateral wall, low	V_5, V_6	II, III, aV_F	Left anterior descending or circumflex
Lateral wall, high	I, aV_L	II, III, aV_F	Circumflex
Inferior wall	II, III, aV_F	I, aV_L, V_5, V_6	Right coronary artery

Ischemia

Typical ECG changes that are seen in myocardial ischemia include ST-segment depression, T-wave inversion, or both (Figure 38-29, *A*). ST-segment depression is significant if it is at least 1 mm (one small box) below the isoelectric line (see Figure 38-5). The isoelectric line is flat and represents the normal times in the cardiac cycle when the ECG is not recording any electrical activity in the heart. These times are as follows: (a) from the end of the P wave to the start of the QRS complex, (b) the entire ST segment, and (c) from the end of the T wave to the start of the next P wave (see Figure 38-9). ST-segment depression, T-wave inversion, or both occur in response to the electrical disturbance in the myocardial cells that is caused by an inadequate supply of blood and oxygen. Once the cause of the disturbance is treated (adequate blood flow is restored), the ECG changes resolve, and the ECG returns to the patient's baseline. (See Chapter 36 for a complete discussion of ACS.)

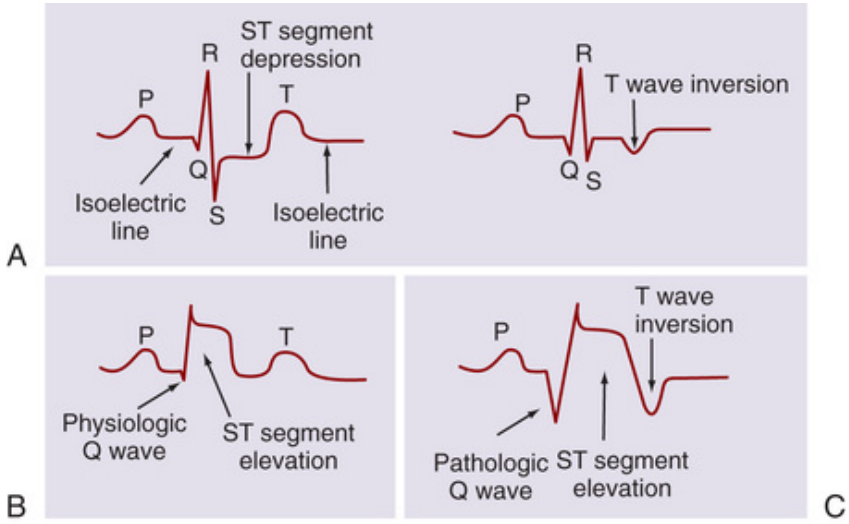

FIGURE 38-29 Diagrams of changes in ST segment, T wave, and Q wave in association with myocardial ischemia **(A)**, injury **(B)**, and infarction **(C).**

Injury and Infarction

Myocardial injury represents a stage of worsening ischemia that is potentially reversible but may evolve to infarction (necrosis) of myocardial cells. The typical ECG change seen during injury is ST-segment elevation. ST-segment elevation is significant if it is at least 1 mm above the isoelectric line (see Figure 38-29, *B*). If treatment is prompt and effective, it is possible to restore oxygen to the myocardium and avoid infarction. Avoidance of infarction is confirmed by the absence of serum cardiac markers. If serum cardiac markers are present, infarction has occurred and is referred to as an *ST-segment–elevation myocardial infarction* (STEMI).

In addition to ST-segment elevation, a pathological Q wave may be seen on the ECG with infarction (see Figure 38-29, *C*). A physiological Q wave is the first negative deflection (wave) after the P wave (see Figure 38-9). It is normally very small and narrow (<0.04 seconds in duration). A pathological Q wave that develops during infarction is deep and more than 0.03 seconds in duration. If it does appear, it indicates that at least half the thickness of the heart wall is involved, which is referred to as a *Q-wave MI* (Aehlert, 2013). The pathological Q wave may be present on the ECG indefinitely.

T-wave inversion related to infarction occurs within hours after an infarction and may persist for months. The ECG changes seen in injury and infarction reflect electrical disturbances in the myocardial cells that are

caused by a prolonged lack of blood and oxygen leading to necrosis (Figure 38-30).

FIGURE 38-30 ECG findings with anteroseptal lateral wall myocardial infarction. Normally, leads I, aV_L, and V_1 to V_3 have a positive R wave. Note the pathological Q waves in these leads and the ST-segment elevation in leads V_2 to V_5 *(arrows)*.

Patient Monitoring

Monitoring guidelines for patients with suspected ACS include continuous, multi-lead ECG and ST-segment monitoring (Pelter et al., 2014). The leads selected for monitoring should minimally include the leads that reflect the area of ischemia, injury, or infarction.

Syncope

Syncope—a brief lapse in consciousness accompanied by a loss in postural tone (fainting)—is a common diagnosis in the emergency department and the hospital. The causes of syncope can be categorized as cardiovascular or noncardiovascular. The most common cardiovascular causes of syncope include (a) neuro-cardiogenic syncope or "vasovagal" syncope (e.g., carotid sinus sensitivity) and (b) primary cardiac dysrhythmias (e.g., tachycardias, bradycardias). Other causes can be related to prosthetic valve malfunction, pulmonary emboli, aortic dissection, and hypertrophic cardiomyopathy. Noncardiovascular causes are varied and can include hypoglycemia, hysteria, unwitnessed seizure, and vertebrobasilar transient ischemic attack (Jarvis et al., 2013).

A diagnostic workup for a patient with syncope from a suspected cardiac cause begins with ruling out structural or ischemic heart disease or both. This is done with echocardiography and stress testing. In older-adult patients, who are more likely to have ischemic and structural heart disease, EPS is used to diagnose atrial and ventricular tachydysrhythmias, as well as conduction system disease causing bradydysrhythmias, all of which can cause syncope. These problems can be treated with antidysrhythmia drug therapy, pacemakers, ICDs, catheter ablation therapy, or a combination.

In patients without structural heart disease or in whom the results of EPS testing are not diagnostic, head-upright tilt-table testing may be performed. Normally, an upright position results in gravity displacing 300 to 800 mL of blood to the lower extremities. Specialized nerve fibres called *mechanoreceptors* are located throughout the vascular system. These receptors respond to the increased blood volume by initiating a reflex increase in sympathetic stimulation and decrease in parasympathetic output. The end results are slight increases in HR and diastolic BP and a slight decrease in systolic BP.

In neuro-cardiogenic syncope, the increase in venous pooling that occurs in the upright position reduces venous return to the heart. This results in a sudden, compensatory increase in ventricular contraction. This reaction is misinterpreted by the brain as a hypertensive state, and sympathetic stimulation is consequently withdrawn. This produces a paradoxical vasodilation and bradycardia (vasovagal response). The end results are bradycardia, hypotension, cerebral hypoperfusion, and syncope.

In the head-upright tilt-table test, the patient is placed supine on a table and supported by belts across the torso and the feet. Baseline ECG, BP, and HR are obtained in the horizontal position. Next, the table is tilted 60 to 80 degrees, and the patient is maintained in this upright position for 20 to 60 minutes. The ECG and HR are recorded continuously, and BP is measured every 3 minutes throughout the test. In healthy individuals, venous pooling activates the mechanoreceptors, resulting in the normal response just described.

If the patient's BP and HR responses are abnormal and clinical symptoms are reproduced (e.g., faintness), the test result is considered positive. If after 30 minutes there is no response, the table is returned to the horizontal position and an intravenous infusion of low-dose isoproterenol may be started in an attempt to provoke a response. Neurocardiogenic syncope that recurs frequently and interferes with normal activities can be treated with a variety of drugs (e.g., metoprolol).

Other diagnostic tests for syncope include various recording devices. Holter monitors and event monitors are used and are discussed in this chapter and Chapter 34. A subcutaneously implanted loop-recording device can also be used to record the ECG during presyncopal and syncopal events. The device can be interrogated after a syncopal event in order to determine the ECG rhythm at the time of the event.

Case Study

Dysrhythmia

Patient Profile

Jacob Singer, a 68-year-old retired postal worker, is admitted to the cardiac care unit after cardiac arrest. Defibrillation was performed by

paramedics at his home. Mr. Singer is awake and lethargic but responding appropriately.

Subjective Data

- Has had two MIs and a history of HF
- Has shortness of breath, even in a sitting position

Objective Data

Physical Examination

- Appears anxious
- BP 92/60 mm Hg, pulse 98/min, respirations 28/min
- Lungs: bilateral coarse crackles
- Heart: S_3 gallop at apex

Diagnostic Studies

- ECG: frequent PVCs
- Echocardiogram: severe left ventricular dysfunction with ejection fraction (EF) of 20%
- Serum potassium level: 2.9 mmol/L

Collaborative Care

- Amiodarone infusion
- Scheduled for electrophysiology study (EPS)

Discussion Questions

1. Why is Mr. Singer at risk for ventricular fibrillation?
2. Why is amiodarone used after ventricular fibrillation?
3. What methods may be used to assess the effectiveness of an antidysrhythmia drug?
4. Would Mr. Singer be a candidate for an ICD?

5. If ventricular fibrillation recurred while Mr. Singer was receiving amiodarone infusion, what other IV medications would be tried?
6. What is the significance of the serum potassium value?
7. ***Priority decision:*** On the basis of these nursing diagnoses, what are the priority nursing interventions for Mr. Singer?
8. ***Evidence-informed practice:*** Once Mr. Singer is stable, he is scheduled for the insertion of a CRT/ICD. On the nurse's rounds, he asks why he needs two devices.

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. A client with a stable blood pressure and no symptoms has the following ECG characteristics: atrial rate, 74 beats/minute and regular; ventricular rate, 62 beats/minute and irregular; P wave, normal contour; PR interval, lengthens progressively until a P wave is not conducted; QRS complex, normal contour. What would be the appropriate treatment for this rhythm?
   a. Epinephrine, 1 mg IV push
   b. Isoproterenol, IV continuous drip
   c. Immediate insertion of a temporary pacemaker
   d. Careful observation for signs of further heart block
2. The nurse is monitoring the ECG of a client admitted with ACS. Which of the following ECG characteristics would be most suggestive of ischemia?
   a. Sinus rhythm with a pathological Q wave
   b. Sinus rhythm with an elevated ST segment
   c. Sinus rhythm with a depressed ST segment
   d. Sinus rhythm with premature atrial contractions
3. The cardiac monitor of a client in the cardiac care unit after an acute myocardial infarction indicates ventricular bigeminy. What would be the most appropriate intervention from the following list?
   a. Performing defibrillation
   b. Treatment with intravenous amiodarone
   c. Insertion of a temporary pacemaker
   d. Continuing to monitor and attempt to determine the underlying cause
4. How does defibrillation differ from cardioversion?
   a. Defibrillation requires a greater dose of electrical current.
   b. Defibrillation is synchronized to countershock during the QRS complex.
   c. Cardioversion is indicated only for treatment of atrial tachydysrhythmias.

d. Cardioversion may be done on a nonemergency basis with sedation of the client.

5. Which client teaching points should the nurse include when providing discharge instructions to a client with a new permanent pacemaker and the caregiver? *(Select all that apply)*
   a. Avoid or limit air travel.
   b. Take and record a daily pulse rate.
   c. Obtain and wear a medical alert bracelet at all times.
   d. Avoid lifting the arm on the side of the pacemaker above shoulder height.
   e. Avoid microwave ovens because they interfere with pacemaker function.
6. Which of the following is true when the client has an implantable cardiac defibrillator?
   a. Antidysrhythmia drugs can be discontinued.
   b. All members of the client's family should learn CPR.
   c. The client should not drive until the physician approves it after the ICD has been implanted.
   d. The client is usually relieved to have the device implanted to prevent dysrhythmias.
7. Which of the following would be essential to teach a client about before electrophysiological monitoring?
   a. A catheter will be placed in each of the femoral arteries to allow double-catheter use.
   b. The client will be given a general anaesthetic to prevent the awareness of “near-death” experiences.
   c. Ventricular tachycardia and ventricular fibrillation may be induced and treated during the procedure.
   d. The procedure is used to “burn” or ablate areas of the conduction system that are causing tachydysrhythmias.

1. d; 2. c; 3. d; 4. d; 5. b, c, d; 6. c; 7. d.

CHAPTER 39

Nursing Management

Inflammatory and Structural Heart Disorders

Written by, Nancy Kupper, De Ann F. Mitchell

Adapted by, Sheila Rizza

LEARNING OBJECTIVES

1. Describe the etiology, pathophysiology, and clinical manifestations of infective endocarditis and pericarditis.
2. Discuss the collaborative care and nursing management of infective endocarditis and pericarditis.
3. Explain the importance of prophylactic antibiotic therapy in infective endocarditis.
4. Explain the etiology and clinical manifestations of myocarditis, along with the collaborative care and nursing management of patients with myocarditis.
5. Describe the etiology, pathophysiology, and clinical manifestations of rheumatic fever and rheumatic heart disease.
6. Discuss the collaborative care and nursing management of patients with rheumatic fever and rheumatic heart disease.
7. Identify the etiologies of congenital and acquired valvular heart diseases.
8. Discuss the pathophysiology and clinical manifestations of the various types of valvular heart problems and the diagnostic studies used in connection with them.

9. Describe the collaborative care and nursing management of patients with valvular heart disease.
10. Describe surgical interventions used in management of patients with valvular heart problems.
11. Describe the pathophysiology and clinical manifestations of the different types of cardiomyopathies.
12. Discuss the nursing care and collaborative management of patients with different types of cardiomyopathies.

Inflammatory Disorders of the Heart

Infective Endocarditis

Infective endocarditis (IE), previously known as *bacterial endocarditis*, is an infection of the heart valves or the endocardial surface of the heart. The name of this disorder has changed because it is now recognized that organisms other than bacteria may cause the disease (Heart and Stroke Foundation of Canada, 2017a). The endocardium, the inner layer of the heart (Figure 39-1), is contiguous with the valves of the heart. Therefore, inflammation from IE affects the cardiac valves.

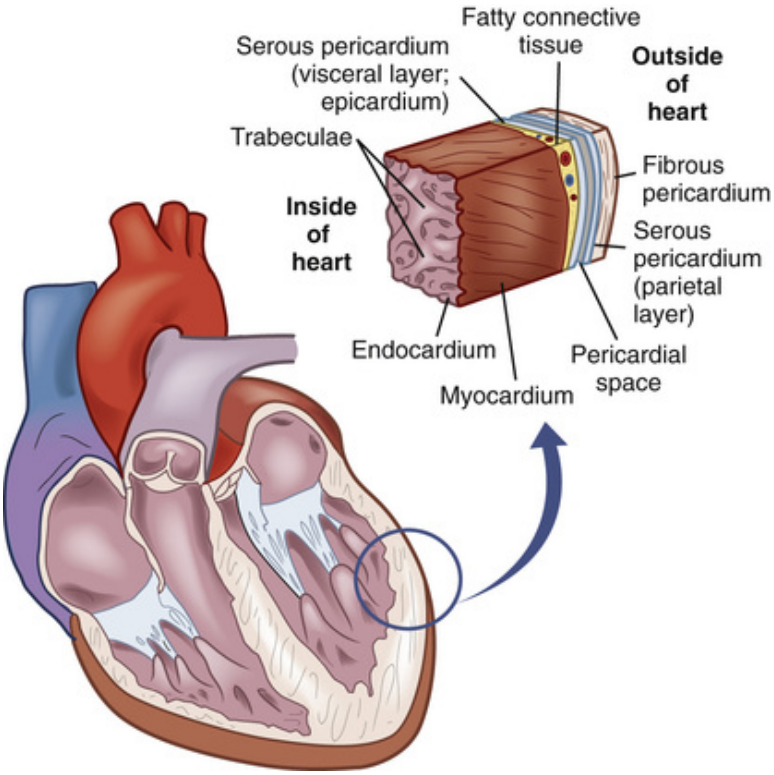

FIGURE 39-1 Layers of the heart muscle and pericardium. Source: Adapted from Patton, K. T., & Thibodeau, G. A. (2014). *The human body in health and disease* (6th ed., p. 371). St Louis: Mosby.

Before the era of antibiotics, IE was almost always fatal. The advent of penicillin therapy changed the prognosis dramatically, and mortality rates decreased appreciably.

Classification

Four different categories of IE describe the site of infection, the presence of cardiovascular devices, and how the individual acquired the infection: left-sided native valve IE, left-sided prosthetic valve IE, right-sided IE (includes intravenous [IV] drug use), and intracardiac and intravascular devices (e.g., pacemaker/defibrillator wires, hemodialysis). IE is identified as being community-acquired IE or health care–associated IE (Habib, Lancellotti, Antunes, et al., 2015; Que & Moreillon, 2011).

Etiology and Pathophysiology

The most common causative organisms of IE, *Staphylococcus aureus,* oral *Streptococcus,* and *Enterococci* are Gram-positive bacterial organisms responsible for more than 80% of IE cases (Table 39-1). Other possible pathogens include fungi and viruses. Newly identified pathogens, which are difficult to cultivate (e.g., *Bartonella, Tropheryma whippelii*), have been found to cause IE. Resistant organisms (e.g., methicillin-resistant *S. aureus*) also cause IE and are challenging conventional antibiotic therapy (Que & Moreillon, 2011; Baddour, Wilson, Bayer, et al., 2015).

TABLE 39-1

CAUSATIVE ORGANISMS ASSOCIATED WITH INFECTIVE ENDOCARDITIS

Bacteria
• *Bartonella quintana*
• *Chlamydiae*
• Coagulase-negative staphylococci
• *Enterococci*
• HACEK group (*Haemophilus, Actinobacillus, Cardiobacterium, Eikenella, Kingella* species)
• Methicillin-resistant *Staphylococcus aureus*
• Vancomycin-resistant *S. aureus*
• *Rickettsiae*
• *S. aureus*
• *Staphylococcus epidermidis*
• *Streptococcus bovis*
• Groups A, B, and C streptococci
• *Streptococcus pneumoniae*
• Viridans streptococci
• *Tropheryma whippelii*
Fungi
• *Candida albicans*
• *Candida parapsilosis*
• *Aspergillus*
Viruses
• Coxsackievirus B

IE occurs when blood flow turbulence within the heart allows the causative organism to infect previously damaged valves or other endothelial surfaces. It can occur in individuals with a variety of underlying cardiac conditions. The principal risk factors for IE are prior endocarditis, prosthetic valves, acquired valvular disease, and cardiac lesions. Several noncardiac conditions and procedures also can allow large numbers of organisms to enter the bloodstream and initiate the infectious process (Tables 39-2 and 39-3).

TABLE 39-2

PREDISPOSING CONDITIONS FOR THE DEVELOPMENT OF INFECTIVE ENDOCARDITIS

Cardiac Conditions
• Prior endocarditis • Prosthetic valves • Cardiac valvulopathy in cardiac transplant recipients • Rheumatic heart disease (e.g., mitral valve regurgitation) • Unrepaired cyanotic congenital heart disease, including palliative shunts and conduits • Repaired congenital heart defect with prosthetic material or device, surgically or through catheterization, during the first 6 months when endothelialization occurs
Noncardiac Conditions
• Intravenous drug abuse • Hospital-acquired bacteremia
Procedure-Associated Risks
• Intravascular devices (e.g., hemodialysis catheters) • Procedures listed in Table 39-3

TABLE 39-3

PROCEDURES NECESSITATING ANTIBIOTIC PROPHYLAXIS TO PREVENT INFECTIVE ENDOCARDITIS*

Oropharyngeal
• All dental procedures likely to produce gingival or mucosal bleeding (not simple adjustment of orthodontic appliances or shedding of deciduous teeth), including professional cleaning • Tonsillectomy or adenoidectomy
Respiratory
• Surgical procedures or biopsy involving respiratory mucosa
Integument
• Procedures on infected skin, skin structures, or musculo-skeletal tissues with incision of the tissue • Prophylactic administration of antimicrobial agents to prevent infective endocarditis in patients undergoing genito-urinary or gastro-intestinal procedures no longer recommended (Baddour, Wilson, Bayer, et al., 2015)

*This table lists select procedures but is not all-inclusive.

Vegetations, the primary lesions of IE, consist of fibrin, leukocytes, platelets, and microbes that adhere to the valve surface or the endocardium (Figure 39-2). The loss of portions of these friable vegetations

into the circulation results in *emboli*. As many as 22% to 50% of patients with IE will experience systemic embolization. These emboli arise from left-sided heart vegetations and progress to various organs (particularly the brain, the kidneys, and the spleen), causing infarction, and to the extremities, causing limb infarction. Right-sided heart lesions embolize to the lungs. The risk of embolization is greatest within the first few days of commencing antimicrobial therapy (Habib, Lancellotti, Antunes, et al., 2015).

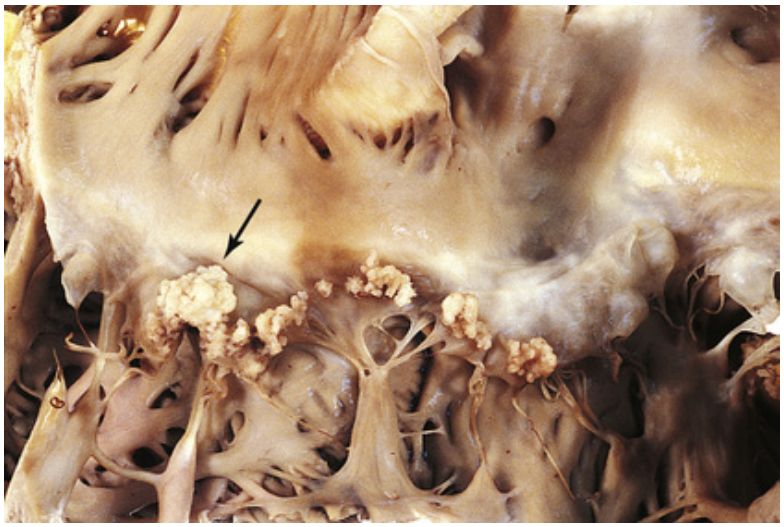

FIGURE 39-2 Bacterial endocarditis of the mitral valve. The valve is covered with large, irregular vegetations (*arrow*). Source: Damjanov, I., & Linder, J. (2000). *Pathology: A color atlas.* St. Louis: Mosby.

The infection may spread locally to cause damage to the valves or to their supporting structures. This damage results in dysrhythmias, valvular incompetence, and eventual invasion of the myocardium, leading to heart failure (HF), sepsis, and heart block (Figure 39-3).

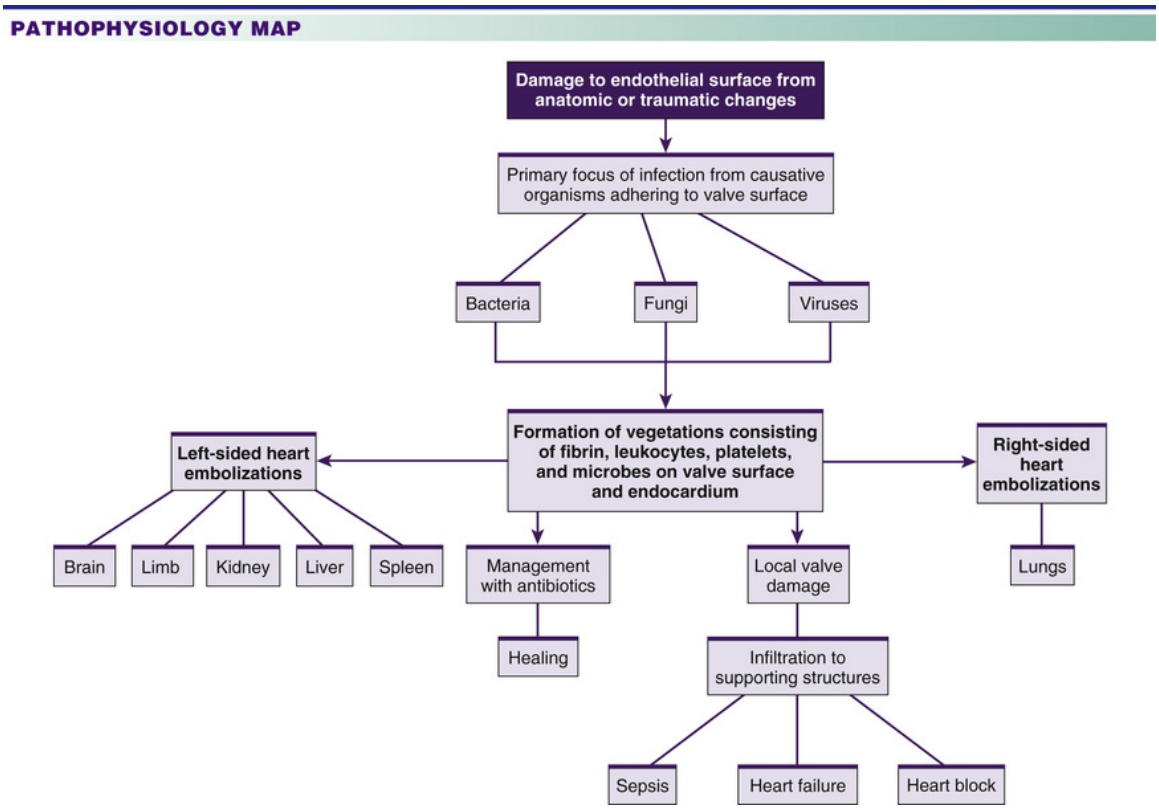

FIGURE 39-3 Pathogenesis of infective endocarditis.

Rheumatic heart disease was, at one time, the most common cause of IE; it now accounts for fewer than 20% of cases. Currently, the main contributing factors include (1) degenerative valve sclerosis; (2) recreational IV drug use; (3) use of prosthetic valves; (4) proliferation of intravascular device placement, resulting in health care–associated infections; and (5) renal dialysis (Habib, Lancellotti, Antunes, et al., 2015). Left-sided endocarditis is more common in patients with bacterial infections and underlying heart disease. The primary cause of right-sided endocarditis is IV use of illicit drugs. However, the incidence of affected left-sided valves has increased, especially with cocaine abuse. *S. aureus* is the most common causative organism in IV drug use IE.

Clinical Manifestations

The findings in IE are nonspecific and can involve multiple organ systems. Low-grade fever occurs in more than 90% of patients but may be absent in older adults and in immuno-compromised patients. Other nonspecific manifestations include chills, weakness, malaise, fatigue, and anorexia. Arthralgias, myalgias, back pain, abdominal discomfort, weight loss,

headache, and clubbing of fingers may occur in subacute forms of endocarditis.

Vascular manifestations of IE include *splinter hemorrhages* (longitudinal black streaks) that occur in the nail beds. Petechiae may occur as a result of fragmentation and microembolization of vegetative lesions and are common in the conjunctivae, the lips, the buccal mucosa, and the palate, and over the ankles, the feet, and the antecubital and popliteal areas. Osler's nodes (painful, tender, red or purple, pea-size lesions that last 1 to 2 days) may be found on the fingertips or the toes. Janeway's lesions (flat, painless, small, red spots) may be found on the palms and the soles. Funduscopic examination may reveal hemorrhagic retinal lesions called *Roth's spots*.

The onset of a new or changing murmur is noted in most patients with IE, with the aortic and mitral valves most commonly affected. The mitral murmur of endocarditis is generally a mid-tolate systolic regurgitant type. The aortic murmur may be early diastolic. Murmurs are often absent in tricuspid endocarditis because right-sided heart pressures are too low to be heard. HF is observed in 42% to 60% of patients with IE, more often in those with aortic valve endocarditis (29%) than in patients with mitral valve endocarditis (20%) (Habib, Lancellotti, Antunes, et al., 2015).

Clinical manifestations secondary to embolization in various body organs may also be present. Embolization to the spleen may result in sharp, left upper quadrant pain and splenomegaly. Local tenderness and abdominal rigidity may be present. Embolization to the kidneys may cause pain in the flank, hematuria, and azotemia. Emboli may lodge in small peripheral blood vessels of the arms and legs and may cause gangrene. Embolization to the brain may cause neurological problems such as hemiplegia, ataxia, aphasia, visual changes, and change in the level of consciousness. Pulmonary emboli may occur in right-sided endocarditis.

Diagnostic Studies

Obtaining the patient's recent health history is important in assessing IE. Inquiry should be made regarding any recent (within the past 3–6 months) dental, urological, surgical, or gynecological procedures, including normal or abnormal obstetrical delivery. Previous history of use of illicit IV drugs, previous valvular or congenital heart disease, intracardiac prosthetic device, recent cardiac catheterization, and skin, respiratory, or urinary tract infections should be documented.

Laboratory data, especially blood cultures, should also be assessed. Two blood cultures drawn 60 minutes apart will be positive in more than 90% of patients. Culture-negative endocarditis is often associated with antibiotic usage within the previous 2 weeks or caused by a pathogen not easily detected by standard culture procedures (e.g., *Bartonella* species). Negative cultures should be kept for 3 weeks if the clinical diagnosis remains endocarditis because of the possibility that a slow-growing causative organism may be detected.

A mild leukocytosis occurs in acute endocarditis (but is uncommon in the subacute form), with average white blood cell (WBC) counts ranging from 10 to 11 × 10^9/L. The erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) levels may be elevated.

Echocardiography is valuable in the diagnostic workup for a patient with IE when the blood cultures are negative or for the patient who is a surgical candidate and has an active infection. Transesophageal echocardiograms and digital imaging using two-dimensional transthoracic echocardiograms can detect vegetation, destructive lesions, and abscesses on valves (Habib, Lancellotti, Antunes, et al., 2015). A chest radiograph is done to detect the presence of *cardiomegaly* (an enlarged heart). An electrocardiogram (ECG) may show first- or second-degree atrioventricular (AV) block because the cardiac valves lie in proximity to cardiac conductive tissue, especially the AV node. Cardiac catheterization may be used to evaluate coronary artery patency and valvular function when surgical intervention is being considered for patients with IE.

Collaborative Care

Prophylactic Treatment.

Antibiotic prophylaxis is recommended for patients with specific cardiac conditions before they undergo certain dental or surgical procedures (Baddour, Wilson, Bayer et al., 2015; Habib, Lancellotti, Antunes, et al., 2015). Procedures for which endocarditis prophylaxis is recommended are summarized in Table 39-4. Specific antibiotic regimens are recommended for dental procedures that require manipulation of the gingival or periapical region of the teeth or perforation of the oral mucosa and respiratory tract. Current guidelines suggest that routine activities of oral hygiene contribute to bacteremia that may result in IE (Habib, Lancellotti, Antunes, et al., 2015).

TABLE 39-4

COLLABORATIVE CARE
Cardiac Conditions* Necessitating Antibiotic Prophylaxis to Prevent Infective Endocarditis

• Prosthetic cardiac valves • History of endocarditis • Surgically constructed systemic–pulmonary shunts • Complex cyanotic congenital heart disease • Vascular grafts (first 6 mo after implantation) • Cardiac transplantation requiring valvulopathy

*This table lists common cardiac conditions associated with high risk for infective endocarditis but is not all-inclusive.

Source: Habib, G., Lancellotti, P, Antunes, M., et al. (2015). Guidelines for the management of infective endocarditis. *European Heart Journal*, *36*(44), 3075–3128. doi:10.1093/eurheartj/ehv319

Drug Therapy.

Accurate identification of the infecting organism is the key to successful treatment of IE. Long-term treatment is necessary to kill dormant bacteria clustered within the valvular vegetations. Complete eradication of the organism generally takes weeks to achieve, and relapses are common. Initially, patients are hospitalized and IV antibiotic therapy is started. Table 39-5 outlines suggested antibiotic regimens for patients with IE from various causative organisms and with different clinical circumstances.

TABLE 39-5

DRUG THERAPY
Treatment of Infective Endocarditis With Outpatient Antibiotic Therapy*

Causative Agent	Antibiotic Regimen Options
Streptococcal endocarditis involving native valve	IV penicillin G or IV or IM ceftriaxone; IV penicillin G or IV or IM ceftriaxone plus IV or IM gentamicin; or IV vancomycin (Vancocin)
Enterococcal endocarditis involving native or prosthetic valve	IV ampicillin plus IV or IM gentamicin; or IV penicillin G plus IV or IM gentamicin; or IV vancomycin plus IV or IM gentamicin
Staphylococcal endocarditis in absence of prosthetic materials	IV cloxacillin or IV cefazolin for penicillin allergy
Fungal endocarditis in native or prosthetic valves	IV amphotericin B (Fungizone)

*This table lists common drug regimens but is not all-inclusive.

IM, intramuscular; *IV,* intravenous.

Subsequent blood cultures may be performed to evaluate the effectiveness of antibiotic therapy. Blood cultures that remain positive

indicate inadequate or inappropriate antibiotic administration, aortic root or myocardial abscess, or the wrong diagnosis (e.g., an infection elsewhere). Serum antibiotic drug levels are often monitored to establish therapeutic dosages. Finally, renal function is monitored when antibiotics are used that are nephrotoxic (e.g., vancomycin [Vancocin]) and for patients with poor kidney function.

Fungal infection and prosthetic valve endocarditis (PVE) are most frequently observed in IV drug users and immuno-compromised patients and respond poorly to antibiotic therapy alone. Early prolonged (≥6 weeks) drug therapy is recommended in these situations (Habib, Lancellotti, Antunes, et al., 2015). Valve replacement has become an important adjunct procedure in the management of IE. It is used in more than 25% of cases. (Valve replacement is discussed later in this chapter.)

Fever may persist for 5 to 10 days after treatment has been started and can be treated with acetylsalicylic acid (ASA; Aspirin), acetaminophen (Tylenol), ibuprofen (Motrin), fluids, and rest. Complete bed rest is usually not indicated unless the temperature remains elevated or there are signs of HF. Endocarditis coupled with HF responds poorly to both drug therapy and valve replacement and is often life-threatening.

Nursing Management Infective Endocarditis

Nursing Assessment

Subjective and objective data that should be obtained from a patient with IE are presented in Table 39-6. Heart sounds should be assessed together with vital signs to detect a murmur or a change in the character of a pre-existing murmur and the presence of extradiastolic sounds.

TABLE 39-6

NURSING ASSESSMENT
Infective Endocarditis

Subjective Data
Important Health Information
Past health history: Valvular, congenital, or syphilitic cardiac disease (including valve repair or replacement); previous endocarditis, childbirth, staphylococcal or streptococcal infections, health care–associated bacteremia *Medications:* Immuno-suppressive therapy, recreational IV drug use *Surgery or other treatments:* Recent obstetrical or gynecological procedures; invasive techniques including catheterization, cystoscopy, intravascular procedures; recent dental or surgical procedure; GI procedures (endoscopy)
Symptoms
• Exercise intolerance, generalized weakness, fatigue, malaise • Cough, dyspnea on exertion, orthopnea • Palpitations, night sweats • Chest, back, or abdominal pain • Headache, joint tenderness, muscle tenderness • Weight gain or loss; anorexia • Chills, diaphoresis • Bloody urine
Objective Data
General
Fever
Integumentary
Osler's nodes on extremities; splinter hemorrhages under nail beds; Janeway's lesions on palms and soles; petechiae of skin, mucous membranes, or conjunctivae; purpura; peripheral edema, finger clubbing
Respiratory
Tachypnea, crackles
Cardiovascular
Dysrhythmias, tachycardia, new or enhanced murmurs, S_3, S_4, retinal hemorrhages
Possible Findings
Leukocytosis, anemia, ↑ ESR, ↑ CRP and cardiac enzymes; positive blood cultures; microscopic hematuria; echocardiogram showing chamber enlargement, valvular dysfunction, and vegetations; chest radiograph showing cardiomegaly and pulmonary infiltrates; ECG demonstrating ischemia and conduction defects, signs of systemic embolization or pulmonary embolism

CRP, C-reactive protein*; ECG,* electrocardiogram; *ESR,* erythrocyte sedimentation rate; *GI,* gastro-intestinal; *IV,* intravenous; S_3, third heart sound; S_4, fourth heart sound.

Arthralgia is common, may involve multiple joints, and may be accompanied by myalgias. The patient should be assessed for joint tenderness, decreased range of motion, and muscle tenderness. The oral mucosa, conjunctivae, upper chest, and lower extremities should be examined for petechiae. A general systems assessment should be completed to facilitate recognition of hemodynamic and embolic complications.

Nursing Diagnoses

Nursing diagnoses for the patient with IE may include but are not limited to the following:

- *Decreased cardiac output* (related to altered heart rhythm, valvular insufficiency, and fluid overload)
- *Activity intolerance* related to *physical deconditioning* (generalized weakness, arthralgia, valvular dysfunction)

Additional information on nursing diagnoses for the patient with IE is presented in Nursing Care Plan 39-1, available on the Evolve website for this chapter.

Planning

The overall goals for the patient with IE include (a) normal or baseline cardiac function, (b) performance of activities of daily living without fatigue, and (c) knowledge of the therapeutic regimen to prevent recurrence of endocarditis.

Nursing Implementation

Health Promotion.

The incidence and the recurrence of IE can be decreased by identifying individuals who are at risk for the development of endocarditis (see Tables 39-2 and 39-4) and those who have had IE in the past and providing teaching to them. Assessment of a patient's history and an understanding of the disease process are crucial for planning and implementing appropriate health-promotion strategies. Teaching is crucial for patients

with IE so that they understand and adhere to the planned treatment regimen. Patients should understand the need to avoid people with infection, especially upper respiratory infection, and to report cold, flu, and cough symptoms. The importance of avoiding excessive fatigue and the need to plan rest periods before and after activity should be carefully explained to patients. Good oral hygiene, including daily care and regular dental visits, is also important. Patients must inform all health care providers performing dental, medical, or surgical procedures of their history of IE. Patients should understand the significance of the prescribed prophylactic antibiotic therapy before any invasive procedure. Patients with a history of IV drug use should be referred for drug treatment.

Ambulatory and Home Care.

Patients with IE will require nursing management (see NCP 39-1 for nursing diagnoses and interventions, available on the Evolve website for this chapter). IE generally requires treatment with antibiotics for 4 to 6 weeks, depending on the results of blood cultures (see Table 39-5). After initial treatment in the hospital, a patient who is hemodynamically stable and compliant may continue treatment in the home setting. The adequacy of the home environment in terms of in-home support and hospital access must be determined for successful management. Patients who receive outpatient IV antibiotics will require vigilant home nursing care.

Assessment findings are often nonspecific (see Table 39-6) but can help assist with the treatment plan. Fever, chronic or intermittent, is a common early sign. The patient or the caregiver needs instructions about the importance of monitoring body temperature because persistent, prolonged temperature elevations may mean that the drug therapy is ineffective. Patients with IE are at risk for life-threatening complications, such as cerebral emboli, pulmonary edema, and HF. Patients and caregivers must be taught to recognize signs and symptoms of these complications (e.g., change in mental status, dyspnea, chest pain).

Patients with IE need adequate periods of physical and emotional rest. Bed rest may be necessary when fever is present or when there are complications (e.g., heart damage). Otherwise, the patient may ambulate and perform moderate activity. To prevent problems because of immobility, the patient should wear elastic compression stockings, perform range-of-motion exercises, and cough and deep-breathe every 2 hours. Patients may experience anxiety and fear associated with the illness.

The nurse must recognize such feelings and implement strategies to help the patient cope with the illness.

Laboratory data should be monitored to determine the effectiveness of the antibiotic therapy. Ongoing monitoring of blood cultures is necessary to ensure eradication of the infecting organism. IV lines should be monitored for patency, and antibiotics should be given according to schedule. Patients should be monitored continuously for adverse drug reactions.

During the course of therapy in either the home or the hospital setting, management will also focus on teaching the patient about the nature of the disease and on reducing the risk for reinfection. The nurse must explain to the patient the relationship of follow-up care, good nutrition, and early treatment of common infections (e.g., colds) to maintain good health. The patient should be instructed about symptoms that may indicate recurrent infection, such as fever, fatigue, malaise, and chills. If any of these symptoms occur, the patient should be aware of the importance of notifying a health care provider. Finally, the patient must be instructed about the need for and importance of prophylactic antibiotic therapy before invasive procedures (see Table 39-3).

Evaluation

Expected outcomes for the patient with IE are presented in NCP 39-1.

Acute Pericarditis

Pericarditis, which may occur on an acute basis, is a condition caused by inflammation of the pericardial sac (the pericardium). The pericardium is composed of the inner serous membrane (visceral pericardium), which closely adheres to the epicardial surface of the heart and the outer fibrous (parietal) layer (see Figure 39-1). The pericardial space is the cavity between these two layers, and in the normal state, it contains 10 to 30 mL of serous fluid. Although the pericardium may be congenitally absent or surgically removed, it serves a useful anchoring function, provides lubrication to decrease friction during systolic and diastolic heart movements, and assists in preventing excessive dilation of the heart during diastole.

Etiology and Pathophysiology

The common causes of acute pericarditis are listed in Table 39-7. Acute pericarditis most often (80%–85% of the time) is idiopathic, with a variety of suspected viral causes. The coxsackievirus B group is the most commonly identified virus. In addition to idiopathic or viral pericarditis, causes of this syndrome include bacterial infection, fungal infection, acute myocardial infarction (MI), tuberculosis, neoplasm, autoimmune conditions, drug reactions, metabolic disorders, and trauma (Adler, Charron, Imazio, et al., 2015; Imazio, Gaita, & LeWinter, 2015).

TABLE 39-7
ETIOLOGIES OF PERICARDITIS

Infectious
• Viral: coxsackievirus A and B, echovirus, adenovirus, mumps, rubella, Epstein-Barr, varicella-zoster, hepatitis B, hepatitis C, human immunodeficiency virus • Bacterial: *Mycobacterium tuberculosis* (most common; rarely other bacteria); pneumococci, staphylococci, streptococci, *Neisseria gonorrhoeae, Legionella pneumophila,* septicemia from Gram-negative organisms • Fungal: *Histoplasma, Candida* species • Infections: toxoplasmosis, Lyme disease
Noninfectious
• Uremia • Myxedema • Acute myocardial infarction • Neoplasms: lung cancer, breast cancer, leukemia, Hodgkin's lymphoma, non-Hodgkin's lymphoma • Trauma: thoracic surgery, pacemaker insertion, cardiac diagnostic procedures • Radiation • Dissecting aortic aneurysm
Hypersensitive or Autoimmune
• Delayed post–myocardial-pericardial injury • Post–myocardial infarction (Dressler's) syndrome • Postpericardiotomy syndrome • Rheumatic fever • Drug reactions: procainamide, hydralazine (Apresoline), isoniazid, doxorubicin, and daunorubicin (often associated with cardiomyopathy) • Rheumatological diseases: rheumatoid arthritis, systemic lupus erythematosus, systemic sclerosis (scleroderma), ankylosing spondylitis

Pericarditis in the acute MI patient may be described as two distinct syndromes: (a) *acute pericarditis*, which may occur within the initial 48 to 72 hours after an MI, and (b) *Dressler's syndrome* (late pericarditis), which appears 4 to 6 weeks after an MI (see Chapter 36).

An inflammatory response—including an influx of neutrophils, increased pericardial vascularity, and eventually fibrin deposition on the visceral pericardium—is the characteristic pathological finding in acute pericarditis (Figure 39-4).

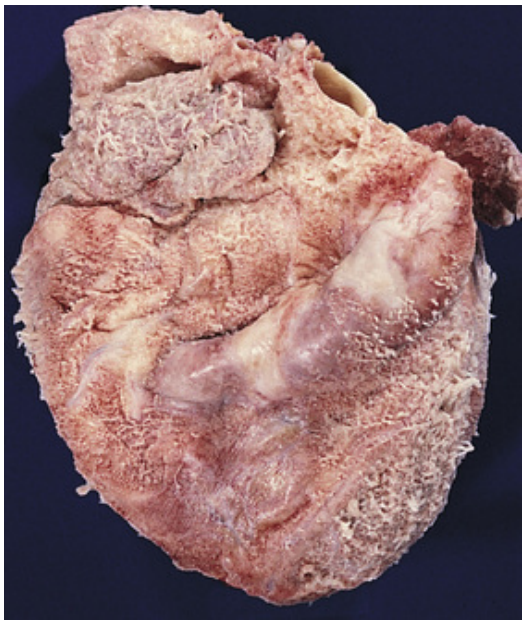

FIGURE 39-4 Acute pericarditis. Note the shaggy coat of fibrin covering the surface of the heart. Source: Damjanov, I., & Linder, J. (2000). *Pathology: A color atlas.* St. Louis: Mosby.

Clinical Manifestations

Characteristic clinical manifestations found in acute pericarditis include progressive, frequently severe chest pain that is sharp and pleuritic in nature. The pain is generally worse with deep inspiration and when lying supine. It is relieved by sitting upright. The pain may radiate to the neck, arms, or left shoulder, making it difficult to differentiate from angina. One distinction is that the pain from pericarditis can be referred to the trapezius muscle (shoulder, upper back) because the phrenic nerve innervates these two regions. Pericarditis is diagnosed in 5% of people presenting to the emergency department with chest pain (Imazio, Gaita, & LeWinter, 2015; Adler, Charron, Imazio, et al., 2015). The dyspnea that accompanies acute pericarditis is related to the patient's need to breathe in rapid, shallow breaths to avoid chest pain and may be aggravated by fever and anxiety.

The hallmark finding in acute pericarditis is the pericardial friction rub. The rub is a scratching, grating, high-pitched sound believed to arise from friction between the roughened pericardial and epicardial surfaces. It is best heard with the stethoscope placed at the lower left sternal border of the chest with the patient leaning forward. Since it is difficult to tell a pericardial friction rub from a pleural friction rub, patients can be asked to

hold their breath. If the rub is still heard, then it is cardiac. Pericardial friction rubs may require frequent attempts to identify because they are often intermittent and short-lived.

Complications

Two major complications that may result from acute pericarditis are pericardial effusion and cardiac tamponade. Pericardial effusion is an accumulation of excess fluid in the pericardium. It can occur rapidly (e.g., chest trauma) or slowly (e.g., tuberculous pericarditis). Large effusions may compress adjoining structures. Pulmonary tissue compression can cause cough, dyspnea, and tachypnea. Phrenic nerve compression can induce hiccups, and compression of the recurrent laryngeal nerve may result in hoarseness. Heart sounds are generally distant and muffled, although blood pressure (BP) is usually maintained by compensatory mechanisms.

Cardiac tamponade, also referred to as *pericardial tamponade*, develops as fluid accumulates in the pericardial sac (pericardial effusion), causing an increase in intrapericardial pressure and producing compression of the heart. The speed of fluid accumulation affects the severity of clinical manifestations. Cardiac tamponade can occur acutely (e.g., rupture of heart, trauma) or subacutely (e.g., secondary to uremia, malignancy). The patient with cardiac tamponade may report chest pain and is often confused, anxious, and restless. As the compression of the heart increases, heart sounds become muffled and the pulse pressure is narrowed. The patient will develop tachypnea, tachycardia, and a decreased cardiac output (CO). The neck veins are usually markedly distended because of increased jugular venous pressure, and a significant pulsus paradoxus is present. *Pulsus paradoxus* is a decrease in systolic BP with inspiration that is exaggerated in cardiac tamponade. (See Table 39-8 for the measurement technique.) In a patient with a slow onset of a cardiac tamponade, dyspnea may be the only clinical manifestation.

TABLE 39-8
MEASUREMENT OF PULSUS PARADOXUS

1. Make determination during quiet breathing with stable rhythm.
2. Determine systolic blood pressure.
3. Inflate blood pressure cuff until no sounds are heard with stethoscope.
4. Deflate cuff slowly until systolic sounds are heard on expiration, and note the pressure.
5. Deflate cuff until systolic sounds are heard throughout the respiratory cycle, and note the pressure.
6. Determine the difference between the measurements taken in Steps 4 and 5. This will equal the amount of paradox:

Sounds heard in expiration at	110 mm Hg
Sounds heard throughout cycle at	82 mm Hg
Amount of paradox	28 mm Hg

The difference is usually <10 mm Hg. If the difference is >10 mm Hg, cardiac tamponade may be present.

Diagnostic Studies

The ECG is useful in the diagnosis of acute pericarditis, with changes noted in approximately 90% of cases. The most sensitive ECG changes include diffuse (widespread) ST-segment elevations. This reflects the abnormal repolarization that develops secondary to the pericardial inflammation. It is important to differentiate these changes from the ST changes seen in MI. (See Chapter 38 for more information on ECG monitoring.) The chest radiographic findings are generally normal, but cardiomegaly may be seen in a patient who has a large pericardial effusion (Figure 39-5). Echocardiographic findings are more useful in determining the presence of a pericardial effusion or cardiac tamponade. Newer methods such as tissue Doppler imaging and colour M-mode Doppler imaging of early left ventricular flow help to assess diastolic function and diagnose constrictive pericarditis (discussed later in the chapter). Computed tomography (CT) and cardiac magnetic resonance imaging (CMRI) provide for visualization of the pericardium and pericardial space (Imazio, Gaita, & LeWinter, 2015).

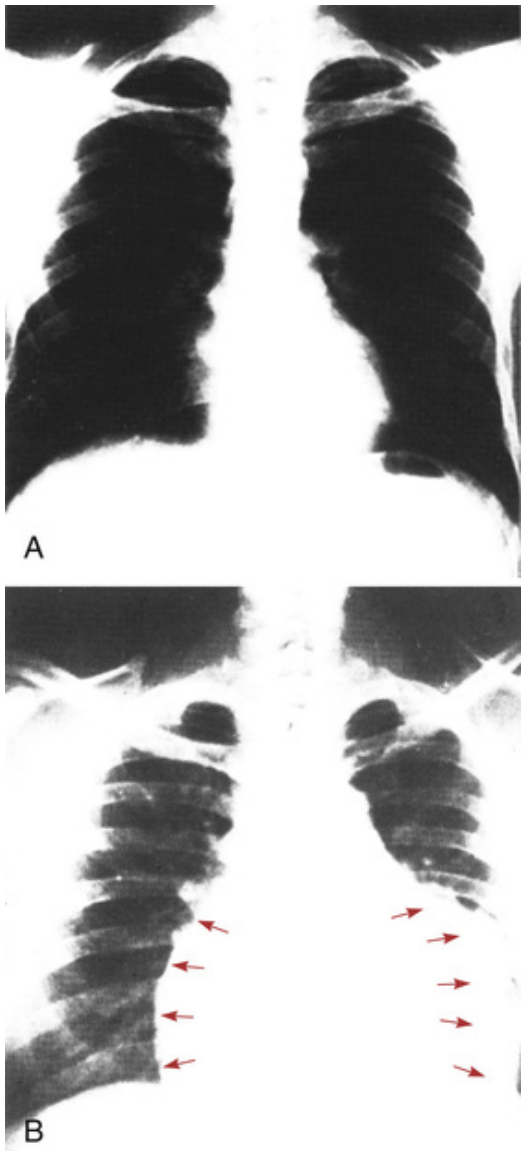

FIGURE 39-5 **A,** Radiograph of a normal chest. **B,** Pericardial effusion is present and the cardiac silhouette is enlarged with a globular shape (*arrows*). Source: Guzetta, C. E., & Dossey, B. M. (1992). *Cardiovascular nursing: Holistic practice.* St. Louis: Mosby.

Common laboratory findings include leukocytosis and elevation of CRP and ESR. Troponin levels may be elevated in patients with ST-segment elevation and acute pericarditis, a reading that would indicate concurrent myocardial damage. The fluid obtained during pericardiocentesis (Figure 39-6) or the tissue from a pericardial biopsy may also be analyzed to determine the cause of the pericarditis.

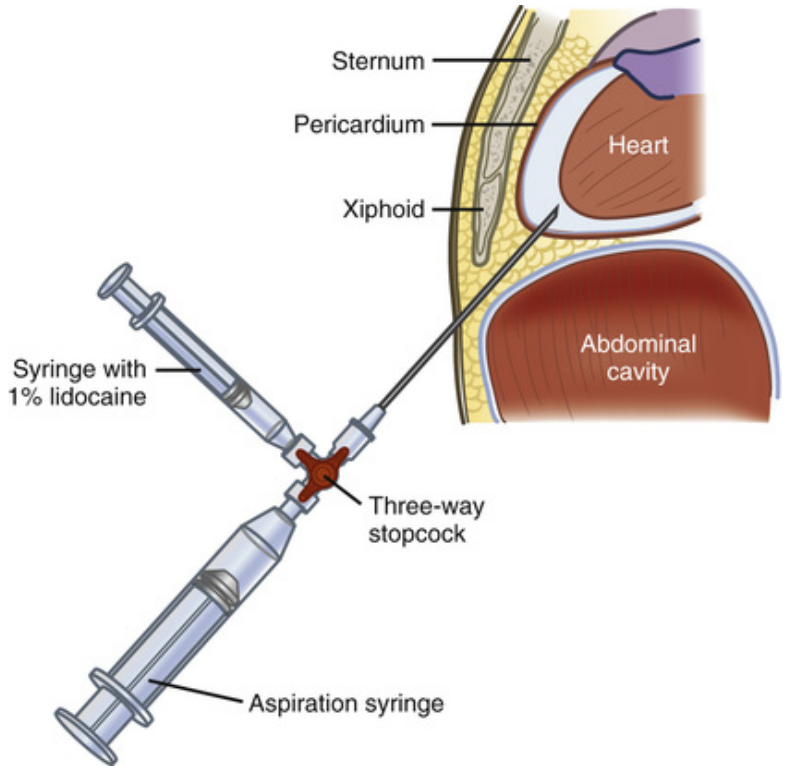

FIGURE 39-6 Pericardiocentesis performed under sterile conditions in conjunction with electrocardiogram (ECG) and hemodynamic measurements.

Collaborative Care

Management of acute pericarditis is directed toward identification and treatment of the underlying problem (Table 39-9). Antibiotics should be used to treat bacterial pericarditis. Corticosteroids are generally reserved for patients with pericarditis secondary to systemic lupus erythematosus, patients already taking corticosteroids for a rheumatological or other immune system condition, or patients who do not respond to nonsteroidal anti-inflammatory drugs (NSAIDs). When necessary, prednisone is usually given according to a tapering dosage schedule. Corticosteroids are administered cautiously because of their numerous adverse effects, such as upper gastro-intestinal bleeding, sodium retention, hyperglycemia, hypokalemia, and Cushing's syndrome (see Chapter 51).

TABLE 39-9

COLLABORATIVE CARE
Acute Pericarditis

Diagnostic	Collaborative Therapy
• History and physical examination • Auscultation of chest • ECG • Laboratory: CRP, ESR, white blood cell count, BUN,* serum creatinine • TB test • Chest radiographic examination • Echocardiogram • Pericardiocentesis • Pericardial biopsy • CT scan • Cardiac nuclear scan	• Treatment of underlying disease • Bed rest • ASA (Aspirin) • NSAIDs • Colchicine • Corticosteroids • Pericardiocentesis (for large pericardial effusion or tamponade) • Pericardial window (for tamponade or ongoing pericardial effusion)

*Serum urea (nitrogen).

ASA, acetylsalicylic acid; *BUN,* blood urea nitrogen; *CRP,* C-reactive protein; *CT,* computed tomography; *ECG,* electrocardiogram; *ESR,* erythrocyte sedimentation rate; *NSAIDs,* nonsteroidal anti-inflammatory drugs; *TB*, tuberculosis.

The pain and inflammation of acute pericarditis are usually treated with NSAIDs (e.g., ibuprofen) or high-dose salicylates (e.g., ASA [Aspirin]). Colchicine, an anti-inflammatory medication used for gout and previously used for recurrent pericarditis, is now recommended in the treatment of acute pericarditis (Adler, Charron, Imazio, et al., 2015). The COPE trial (**co**lchicine for acute **pe**ricarditis) demonstrated that the use of colchicine with ASA reduced recurrence rates by 10.7% (from 32.3% to 21.6%) and reduced symptoms at 72 hours to 11.7% from 36.7% compared with conventional therapy (Imazio, Gaita, & LeWinter, 2015).

If surgical drainage is necessary, a pericardiocentesis may be performed. During this procedure, a 16- to 18-gauge needle is inserted into the pericardial space to remove fluid for analysis and to relieve cardiac pressure. The procedure is rapid and safe and done using a percutaneous approach that is guided by ECG and echocardiography. It is usually performed for pericardial effusion with acute cardiac tamponade, purulent pericarditis, and a high index of suspicion of neoplasm (see Figure 39-6). Hemodynamic support for the patient being prepared for the pericardiocentesis may include administration of volume expanders and inotropic drugs (e.g., dopamine) and the discontinuation of any anticoagulants. Complications from pericardiocentesis include dysrhythmias, further cardiac tamponade, pneumomediastinum, pneumothorax, myocardial laceration, and coronary artery laceration.

Nursing Management Acute Pericarditis

The management of the patient's pain and anxiety during acute pericarditis is a primary nursing consideration. Assessment of the amount, the quality, and the location of the pain is important, particularly in distinguishing the pain of myocardial ischemia (angina) from the pain of pericarditis. Pericarditic pain is usually located in the precordium or left trapezius ridge and has a sharp, pleuritic quality that increases with inspiration. Pain is often relieved by sitting or leaning forward, and the pain is worsened when lying supine. ECG monitoring can aid in distinguishing these types of pain because ischemia usually involves localized ST-segment changes, as compared with the diffuse ST-segment changes present in acute pericarditis.

Pain relief measures include maintaining the patient on bed rest with the head of the bed elevated to 45 degrees and providing an overbed table for support. Anti-inflammatory medications help alleviate the patient's pain; however, in high doses, they can cause upper gastro-intestinal bleeding. Nursing interventions, therefore, should be directed toward identification and management of this potential problem. Specific interventions include administering these drugs with food or milk and instructing the patient to avoid any alcoholic beverages while taking the medications.

Other drugs, such as misoprostol, or a proton pump inhibitor may be ordered to protect the gastric mucosa. Anxiety-reducing measures for patients with acute pericarditis include providing simple, complete explanations of all procedures performed and the possible cause of the pain. These explanations are particularly important for patients whose diagnosis of acute pericarditis is being established and for patients who have already experienced angina or an acute MI.

The potential for decreased CO exists for patients with acute pericarditis because of the possibility of cardiac tamponade. Monitoring for the signs and symptoms of tamponade and preparing for possible pericardiocentesis are important nursing responsibilities.

Chronic Constrictive Pericarditis

Etiology and Pathophysiology

Chronic constrictive pericarditis results from scarring with consequent loss of elasticity of the pericardial sac. It usually begins with an initial episode of

acute pericarditis (often secondary to idiopathic causes, cardiac surgery, or radiation) and is characterized by fibrin deposition with a clinically undetected pericardial effusion. Resorption of the effusion slowly follows, with progression toward the chronic stage of fibrous scarring, thickening of the pericardium from calcium deposition, and eventual obliteration of the pericardial space. The fibrotic, thickened, and adherent pericardium encases the heart, thereby impairing the ability of the atria and ventricles to stretch adequately during diastole.

Clinical Manifestations

Manifestations of chronic constrictive pericarditis occur over an extended period and mimic those of HF and cor pulmonale. Many of the clinical manifestations are related to decreased CO. They include dyspnea on exertion, peripheral edema, ascites, fatigue, anorexia, and weight loss. The most prominent finding upon physical examination is elevated jugular venous pressure. Unlike with cardiac tamponade, the presence of significant pulsus paradoxus is uncommon. Auscultatory findings include a *pericardial knock,* which is a loud early diastolic sound often heard along the left sternal border.

Diagnostic Studies

ECG results are often nonspecific in chronic constrictive pericarditis. The cardiac silhouette on the chest radiograph may be normal or enlarged depending on the degree of pericardial thickening and the presence of a coexisting pericardial effusion. Two-dimensional echocardiography is insensitive for determining pericardial thickness but may inform the health care provider about the physiology. Colour M-mode and tissue Doppler imaging are used to confirm constrictive pericarditis. CT and MRI provide measurement of pericardial thickness and assessment of diastolic filling patterns. Cardiac catheterization is indicated when noninvasive investigation such as Doppler echocardiography, CT, or MRI do not provide definitive diagnosis (Adler, Charron, Imazio, et al., 2015).

Nursing and Collaborative Management Chronic Constrictive Pericarditis

Unless the patient is free of symptoms or the condition is inoperable, the treatment of choice for chronic constrictive pericarditis is a *pericardiectomy*. This procedure involves complete resection of the pericardium through a median sternotomy with the use of cardiopulmonary bypass. Some patients show immediate improvement after surgery, but others may take weeks. The postoperative prognosis is improved when the surgery is performed before severe clinical disability has developed.

Myocarditis

Etiology and Pathophysiology

Myocarditis is a focal or diffuse inflammation of the myocardium. Possible causes include viruses, bacteria, fungi, parasites, radiation therapy, and pharmacological and chemical factors. Viruses, particularly coxsackievirus types A and B, are the most common causative agents of myocarditis in Canada and the United States. Autoimmune disorders (e.g., polymyositis) also have been associated with the development of myocarditis. In some cases, no causative agent or factor can be identified (i.e., idiopathic myocarditis). Myocarditis is frequently associated with acute pericarditis, particularly when it is caused by coxsackievirus B strains or echoviruses (Caforio, Pankuweit, Arbustini et al., 2013). When the myocardium becomes infected, the causative agent invades the myocytes and causes cellular damage and necrosis. The immune response is activated, and cytokines and oxygen free radicals are released. As the infection progresses, an autoimmune response is activated, leading to further destruction of myocytes. Myocarditis results in cardiac dysfunction and has been linked to the development of dilated cardiomyopathy (DCM) (discussed later in this chapter).

Clinical Manifestations

The clinical features of myocarditis are variable, ranging from a benign course without any overt manifestations to severe heart involvement or sudden cardiac death (SCD). Fever, fatigue, malaise, myalgias,

pharyngitis, dyspnea, lymphadenopathy, and nausea and vomiting are early systemic manifestations of the viral illness.

Early cardiac manifestations appear 7 to 10 days after viral infection. These include pleuritic chest pain with a pericardial friction rub and effusion, because pericarditis often accompanies myocarditis. Late cardiac signs relate to the development of HF and may include a third heart sound (S_3), crackles, jugular venous distension, syncope, peripheral edema, and angina.

Diagnostic Studies

The ECG changes for a patient with myocarditis are often nonspecific and reflect associated pericardial involvement (e.g., diffuse ST-segment abnormalities). Dysrhythmias and conduction disturbances may be present. Laboratory findings are also often inconclusive. They may include mild to moderate leukocytosis and atypical lymphocytes, increased ESR and CRP levels, elevated levels of myocardial markers such as troponin, and elevated viral titres (virus is generally present in tissue and fluid samples only during the initial 8–10 days of illness). Histological confirmation of myocarditis is done through endomyocardial biopsy (EMB). This technique involves removing several small pieces of myocardial tissue percutaneously from the right ventricle with a special instrument called a *bioptome* and microscopically examining the samples (Caforio, Pankuweit, Arbustini, et al., 2013). A biopsy done during the initial 6 weeks of acute illness is most diagnostic because, in this period, lymphocytic infiltration and myocyte damage indicative of myocarditis are present. Other studies to evaluate cardiac function include echocardiography, nuclear scans, and MRI.

Collaborative Care

The treatment for myocarditis in patients with fulminant HF includes cardiovascular support with inotropic or vasopressor therapy or both and mechanical circulatory support (e.g., left ventricular assist device [LVAD]). Care of patients with both myocarditis and HF is the same usual care for HF patients: beta blockers, angiotensin-converting enzyme (ACE) inhibitors, and diuretic therapy, the last of which may help to reduce fluid volume and decrease preload (Howlett, Chan, Exekoitz, et al., 2016). Immuno-suppressive therapy with drugs such as prednisone, azathioprine (Imuran), and cyclosporine is not routinely recommended in the management of the patient with myocarditis but may be trialled in

patients with an autoimmune disorder and those who are severely hemodynamically compromised and not responding to treatment. Intravenous immunoglobulin (IVIG) has not demonstrated improved outcomes but may be of use for the pediatric population (Kindermann, Barth, Mahfoud, et al., 2012). Antiviral and immuno-suppressive agents remain controversial, but these drugs have been shown to improve New York Heart Association (NYHA) functional classification (Kindermann, Barth, Mahfoud, et al., 2012; Caforio, Pankuweit, Arbustini, et al., 2013). Oxygen therapy, bed rest, restricted activity, and maintenance of standby emergency equipment are general supportive measures in the management of myocarditis.

Nursing Management Myocarditis

Decreased CO is an ongoing nursing diagnosis in the care of the patient with myocarditis. Interventions focus on assessment for the signs and symptoms of HF. Important nursing measures to decrease cardiac workload include using semi-Fowler's position, spacing out activity and rest periods, and providing a quiet environment. Prescribed medications that increase the heart's contractility and decrease the preload, the afterload, or both require careful monitoring. Ongoing evaluation of the effectiveness of these interventions is necessary.

Patients may be anxious about the diagnosis of myocarditis, recovery from myocarditis, and the therapeutic plan. Nursing measures include assessing the level of anxiety, instituting measures to decrease anxiety, and keeping the patient and caregivers informed about therapeutic measures.

Patients who receive immuno-suppressive therapy have additional problems of alterations in the immune response with the potential for infection and complications related to the therapy. Guidelines for care include monitoring for complications and providing the patient with a clean, safe environment by following proper infection-control procedures. Most patients with myocarditis recover spontaneously, although some may develop DCM. If severe HF occurs, the patient may require heart transplantation.

Rheumatic Fever and Heart Disease

Rheumatic fever is defined by the Heart and Stroke Foundation of Canada (2017b) as "an inflammatory disease that may affect several connective tissues of the body, especially those of the heart, brain, joints, or skin." Rheumatic fever potentially involves all layers of the heart (endocardium, myocardium, and pericardium). Rheumatic heart disease is a chronic condition resulting from rheumatic fever that is characterized by scarring and deformity of the heart valves.

Etiology and Pathophysiology

Acute rheumatic fever (ARF) is a complication that occurs as a delayed result (usually after 2–3 weeks) of group A streptococcal pharyngitis (Burke, 2015). Manifestations of ARF appear to be related to an abnormal immunological response to group A streptococcal cell membrane antigens.

ARF has declined in developed countries as a result of the effective use of antibiotics to treat streptococcal infections. However, it remains an important public health problem in developing countries. The sequela of ARF, rheumatic heart disease, is found primarily in young adults.

Cardiac Lesions and Valvular Deformities.

About 40% of ARF episodes are marked by carditis, and all layers of the heart (endocardium, myocardium, and pericardium) may be involved (see Figure 39-1). This generalized involvement gives rise to the term *rheumatic pancarditis*.

Rheumatic endocarditis is found primarily in the valves, with swelling and erosion of the valve leaflets. Vegetations form from deposits of fibrin and blood cells in areas of erosion. The lesions initially create fibrous thickening of the valve leaflets, fusion of commissures and chordae tendineae, and fibrosis of the papillary muscle. Valve leaflets may fuse and become thickened or even calcified, resulting in stenosis. Reduction in the mobility of valve leaflets may occur with failure of the leaflets, resulting in regurgitation. The mitral and aortic valves are most commonly affected.

Myocardial involvement is characterized by Aschoff bodies**,** which are tiny, rounded or spindle-shaped nodules formed by a reaction to inflammation with accompanying swelling and fragmentation of collagen fibres. As the Aschoff bodies age, they become more fibrous, and scar tissue forms in the myocardium. In addition to Aschoff bodies, a diffuse cellular infiltrate is present in interstitial tissues. Rheumatic pericarditis affects both layers of the pericardium, which become thickened and covered with a fibrinous exudate, and a serosanguineous pericardial effusion may develop. When healing occurs, fibrosis and adhesions develop that partially or completely obliterate the pericardial sac, but constrictive pericarditis does not occur.

These pathophysiological changes in the heart may occur as a result of an initial attack of rheumatic fever. However, recurrent infections may cause further structural damage.

Extracardiac Lesions.

The lesions of rheumatic fever are systemic, involving the connective tissues especially. The joints (polyarthritis), skin (subcutaneous nodules), and central nervous system may be involved in rheumatic fever.

Clinical Manifestations

Symptoms of ARF can include chest pain, excessive fatigue, heart palpitations (the heart fluttering or missing beats), a thumping sensation in the chest, shortness of breath, and swollen ankles, wrists, or stomach (Heart and Stroke Foundation of Canada, 2017a). The diagnosis of ARF is suggested by a clustering of signs and symptoms as well as by laboratory findings. When not observed in its most severe form, the disease may be difficult to differentiate from many illnesses with similar clinical manifestations. Criteria established by T. D. Jones in 1944 have been revised by the American Heart Association and provide a basis for diagnosis (Gewitz, Baltimore, Tani, et al., 2015) (Table 39-10). The presence of two major criteria or one major and two minor criteria plus evidence of a preceding group A streptococcal infection indicates a high probability of ARF.

TABLE 39-10
MODIFIED JONES CRITERIA FOR ACUTE RHEUMATIC FEVER

Major Criteria	Minor Criteria	Evidence of Group A Streptococcal Infection
• Carditis • Mono- or polyarthritis • Sydenham chorea • Erythema marginatum • Subcutaneous nodules	• Clinical findings: fever, polyarthralgia • Laboratory findings: ↑ ESR, ↑ WBC count, ↑ CRP • ECG findings: prolonged PR interval	• Laboratory findings: ↑ antistreptolysin O titre, positive throat culture, positive rapid antigen test for group A streptococci

CRP, C-reactive protein; *ECG*, electrocardiogram; *ESR*, erythrocyte sedimentation rate; *WBC*, white blood cell.

Major Criteria.

Carditis is the most important manifestation of ARF and results in three signs: (a) an organic heart murmur or murmurs of mitral or aortic regurgitation or mitral stenosis; (b) cardiac enlargement and HF occurring secondary to myocarditis; and (c) pericarditis resulting in muffled heart sounds, chest pain, a pericardial friction rub, or signs of effusion.

Mono- or *polyarthritis* is the most common finding in rheumatic fever. The inflammatory process affects the synovial membranes of the joints, causing swelling, heat, redness, tenderness, and limitation of motion. The larger joints are most frequently affected, particularly knees, ankles, elbows, and wrists.

Chorea (Sydenham chorea) is the major central nervous system manifestation of ARF, often a delayed sign occurring several months after the initial infection. It is characterized by involuntary movements, especially of the face and the limbs, muscle weakness, and disturbances of speech and gait.

Erythema marginatum lesions are a less common feature of ARF. The bright pink maplike macular lesions occur mainly on the trunk and the proximal extremities and may be exacerbated by heat (e.g., warm bath). Subcutaneous nodules, usually associated with severe carditis, are firm, small, hard, painless swellings located over extensor surfaces of the joints, particularly knees, wrists, and elbows.

Minor Criteria.

Minor clinical manifestations (see Table 39-10) are frequently present and are helpful in diagnosing the disease. The minor criteria are used as supplemental data to confirm the presence of rheumatic fever when only one major criterion is present.

Complications

A complication that can result from ARF is *chronic rheumatic carditis.* It results from changes in valvular structure that may occur months to years after an episode of ARF. Rheumatic endocarditis can result in fibrous tissue growth in valve leaflets and chordae tendineae with scarring and contractures. The mitral valve is most frequently involved; the aortic or tricuspid valve or both may also be affected.

Diagnostic Studies

No single diagnostic test exists for rheumatic fever (see Table 39-10). An echocardiogram may show valvular insufficiency and pericardial fluid or thickening. A chest radiographic study may show an enlarged heart if HF is present. The most consistent ECG change is delayed AV conduction as evidenced by prolongation of the PR interval.

Collaborative Care

Treatment consists of drug therapy and supportive measures (Table 39-11). Antibiotic therapy does not modify the course of the acute disease or the development of carditis. It does eliminate residual group A streptococci remaining in the tonsils and the pharynx and prevent the spread of

organisms to close contacts. Salicylates, NSAIDs, and corticosteroids are the anti-inflammatory drugs most widely used in the management of ARF. All are effective in controlling the fever and joint manifestations. Salicylates or NSAIDs are used when arthritis is the main manifestation, and corticosteroids are used if severe carditis is present.

TABLE 39-11

COLLABORATIVE CARE
Rheumatic Fever

Diagnostic	Collaborative Therapy
• History and physical examination • Laboratory findings (see Table 39-10) • Throat culture • Chest radiograph • Echocardiogram • ECG	• Bed rest (modified) • Benzathine penicillin (1.2 million units IM) daily for 10 days • Acetylsalicylic acid • Corticosteroids • Codeine • Carbamazepine, valproic acid, phenobarbital

ECG, electrocardiogram; *IM,* intramuscularly.

Nursing Management Rheumatic Fever and Heart Disease

Nursing Assessment

Subjective and objective data that should be obtained from a patient with rheumatic fever and heart disease are presented in Table 39-12. It is important to note that rheumatic fever is more likely to reoccur in a person with a previous history of rheumatic fever than to occur in the general population. The skin of the patient should be assessed for subcutaneous nodules and erythema marginatum. The procedure involves palpation for subcutaneous nodules over all bony surfaces and along extensor tendons of the hands and feet. The nodules range in size from 1 to 4 cm and are hard, painless, and freely movable. Erythema marginatum can occur on the trunk and the inner aspects of the upper arm and the thigh. The erythematous maplike macules do not itch and are not raised. The possible presence of these bright pink macules should be assessed in good light because the rash is difficult to observe, especially if the patient is dark skinned.

TABLE 39-12

NURSING ASSESSMENT
Rheumatic Fever and Rheumatic Heart Disease

Subjective Data
Important Health Information
Past health history: Recent β-hemolytic streptococcal infection, previous rheumatic fever or rheumatic heart disease, family history of rheumatic fever
Symptoms
• Malaise, generalized weakness, fatigue • Anorexia; weight loss • Palpitations • Ataxia; migratory joint pain and tenderness (especially large joints) • Chest pain
Objective Data
General
Low-grade fever
Integumentary
Subcutaneous nodules and erythema marginatum
Cardiovascular
Tachycardia, pericardial friction rub, distant heart sounds; gallop rhythm, diastolic and systolic murmurs, peripheral edema
Neurological
Chorea (involuntary, purposeless, rapid motions; facial grimaces)
Musculo-Skeletal
Signs of polyarthritis including swelling, heat, redness, limitation of motion (especially of knees, ankles, elbows, shoulders, and wrists)
Possible Findings
Cardiomegaly on chest radiographic study; delayed AV conduction on ECG; valve abnormalities, chamber dilation, and pericardial effusion on echocardiogram; ↑ ASO titre, ↑ ESR, ↑ CRP, leukocytosis

ASO, antistreptolysin O; *AV,* atrioventricular; *CRP,* C-reactive protein; *ECG,* electrocardiogram; *ESR,* erythrocyte sedimentation rate.

Nursing Diagnoses

Nursing diagnoses for the patient with rheumatic fever and heart disease may include but are not limited to the following:

- *Decreased cardiac output* (related to valve dysfunction or HF)
- *Activity intolerance* related to *physical deconditioning* (arthralgia, arthritis, pain from pericarditis)
- *Ineffective health management* related to *insufficient knowledge of therapeutic regimen* (need for long-term prophylactic antibiotic therapy)

Planning

The overall goals for a patient with rheumatic fever include (a) normal or baseline heart function, (b) resumption of daily activities without joint pain, and (c) verbalization of the ability to manage the disease.

Nursing Implementation

Health Promotion.

Rheumatic fever is a preventable cardiovascular disease. Prevention involves early detection and immediate treatment of group A β-hemolytic streptococcal pharyngitis. Adequate treatment of streptococcal pharyngitis prevents initial attacks of rheumatic fever. Treatment consists of intramuscular injection of penicillin G benzathine (Bicillin L-A) or oral penicillin V potassium. If the patient is allergic to penicillin, erythromycin or azithromycin (Zithromax) may be substituted. Oral therapy requires faithful adherence to the full course of treatment. The nurse's role is to educate people in the community to seek medical attention for symptoms of streptococcal pharyngitis and to emphasize the need for adequate treatment of this infection.

Acute Intervention.

The primary goals of managing a patient with ARF are to control and eradicate the infecting organism; prevent cardiac complications; relieve joint pain, fever, and other symptoms; and support the patient psychologically and emotionally. The nurse should administer antibiotics as ordered to treat the streptococcal infection and should teach the patient that oral antibiotic therapy requires faithful adherence to the full course of therapy. Antipyretics, NSAIDs, and corticosteroids should be administered as prescribed, and fluid intake monitored. Promotion of optimal rest is essential to reduce the cardiac workload and to diminish the metabolic needs of the body. Relief of joint pain is an important nursing goal. Painful joints should be positioned for comfort and proper alignment. Heat may be applied, and salicylates or NSAIDs administered to relieve joint pain. After the acute symptoms have subsided, the patient without carditis should ambulate. If the patient has carditis with HF, bed rest restrictions should be applied. (See Chapter 37 for care of a patient with HF.) Nonstrenuous activities should be encouraged once recovery has begun.

Ambulatory and Home Care.

Secondary prevention aims to prevent the recurrence of rheumatic fever. The patient with a previous history of rheumatic fever should be taught about the disease process, possible sequelae, and the ongoing or permanent need for prophylactic antibiotics. Prior history of rheumatic fever makes the patient more susceptible to a second attack after a streptococcal infection. The best prevention is monthly injections of long-acting penicillin. Alternative treatment is administration of oral penicillin or erythromycin one or two times a day. Rheumatic fever without carditis after age 18 may require only 5 years of prophylactic antibiotic therapy, or therapy may continue indefinitely in patients with frequent exposure to group A streptococcus. Prophylactic treatment should continue for 10 years or until the age of 40 in individuals who develop residual rheumatic heart disease (Nishimura, Otto, Bonow, et al., 2014).

The dosage of antibiotics used in maintenance prophylaxis of rheumatic fever is not adequate to prevent IE when invasive procedures are performed. Additional prophylaxis is necessary if a patient with known rheumatic heart disease has a dental procedure or an invasive respiratory tract procedure (e.g., tonsillectomy) that involves perforation of the mucosa (see Table 39-3). The nurse must explain the difference between these two prophylactic programs.

Patient teaching should encourage good nutrition, hygienic practices, and adequate rest. The patient should also be cautioned about the possibility of developing valvular heart disease. The nurse should teach the patient to seek medical attention if symptoms such as excessive fatigue, dizziness, palpitations, or exertional dyspnea develop.

Evaluation

The following are expected outcomes for patients with rheumatic fever and heart disease:

- Ability to perform activities of daily living with minimal fatigue and pain
- Adherence to treatment regimen
- Expression of confidence in managing disease
- Prevention of complications

Valvular Heart Disease

The heart contains two AV valves, the mitral and the tricuspid, and two semilunar valves, the aortic and the pulmonic, that are located in four strategic locations to control unidirectional blood flow (see Figure 34-2). Valvular heart disease is defined according to the valve or valves affected and the types of functional alteration: stenosis or regurgitation.

The pressure on either side of an open valve is normally equal. However, in a stenotic valve, the valve orifice is restricted, impeding the forward flow of blood and creating a pressure gradient across an open valve. The degree of stenosis (constriction or narrowing) is reflected in the degree of the pressure gradient (i.e., the higher the gradient, the greater the stenosis). In regurgitation (also called *valvular incompetence* or *insufficiency*), incomplete closure of the valve leaflets results in the backward flow of blood.

Valve disorders occur in children and adolescents primarily when congenital conditions such as tricuspid atresia, pulmonary stenosis, and aortic stenosis are present. Valvular heart disease has remained prevalent because of an increase in the number of older adults, many of whom have some form of cardiovascular disease. Aortic stenosis and mitral regurgitation (MR) are common valve disorders in older adults. Other causes of valve disease in adults include disorders related to acquired immune deficiency syndrome and the use of some antiparkinsonian drugs (Surapaneni, Vinales, Najib, et al., 2011).

Mitral Valve Stenosis

Etiology and Pathophysiology

Most cases of adult mitral valve stenosis result from rheumatic heart disease; rheumatic mitral stenosis is most prevalent in developing countries (Lung & Vahanian, 2011). Less common causes include congenital mitral stenosis, rheumatoid arthritis, and systemic lupus erythematosus. Rheumatic endocarditis causes scarring of the valve leaflets and the chordae tendineae. Contractures and adhesions develop between the commissures (the junctional areas) of the two leaflets (Figure 39-7). These structural deformities cause obstruction of blood flow and create a pressure difference between the left atrium and the left ventricle during diastole. Left atrial pressure and volume elevations cause increased

pulmonary vasculature pressure and subsequent hypertrophy of the pulmonary vessels. In chronic mitral stenosis, pressure overload occurs in the left atrium, the pulmonary bed, and the right ventricle.

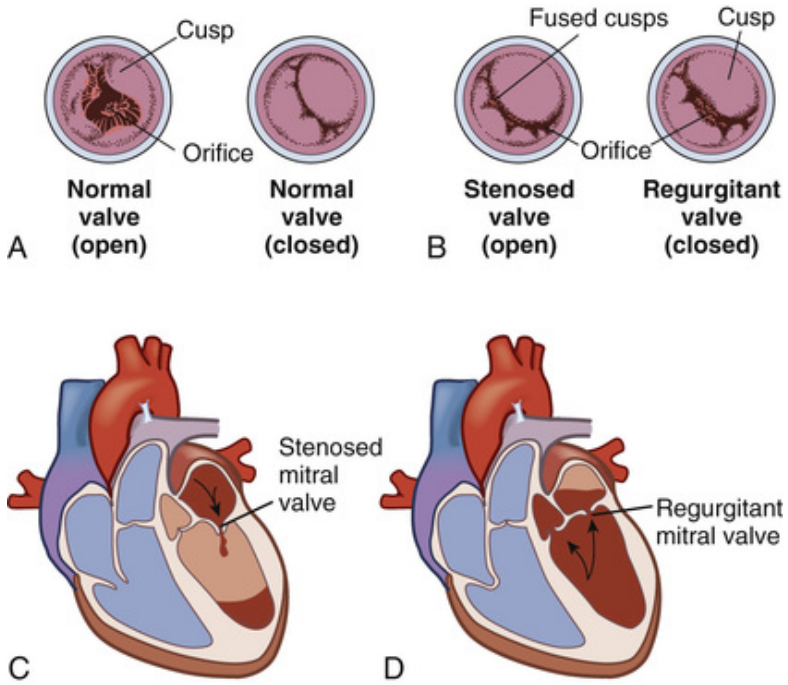

FIGURE 39-7 Valvular stenosis and regurgitation. **A,** Normal position of the valve leaflets, or cusps, when the valve is open and closed. **B,** Open position of a stenosed valve (left) and closed position of regurgitant valve (right). **C,** Hemodynamic effect of mitral stenosis. The stenosed valve is unable to open sufficiently during left atrial systole, inhibiting left ventricular filling. **D,** Hemodynamic effect of mitral regurgitation. The mitral valve does not close completely during left ventricular systole, permitting blood to re-enter the left atrium. At the same time, blood is moving forward through the aortic valve. Source: Huether, S. E., McCance, K. L., Brashers, V. L., et al. (2014). *Pathophysiology: The biologic basis for disease in adults and children* (7th ed., p. 1167). St. Louis: Mosby.

Clinical Manifestations

The primary symptom of mitral stenosis is exertional dyspnea owing to reduced lung compliance (Table 39-13). Fatigue and palpitations from atrial fibrillation may occur. Heart sounds include a loud first heart sound and a low-pitched, rumbling diastolic murmur (best heard at the apex with the stethoscope bell). Less frequently, patients may have hoarseness

(from atrial enlargement pressing on the laryngeal nerve), hemoptysis (from pulmonary hypertension), chest pain (from decreased CO), and seizures or a stroke (from emboli). Emboli can arise from blood stasis in the left atrium.

TABLE 39-13

CLINICAL MANIFESTATIONS AND DIAGNOSTIC FINDINGS OF VALVULAR HEART DISEASES

	Clinical Manifestations	Electrocardiogram	Echocardiogram	Cardiac Catheterization
Mitral valve stenosis	Exertional dyspnea, hemoptysis; fatigue; palpitations; loud, accentuated S_1; opening snap; low-pitched, rumbling diastolic murmur	Right axis deviation, left atrial enlargement, right ventricular hypertrophy, P mitrale (wide, M-shaped P wave), atrial flutter or fibrillation	Restricted movement of mitral valve leaflets; decreased size of orifice; diastolic turbulence	Left atrial pressure increased at end of diastole, reduction in CO
Mitral valve regurgitation	*Acute:* generally poorly tolerated with fulminating pulmonary edema and shock developing rapidly; systolic murmur	Left atrial enlargement, atrial fibrillation	Hyperdynamic left ventricular contraction in association with shock; regurgitant jets and flail* chordae or leaflets	Contrast medium injection in left ventricle showing regurgitation of blood into left atrium
	Chronic: weakness, fatigue, exertional dyspnea, palpitations; an S_3 gallop, holosystolic or pansystolic murmur	P mitrale, left ventricular hypertrophy, atrial flutter or fibrillation	Left atrial enlargement; left ventricular hypertrophy; flail leaflets	Contrast medium injection in left ventricle showing regurgitation of blood into left atrium
Mitral valve prolapse	Palpitations, dyspnea, chest pain, activity intolerance, syncope; mobile midsystolic nonejection click and a late or holosystolic murmur	Usually normal; occasionally T-wave inversion or biplasticity in leads II, III, and aVf are noted; PVCs and tachydysrhythmias possible	On the M-mode echo, late-systolic posterior motion or holosystolic billowing of the mitral leaflets; on two-dimensional echo, systolic billowing of the mitral leaflets	Left ventricular angiogram reveals mitral leaflets with prominent scalloping as the leaflets billow into the left atrium during systole
Aortic valve stenosis	Angina pectoris, syncope, heart failure, normal or soft S_1, prominent S_4, crescendo–decrescendo murmur	Left ventricular hypertrophy, left bundle branch block, complete atrioventricular heart block	Restricted movement of aortic valve; diminished orifice; systolic turbulence	Left ventricular systolic pressure increased, reduction in CO
Aortic valve regurgitation	*Acute:* abrupt onset of profound dyspnea, transient chest pain, progression to shock	Left ventricular strain	Normal-sized left ventricle with hyperdynamic systolic contraction; aortic dissection can be seen, if cause of acute process	Significant elevation of left ventricular diastolic pressure
	Chronic: fatigue, exertional dyspnea; water-hammer pulse; heaving precordial impulse; diastolic high-pitched soft decrescendo diastolic murmur, characteristic Austin Flint murmur at diastolic rumble, systolic ejection click	Left ventricular hypertrophy	Enlarged left ventricle and dilated aortic root	Increase in left ventricular diastolic pressure, aortic root contrast medium injection demonstrating regurgitation of blood into left ventricle

	Clinical Manifestations	Electrocardiogram	Echocardiogram	Cardiac Catheterization
Tricuspid stenosis and regurgitation	Peripheral edema, ascites, hepatomegaly; diastolic low-pitched decrescendo murmur with increased intensity during inspiration (stenosis); pansystolic murmur with increased intensity at inspiration (regurgitation)	Tall, peaked P waves; atrial fibrillation	Right ventricular dilation and paradoxical septal motion; usually poor visualization of tricuspid valve itself	Pressure gradient across tricuspid valve and increased right atrial pressure (stenosis); reflux of contrast medium into right atrium (regurgitation)

*Flail mitral leaflet is a complication of mitral valve prolapse, which can lead to severe mitral regurgitation and left ventricular dysfunction.

aVF, augmented vector foot; *CO*, cardiac output; *PVCs*, premature ventricular contractions; S_1, first heart sound; S_3, third heart sound; S_4, fourth heart sound.

Mitral Valve Regurgitation

Etiology and Pathophysiology

Mitral valve function depends on intact mitral leaflets, mitral annulus, chordae tendineae, papillary muscles, left atrium, and left ventricle. A defect in any of these structures can result in regurgitation. Most cases of MR are caused by MI, chronic rheumatic heart disease, mitral valve prolapse (MVP), ischemic papillary muscle dysfunction, or IE. MI with left ventricular failure increases the risk for rupture of the chordae tendineae and for acute MR.

MR allows blood to flow backward from the left ventricle to the left atrium because of incomplete valve closure during systole. The left ventricle and the left atrium both work harder to preserve an adequate CO. In chronic MR, the additional volume load results in atrial enlargement, ventricular dilation, and eventual ventricular hypertrophy. In acute MR, the left atrium and ventricle do not abruptly dilate. The sudden increase in pressure and volume is transmitted to the pulmonary bed, resulting in pulmonary edema and shock.

Clinical Manifestations

The clinical course of MR is determined by the nature of its onset (see Table 39-13). Patients with acute MR will have thready peripheral pulses and cool, clammy extremities. A low CO may obscure a new systolic murmur. Rapid assessment (e.g., cardiac catheterization) and intervention (e.g., valve repair or replacement) are critical for a positive outcome.

Patients with chronic MR may remain asymptomatic for many years until the development of some degree of left ventricular failure. Initial symptoms of left ventricular failure may include weakness, fatigue, palpitations, and dyspnea that gradually progress to orthopnea, paroxysmal nocturnal dyspnea, and peripheral edema. Accentuated left ventricular filling leads to an audible S_3, even with normal left ventricular function. The murmur is a loud holosystolic or pansystolic murmur at the apex radiating to the left axilla. Patients with asymptomatic MR should be monitored carefully because the natural history for MR can be variable, and surgery (valve repair or replacement) should be considered before significant left ventricular failure or pulmonary hypertension develops (Nishimura, Otto, Bonow, et al., 2014).

Mitral Valve Prolapse

Etiology and Pathophysiology

Mitral valve prolapse (MVP) is a structural abnormality of the mitral valve leaflets and the papillary muscles or chordae that allows the leaflets to prolapse, or buckle, back into the left atrium during ventricular systole (Figure 39-8). The etiology of MVP is unknown but is related to diverse pathogenic mechanisms of the mitral valve apparatus. The term *prolapse* is misleading because, in some cases, the valvular anomaly permits normal function. MVP is one of the most common forms of valvular heart disease.

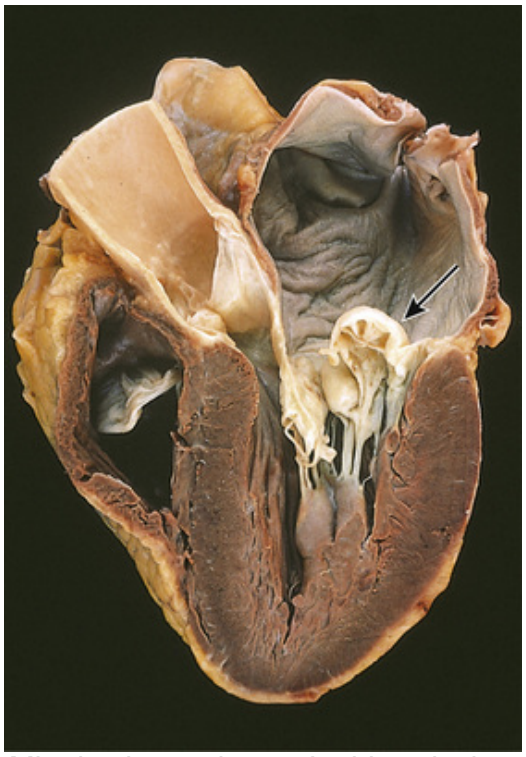

FIGURE 39-8 Mitral valve prolapse. In this valvular abnormality, the mitral leaflets have prolapsed back into the left atrium. They also demonstrate hooding (*arrow*). The left ventricle is on the right. Source: Kumar, V., Abbas, A. K., & Aster, J. (2013). *Robbins basic pathology* (9th ed., p. 391). Philadelphia: Elsevier Saunders.

MVP is usually benign, but serious complications can occur, including MR, IE, SCD, and cerebral ischemia. There is an increased familial incidence (autosomal dominant) among some patients.

Clinical Manifestations

MVP covers a broad spectrum of severity. Most patients are asymptomatic and remain so for their entire lives. A characteristic of MVP is a murmur from regurgitation that gets more intense through systole. This could be a late or holosystolic murmur. Another major sign is one or more clicks usually heard in midsystole to late systole. MVP does not alter the first (S_1) or second (S_2) heart sounds. Severe MR is an uncommon complication of MVP.

M-mode echocardiography confirms MVP by demonstrating late-systolic prolapse, and two-dimensional echocardiography reveals leaflet billowing into the left atrium. Dysrhythmias, most commonly ventricular premature contractions, paroxysmal supraventricular tachycardia, and

ventricular tachycardia, may cause palpitations, light-headedness, and dizziness. IE may occur in patients with MR associated with MVP.

Patients may or may not have chest pain. The cause of the chest pain is not known, but it may be caused by abnormal tension on the papillary muscles. If chest pain occurs, it tends to occur in clusters, especially during periods of emotional stress. Dyspnea, palpitations, and syncope may occasionally accompany the chest pain and do not respond to antianginal treatment (e.g., nitrates). β-Adrenergic blockers may be prescribed to control palpitations and chest pain. Patients with MVP generally have a benign, manageable course unless problems associated with MR are present. A teaching plan for patients with MVP appears in Table 39-14.

TABLE 39-14

PATIENT & CAREGIVER TEACHING GUIDE
Mitral Valve Prolapse

The following information should be included in the teaching plan for a patient with mitral valve prolapse (MVP) and the patient's caregiver.

- Take medications as prescribed (e.g., β-adrenergic blockers to control palpitations, chest pain).
- Adopt healthy eating patterns and avoid caffeine, which is a stimulant and may exacerbate symptoms.
- If using diet pills or other over-the-counter drugs, check for common ingredients that are stimulants (e.g., caffeine, ephedrine) because these will exacerbate symptoms.
- Implement an exercise program, in consultation with a health care provider, to maintain optimal health.
- Contact Emergency Medical Services or health care provider if symptoms develop or worsen (e.g., palpitations, fatigue, shortness of breath, anxiety).

Aortic Valve Stenosis

Etiology and Pathophysiology

Congenitally abnormal stenotic aortic valves are generally discovered in childhood, adolescence, or young adulthood. In older patients, aortic stenosis is a result of rheumatic fever or degeneration that may have an etiology similar to that of coronary artery disease. In rheumatic valvular disease, fusion of the commissures and secondary calcification cause the valve leaflets to stiffen and retract, resulting in stenosis. If aortic stenosis does occur owing to rheumatic heart disease, mitral valve disease accompanies it. Isolated aortic valve stenosis is almost always nonrheumatic in origin. The incidence of rheumatic aortic valvular disease has been decreasing, but senile or degenerative stenosis is expected to increase as the population ages.

An aortic stenosis causes obstruction of blood flow from the left ventricle to the aorta during systole. The effect is left ventricular

hypertrophy and increased myocardial oxygen consumption because of the increased myocardial mass. As the disease course progresses and compensatory mechanisms fail, reduced CO leads to decreased tissue perfusion, pulmonary hypertension, and HF.

Clinical Manifestations

Symptoms of aortic stenosis (see Table 39-13) develop when the valve orifice becomes approximately one-third its normal size. Symptoms include the classic triad of angina, syncope, and exertional dyspnea, reflecting left ventricular failure. The prognosis is poor for a patient with symptoms and whose valve obstruction is not relieved. Use of nitroglycerin is contraindicated for patients with significant aortic stenosis because it would reduce preload, and preload is necessary to help open the stiffened aortic valve. Auscultation of aortic stenosis typically reveals a normal or soft S_1; a diminished or absent S_2; a systolic, crescendo–decrescendo murmur that ends before S_2; and a prominent S_4.

Drug Alert

Nitroglycerin

- This drug must be used cautiously in patients with aortic stenosis because it may cause significant hypotension.
- Chest pain can worsen due to decrease in preload and drop in BP.

Aortic Valve Regurgitation

Etiology and Pathophysiology

Aortic valve regurgitation (AR) may be the result of a primary disease of the aortic valve leaflets, of the aortic root, or of both. Acute AR is caused by IE, trauma, or aortic dissection and constitutes a life-threatening emergency. Chronic AR is generally the result of rheumatic heart disease, a congenital bicuspid aortic valve, syphilis, or chronic rheumatic conditions such as ankylosing spondylitis or Reiter's syndrome.

AR entails retrograde blood flow from the ascending aorta into the left ventricle when the valve should be closed, resulting in volume overload. The left ventricle initially compensates for chronic AR through dilation

and hypertrophy. Myocardial contractility eventually declines, and blood volumes increase in the left atrium and the pulmonary bed. This increase results in pulmonary hypertension and right ventricular failure.

Clinical Manifestations

Patients with acute AR have sudden clinical manifestations of cardiovascular collapse (see Table 39-13). The left ventricle is exposed to aortic pressure during diastole. The patient develops severe dyspnea, chest pain, hypotension (indicating left ventricular failure), and shock, all of which constitute a medical emergency.

Patients with chronic, severe AR develop a *water-hammer pulse* (a strong, quick beat that collapses immediately). Heart sounds may include a soft or absent S_1, presence of S_3 or S_4, and a soft, decrescendo, high-pitched diastolic murmur. A systolic ejection click may also be heard as well as a low-frequency diastolic murmur known as an *Austin Flint murmur.*

The patient with chronic AR generally remains asymptomatic for years and is seen with exertional dyspnea, orthopnea, and paroxysmal nocturnal dyspnea only after considerable myocardial dysfunction has occurred (see Table 39-13). Angina occurs less frequently with AR than with aortic stenosis.

Tricuspid and Pulmonic Valve Disease

Etiology and Pathophysiology

Diseases of the tricuspid and pulmonic valves are uncommon, with stenosis occurring more frequently than regurgitation. *Tricuspid valve stenosis* occurs almost exclusively in patients who have had rheumatic fever, have used IV drugs, have had multiple myocardial biopsies, have had radiation treatment, have used anorectic drugs, or have been treated with a dopamine receptor agonist (e.g., pergolide) (Nishimura, Otto, Bonow, et al., 2014). *Pulmonic valve stenosis* is almost always congenital.

Tricuspid and pulmonic stenosis both result in an increase in blood volume in the right atrium and the right ventricle, respectively. Tricuspid stenosis results in right atrial enlargement and elevated systemic venous pressures. Pulmonic stenosis results in right ventricular hypertension and hypertrophy (see Table 39-13).

Diagnostic Studies for Valvular Heart Disease

Diagnosis of valvular heart disease is generally based on the results of history, physical examination, echocardiogram, and cardiac catheterization (especially if surgery is considered) (Table 39-15). Chest radiograph results, ECG findings, and the clinical manifestations exhibited by the patient also aid in establishing the correct diagnosis.

TABLE 39-15

	• Valve replacement

*Use cautiously in patients with aortic stenosis.

ACE, angiotensin-converting enzyme; *CBC,* complete blood cell count; *ECG,* electrocardiogram; *HF,* heart failure.

An echocardiogram reveals valve structure, function, and chamber size. Transesophageal echocardiography and Doppler colour-flow imaging are valuable in diagnosing and monitoring the progression of valvular heart disease. Real-time three-dimensional echocardiography may be helpful in qualitative assessments of mitral valve and congenital heart disease. Cardiac catheterization detects pressure changes in the cardiac chambers, measures pressure gradients across the valves, and quantifies the size of valve openings. An ECG shows heart rate and rhythm and provides information about any ischemia or chamber enlargement. Chest radiograph reveals the heart size, alterations in pulmonary circulation, and calcification of valves.

Collaborative Care of Valvular Heart Disease

Conservative Therapy.

An important aspect of conservative management of valvular heart disease is prevention of recurrent rheumatic fever and IE (see Table 39-15). Treatment depends on the valve involved and the severity of the disease. It focuses on preventing exacerbations of HF, acute pulmonary edema, thrombo-embolism, and recurrent endocarditis. If manifestations of HF develop, vasodilators, positive inotropes, β-adrenergic blockers, diuretics, and a low-sodium diet are recommended (see Chapter 37). Anticoagulant therapy is used to prevent and treat systemic or pulmonary embolization, and it is also used prophylactically for stroke prevention in patients with atrial fibrillation. Atrial dysrhythmias are common and are treated with digoxin, antidysrhythmia drugs, or electrical cardioversion. β-Adrenergic blockers may be used to slow the ventricular response in patients with atrial fibrillation. (Dysrhythmias are discussed in Chapter 38.)

Percutaneous Aortic Valve Replacement.

Percutaneous aortic valve replacement is an alternative for select patients with severe symptomatic aortic stenosis who are at high risk and cannot be treated with traditional surgical intervention. Canada has been a world leader in this technique (Webb, Rodes-Cabau, Fremes, et al., 2012). The procedure, performed in the cardiac catheterization laboratory, involves inserting a bioprosthetic valve, which is advanced over a stiff guide wire using a femoral arterial approach.

Percutaneous Transluminal Balloon Valvuloplasty.

An alternative treatment for some patients with valvular heart disease is the *percutaneous transluminal balloon valvuloplasty* (PTBV) procedure, which splits open the fused commissures. PTBV is used for mitral, tricuspid, and pulmonic stenosis, and less often for aortic stenosis. The procedure, performed in the cardiac catheterization laboratory, involves threading a balloon-tipped catheter from the femoral artery or vein to the stenotic valve so that the balloon may be inflated in an attempt to separate the valve leaflets. A single- or double-balloon technique may be used for the PTBV procedure. Currently, the use of a single Inoue balloon with hourglass configuration allows sequential inflation. This technique is the most popular because it is easy, has good results, and has fewer complications (e.g., left ventricular perforation) (Nishimura, Otto, Bonow, et al., 2014). The PTBV procedure is generally indicated for older-adult patients and for patients who are poor surgery candidates. PTBV has fewer complications than valve replacement. The long-term results of

PTBV are similar to those of surgical commissurotomy (Nishimura, Otto, Bonow, et al., 2014).

Surgical Therapy.

The decision for surgical intervention is based on the clinical state of the patient. The type of surgery used for a particular patient depends on the valves involved, the valvular pathology, the severity of the disease, and the patient's clinical condition. All types of valve surgery are palliative, not curative, and patients will require lifelong health care. Valve repair is typically the surgical procedure of choice. It is often used in mitral or tricuspid valvular heart disease and has a lower operative mortality rate than replacement. Mitral *commissurotomy (valvulotomy)* is the procedure of choice for patients with pure mitral stenosis. The less precise closed method of commissurotomy has generally been replaced by the open method in Canada, the United States, and Western Europe. The direct vision, or open, procedure requires the use of cardiopulmonary bypass, removal of thrombi from the atrium, excision of the left atrial appendage, commissure incision, and, as indicated, separation of fused chordae, splitting of underlying papillary muscle, and debriding of calcification of the valve. In contrast, the closed procedure is usually performed with the aid of a transventricular dilator inserted through the apex of the left ventricle into the ostium of the mitral valve.

Open surgical *valvuloplasty* involves repairing the valve by suturing the torn leaflets, chordae tendineae, or papillary muscles. It is primarily used to treat mitral or tricuspid regurgitation. Valve repair avoids the risks of replacement but may not establish total valvular competence. *Minimally invasive valvuloplasty* surgery, using mini-sternotomy or parasternal approaches, has shown results comparable with those of the open procedure; it also decreases length of hospitalization, use of blood transfusions, and postoperative atrial fibrillation (Schmitto, Mokashi, & Cohn, 2010).

Further repair or reconstruction of the valve may be necessary and can be achieved by annuloplasty, a procedure also used in cases of mitral or tricuspid regurgitation. *Annuloplasty* entails reconstruction of the annulus, with or without the aid of prosthetic rings.

Informatics in Practice

Heart Surgery DVD or CD

- To learn about a procedure, many patients prefer to watch a DVD or listen to a CD instead of reading a pamphlet. A video can be an effective tool for the nurse to use in teaching the patient facing heart surgery and the patient's caregiver what to expect before and after the procedure.
- The nurse should remember that the DVD or CD is not the teacher.
- Before providing the patient with the DVD or CD, the nurse should discuss with the patient what the DVD or CD will cover and encourage the patient and caregiver to write down questions or to note what they do not understand.
- After the patient and caregiver view or listen to the material, the nurse should be available to answer any questions they have. The nurse should also reinforce important information from the DVD or CD.

Prosthetic Valves.

Valvular replacement may be required for treating mitral, aortic, tricuspid, and occasionally pulmonic valvular disease. This procedure is the surgical treatment of choice for combined aortic stenosis and AR.

A wide variety of prosthetic valves are available. Desirable valves are nonthrombogenic and durable and create minimal stenosis. Prosthetic valves are categorized as mechanical or biological (tissue) valves (Table 39-16 and Figure 39-9).

TABLE 39-16
TYPES OF CARDIAC PROSTHETIC AND TISSUE VALVES

Type	Description	Advantages	Disadvantages
Mechanical			
Caged-ball valve (Starr–Edwards, Magovern–Cromie)	Metal cage with several struts mounted on a circular ring; hollow metal or plastic ball (poppet) inside of cage	High durability (≤20 yr)	Possibility of blood clots forming on or around valve (thrombogenic) with risk for embolism Need for long-term anticoagulation therapy Very large
Tilting-disc valve (Lillehei–Kaster therapy, Medtronic Hall)	Mobile, lens-shaped disc attached to a circular sewing ring by two offset transverse struts; Pyrolite carbon composition	Hemodynamic efficiency High durability Low thrombogenicity	Need for long-term anticoagulation
Bileaflet valve (St. Jude Medical, Edwards Duromedics, Carbomedics)	Two pivoting semicircular discs that open centrally, mounted directly onto a sewing ring	Compact Successful use in children and patients with small aortic roots	Possibility of thrombogenicity and embolism Need for long-term anticoagulation therapy
Biological			
Porcine heterograft (Carpentier–Edwards, Medtronic Hancock)	Harvested aortic valve of pig that is preserved in glutaraldehyde and mounted on specially designed sewing ring	Low thrombogenicity Need for anticoagulation therapy for only 3 mo after placement	Limited durability (failure rate increases sharply after 5–7 yr) Cumbersome structural design
Pericardial heterograft (Carpentier–Edwards, Ionescu–Shiley)	Three leaflets composed of pericardium from 16- to 18-mo-old calves that are preserved in glutaraldehyde and mounted on a Dacron-covered frame	Low thrombogenicity Need for only short-term anticoagulation therapy Less resistance to blood flow; useful in patients with small aortic roots Outstanding durability	Early valve failure secondary to calcification and degeneration

Type	Description	Advantages	Disadvantages
Homograft (cadaver valve)	Harvested aortic valve from human cadaver that is initially frozen until needed for valve replacement, and then thawed, trimmed, and sewn into place with special mounting material	Excellent hemodynamics No hemolysis and low risk for embolism Only rare need for anticoagulation therapy	Limited durability Not useful for mitral or tricuspid valve replacement

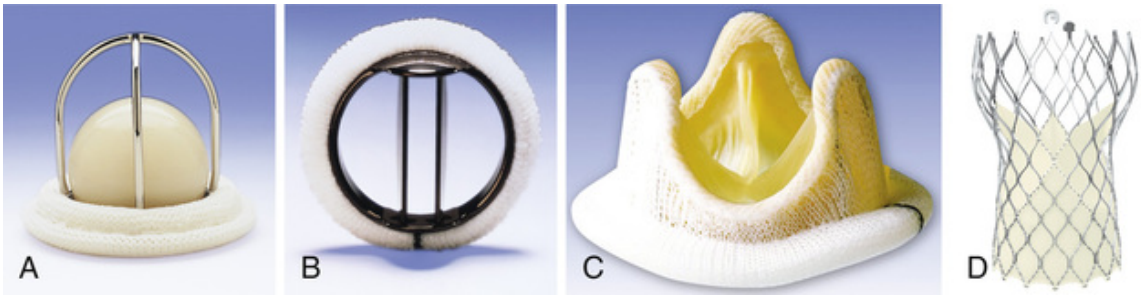

FIGURE 39-9 Different types of prosthetic heart valves. **A,** Starr-Edwards caged ball valve. **B,** St. Jude bi-leaflet valve. **C,** Carpentier-Edwards porcine valve. **D,** CoreValve transcatheter aortic valve (CoreValve Evolut R). Sources: *A* to *C,* Bonow, R. O., Mann, D. L., Zipes, D. P., et al (2012). *Braunwald's heart disease: a textbook of cardiovascular medicine*, ed. 9, Philadelphia: Saunders; *D,* © Medtronic 2017.

Mechanical valves are manufactured from artificial materials and consist of combinations of metal alloys, Pyrolite carbon, and Dacron. *Biological valves* are constructed from bovine, porcine, and human cardiac tissue and usually contain some artificial materials. Innovations in freezing and thawing techniques have enabled human grafts to be preserved for extensive periods while retaining viability. Mechanical prosthetic valves are more durable and last longer than biological valves; however, they create an increased risk for thrombo-embolism, necessitating long-term anticoagulation therapy. The main complication of mechanical valves is hemorrhage from the use of anticoagulants (Nishimura, Otto, Bonow, et al., 2014). Biological valves do not necessitate anticoagulation therapy because of their low thrombogenicity. However, they are less durable because of the tendency for early calcification, tissue degeneration, and stiffening of the leaflets. Risks with both types of prosthetic valves include paravalvular leaks and endocarditis.

Long-term anticoagulation therapy is recommended for all patients with mechanical valves and for those with biological valves and atrial

fibrillation. Some patients with biological valves or annuloplasty with prosthetic rings may need anticoagulation therapy for the first few months after surgery, until the suture lines are covered by endothelial cells (endothelialized).

The choice of valves depends on many factors. For example, if a patient cannot take an anticoagulant (e.g., women of child-bearing age), a biological valve may be considered. A mechanical valve may be best for a younger patient because it is more durable. For patients older than age 65, durability is less important than the risk for hemorrhage from anticoagulants.

Nursing Management Valvular Disorders

Nursing Assessment

Subjective and objective data should be obtained from patients with valvular disease and are presented in Table 39-17.

TABLE 39-17

NURSING ASSESSMENT
Valvular Heart Disease

Subjective Data
Important Health Information
Past health history: Rheumatic fever, endocarditis, congenital defects, myocardial infarction, chest trauma, cardiomyopathy, syphilis, Marfan syndrome, staphylococcal or streptococcal infections, HIV infection, or compromised immune system.
Medications
IV drug abuse
Symptoms
• Fatigue, generalized weakness, activity intolerance • Palpitations, dizziness, fainting • Dyspnea on exertion, cough, hemoptysis, orthopnea, paroxysmal nocturnal dyspnea • Anginal or atypical chest pain
Objective Data
General
Fever
Integumentary
Diaphoresis, flushing, cyanosis, clubbing; peripheral edema
Respiratory
Crackles, wheezes, hoarseness
Cardiovascular
Abnormal heart sounds, including opening snaps, clicks, thrills, systolic and diastolic murmurs, S_3, and S_4; dysrhythmias, including premature atrial contraction, atrial fibrillation; tachycardia; ↑ or ↓ in pulse pressure; hypotension, water-hammer or thready peripheral pulses, brisk carotid pulses
Gastro-Intestinal
Ascites, hepatomegaly
Possible Diagnostic Findings
Cardiomegaly on chest radiograph; ECG abnormalities specific to involved valve; echocardiogram (valve abnormalities and chamber dilation); cardiac catheterization (abnormalities in valves, chamber pressures, gradients, cardiac output, and blood flow depending on involved valve)

ECG, electrocardiogram; *HIV,* human immunodeficiency virus; *IV,* intravenous; S_3, third heart sound; S_4, fourth heart sound.

Nursing Diagnoses

Nursing diagnoses for the patient with valvular heart disease may include but are not limited to the following:

- *Decreased cardiac output* (related to valvular incompetence)
- *Excess fluid volume* related to *excessive fluid intake, excessive sodium intake* (fluid retention secondary to valvular-induced heart failure)
- *Activity intolerance* related to *imbalance between oxygen supply/demand*

Additional information on nursing diagnoses is presented in NCP 39-2, available on the website for this chapter.

Planning

The overall goals for the patient with valvular heart disease include (a) normal cardiac function, (b) improved activity tolerance, and (c) an understanding of the disease process and health maintenance measures.

Nursing Implementation

Health Promotion.

Diagnosing and treating streptococcal infections and providing prophylactic antibiotics for patients with a history of rheumatic fever are critical to preventing acquired rheumatic valvular disease. Patients at high risk for endocarditis and those with valvular prostheses must also be treated with prophylactic antibiotics (see Table 39-4).

Patients must adhere to recommended therapies. Individuals with a history of rheumatic fever, endocarditis, or congenital heart disease should know the symptoms suggestive of valvular heart disease so that early medical treatment may be obtained. The nurse's role is to educate individuals about their condition and the importance of adherence to prescribed therapies. Patient- and family-centred care is important. It is important for patients and caregivers to be well informed about their condition and options for treatment and actively involved in decision making.

Acute Intervention and Ambulatory and Home Care.

Patients with progressive valvular heart disease may require hospitalization or outpatient care for management of HF, endocarditis, embolic disease, or dysrhythmias. HF is the most common reason for an ongoing need for medical care.

The role of the nurse is to implement and evaluate the effectiveness of therapeutic management. Activity should be designed after considering the patient's limitations. An appropriate exercise plan can increase cardiac tolerance. However, activities that regularly produce fatigue and dyspnea should be restricted, and an explanation should be provided to the patient. Smoking cessation should be discussed and encouraged. Strenuous physical exercise should be avoided because damaged valves may not be able to handle the required increase in CO. Patients should be assisted in planning activities of daily living, with an emphasis on conserving energy, setting priorities, and taking planned rest periods. Referral to a vocational counsellor may be necessary for patients with a physically or emotionally demanding job.

Auscultation of the heart should be performed to monitor the effectiveness of digoxin, β-adrenergic blockers, and antidysrhythmic drugs. Teaching regarding the actions and adverse effects of drugs is important to achieve compliance. Patients must understand the importance of prophylactic antibiotic therapy to prevent IE (see Table 39-4). If the valve disease was caused by rheumatic fever, ongoing prophylaxis to prevent recurrence is necessary.

When valvular heart disease can no longer be managed medically, surgical intervention becomes necessary. Patients who are on anticoagulation therapy after surgery for valve replacement must have their international normalized ratio (INR) checked regularly (usually monthly) to assess the adequacy of therapy. The INR is a standardized system of reporting prothrombin time. Values of 2.5 to 3.5 are therapeutic for patients with mechanical valves.

Patients must realize that valve surgery is not a cure and that regular follow-up examinations by the health care provider will be required. The nurse also must teach the patient about when to seek medical care. Any manifestations of infection or HF, any signs of bleeding, and any planned invasive or dental procedures require the patient to notify the health care provider. Finally, patients should be encouraged to wear medical alert identification (e.g., bracelet).

Evaluation

The expected outcomes for a patient with valvular heart disease are addressed in NCP 39-2, available on the website for this chapter.

Ethical Dilemmas

Do Not Resuscitate

Situation

A 68-year-old man has been admitted for a second mitral valve surgery and coronary artery bypass graft surgery. He did not adhere to the treatment plan following his original surgery 7 years ago. The nurse is worried about his future adherence to medication, diet, and exercise regimens. His kidneys are failing, and he is on dialysis, making him a high-risk surgical patient. The patient and caregivers want all possible treatment and refuse to discuss do-not-resuscitate (DNR) orders.

Important Points for Consideration

- Nonadherence to the treatment plan in the past does not always indicate the patient will not follow the plan of care in the future. Many circumstances related to nonadherence are outside the patient's control such as finances, transportation, availability of assistance, and declining physical and mental capabilities.
- A competent patient can decide whether he wants continued treatment so as to be able to fight to live. This is even more important when family members support the patient's decision.
- Health care providers have an obligation to respect the patient's request for treatment unless there is no clear benefit to continued treatment. Patients' choices to continue or end treatment are based on their values and beliefs, which may not always coincide with those of the health care provider or team.
- DNR orders should reflect the patient's expressed wishes. These wishes can be expressed either through conversation, advance directives, or a surrogate decision maker.
- DNR orders should be re-evaluated periodically with the patient and family, especially before major diagnostic procedures or treatments.

- A nurse who does not agree with a patient's treatment choice should nevertheless respect the patient's choice and ask the patient to explain more about their situation and decision. The nurse should communicate the patient's choice to the health care team and a referral should be made to an ethics committee or similar group as appropriate.

Discussion Questions

1. What type of information should be provided to a patient and family in discussions about DNR orders? Who should provide this information?
2. What measures or strategies would be beneficial to assist the patient to better adhere to the treatment plan?
3. Who can initiate a referral to an ethics committee?

Cardiomyopathy

Cardiomyopathy comprises a group of diseases that directly affect the structural or functional ability of the myocardium. A diagnosis of cardiomyopathy is made based on the patient's clinical manifestations and noninvasive and invasive diagnostic procedures.

Cardiomyopathy can be classified as primary or secondary. *Primary cardiomyopathy* refers to those conditions in which the etiology of the heart disease is unknown (idiopathic). The heart muscle in this case is the only portion of the heart involved; other cardiac structures are unaffected. In *secondary cardiomyopathy*, the cause of the myocardial disease is known and is secondary to another disease process. Common causes of secondary cardiomyopathy are listed in Table 39-18. Each type has its own pathogenesis, clinical presentation, and treatment protocols (Tables 39-19 and 39-20). Cardiomyopathies can lead to cardiomegaly and HF and are the leading reason for heart transplantation.

TABLE 39-18
CAUSES OF SECONDARY CARDIOMYOPATHY

Dilated	**Hypertrophic**
• Cardiotoxic agents—alcohol, cocaine, doxorubicin	• Aortic stenosis
• Genetic (autosomal dominant) or familial	• Genetic (autosomal dominant)
• Hypertension	• Hypertension
• Ischemia (coronary artery disease)	**Restrictive**
• Metabolic disorders	• Amyloidosis
• Muscular dystrophy	• Endomyocardial fibrosis
• Myocarditis	• Neoplastic tumour
• Pregnancy	• Post–radiation therapy
• Valve disease	• Sarcoidosis
	• Ventricular thrombus

TABLE 39-19
COMPARISON OF CARDIOMYOPATHIES

Dilated	Hypertrophic	Restrictive
Major Manifestations		
Fatigue, weakness, palpitations, dyspnea	Exertional dyspnea, fatigue, angina, syncope, palpitations	Dyspnea, fatigue
Cardiomegaly: moderate to marked	Mild to moderate	Mild
Contractility		
↓	↑ or ↓	Normal or ↓
Valvular Incompetence		
Atrioventricular valves, particularly mitral	Mitral valve	Atrioventricular valves
Dysrhythmias		
Sinoatrial tachycardia, atrial and ventricular dysrhythmias	Atrial and ventricular dysrhythmias	Atrial and ventricular dysrhythmias
Cardiac Output

ACE, angiotensin-converting enzyme; *HCM,* hypertrophic cardiomyopathy.

Dilated Cardiomyopathy

Etiology and Pathophysiology

Dilated cardiomyopathy (DCM) is the most common type of cardiomyopathy. It causes HF in 25% to 40% of cases and has a genetic

link in 40% of cases (Hershberger, Hedges, & Morales, 2013). DCM is characterized by a diffuse inflammation and rapid degeneration of myocardial fibres. These changes result in ventricular dilation, impairment of systolic function, atrial enlargement, and stasis of blood in the left ventricle. Cardiomegaly results from ventricular dilation (Figure 39-10) and causes contractile dysfunction in spite of an enlarged chamber size. In contrast to HF, the walls of the ventricles do not hypertrophy (Figure 39-11).

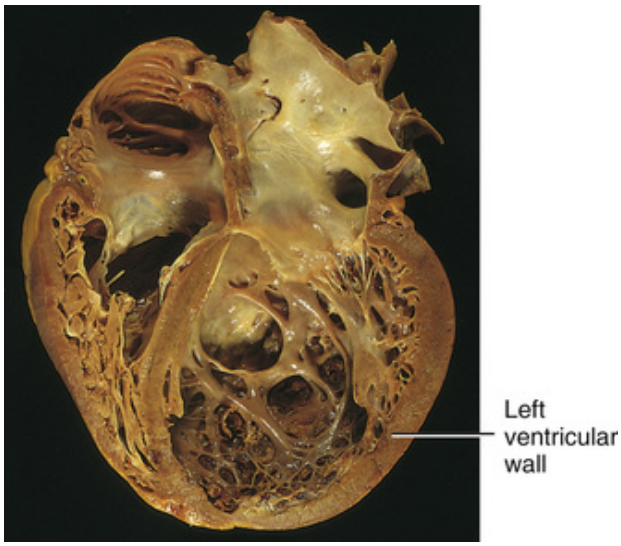

FIGURE 39-10 Dilated cardiomyopathy. The dilated left ventricular wall has thinned, and the chamber size and volume are increased.

Source: Kumar, V., Abbas, A. K., & Aster, J. (2013). *Robbins basic pathology* (9th ed., p. 399). Philadelphia: Elsevier Saunders.

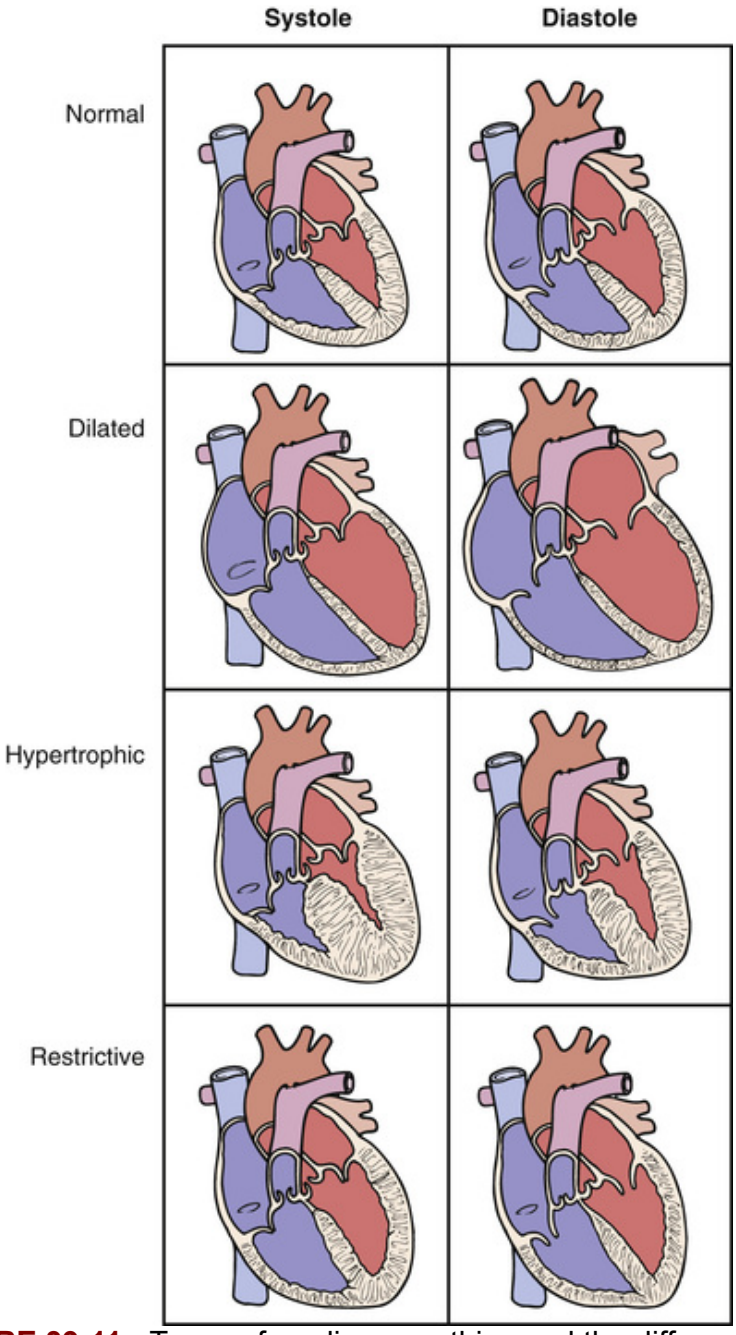

FIGURE 39-11 Types of cardiomyopathies and the differences in ventricular diameter during systole and diastole, compared with a normal heart. Source: Adapted from Urden, L. D., Stacy, K. M., & Lough, M. E. (2014). *Critical care nursing: Diagnosis and management* (7th ed., p. 376). St. Louis: Mosby.

DCM often follows an infectious myocarditis. Other common causes of DCM are listed in Table 39-18.

Clinical Manifestations

The signs and symptoms of DCM may develop acutely after an infectious process or insidiously over time. Most people eventually develop HF. Symptoms can include decreased exercise capacity, fatigue, dyspnea at rest, paroxysmal nocturnal dyspnea, and orthopnea. As the disease progresses, the patient may experience dry cough, palpitations, abdominal bloating, nausea, vomiting, and anorexia. Signs can include an irregular heart rate with an abnormal S_3 or S_4 or both, tachycardia or bradycardia, pulmonary crackles, edema, weak peripheral pulses, pallor, hepatomegaly, and jugular venous distension. Heart murmurs and dysrhythmias are common. Decreased blood flow through an enlarged heart promotes stasis and blood clot formation and may lead to systemic embolization.

Diagnostic Studies

The diagnosis of DCM is made on the basis of the patient's history and by ruling out other conditions that cause HF. Doppler echocardiography provides the basis for the diagnosis of DCM in the majority of patients and distinguishes DCM from other structural abnormalities. The chest radiograph may show cardiomegaly with signs of pulmonary venous hypertension as well as pleural effusion. The ECG may reveal tachycardia, bradycardia, and dysrhythmias with conduction disturbances. Laboratory studies may reveal elevated serum levels of B-type natriuretic peptide (BNP or NT-Pro-BNP) in the presence of HF.

Cardiac catheterization is done to confirm or rule out coronary artery disease, and multiple gated acquisition (MUGA) radionuclide angiocardiographies are done to determine ejection fraction (EF). EFs of less than 20% are associated with a 50% mortality within 1 year. EMB may be done at the time of the right-sided heart catheterization to detect viral antigens in myocardial tissue.

Nursing and Collaborative Management Dilated Cardiomyopathy

Interventions focus on controlling HF by enhancing myocardial contractility and decreasing afterload. Treatment of patients with NYHA class IV, stage D HF is more palliative than curative. Several different types of drugs are used to manage HF (see Chapter 37, Figure 37-7). Nitrates (e.g., nitroglycerin) and loop diuretics (e.g., furosemide [Lasix]) are used to decrease preload, and ACE inhibitors (e.g., captopril) are used to reduce afterload. β-Adrenergic blockers (e.g., metoprolol [Lopresor]) and aldosterone antagonists (e.g., spironolactone [Aldactone]) are used to control the neuro-hormonal stimulation that occurs in HF. Digoxin is used to treat atrial fibrillation but must be used with caution because of increased susceptibility to digoxin toxicity in these patients. Other dysrhythmias are treated with antidysrhythmics (e.g., amiodarone) as indicated (see Chapter 38). Anticoagulation therapy is started to reduce the risk for systemic embolization from clots that may form in the heart chambers.

Drug and nutritional therapy and cardiac rehabilitation may help alleviate symptoms of HF as well as improve CO and quality of life. Patients with secondary DCM must be treated for the underlying disease process. For example, a patient with alcohol-related DCM must abstain from all alcohol intake. (See Chapter 37 for a complete discussion of HF.)

Unfortunately, DCM does not respond well to therapy, and patients may experience multiple episodes of HF. Intermittent dobutamine or milrinone infusions can be used, with patients' often being admitted to the hospital for a continuous infusion followed by aggressive diuresis. Alternatively, these infusions are done as an outpatient treatment or in the home under supervision of a home care nurse. After infusion, many patients experience an improvement in symptoms that lasts for several weeks.

Patients also may benefit from nonpharmacological therapies such as cardiac resynchronization therapy (Howlett, Chan, Ezekoitz, et al., 2016) or a ventricular assist device (VAD) that may allow the heart to rest and recover from acute HF or be a bridge to heart transplantation. Patients with terminal end-stage cardiomyopathy may be considered for heart transplantation or destination therapy with a permanent or implantable VAD (see Chapter 37). Currently, approximately 50% of heart

transplantations are performed for treatment of cardiomyopathy. Heart transplant recipients have a good prognosis for survival. However, donor hearts are difficult to obtain, and many patients with DCM die while awaiting heart transplantation.

Patients with DCM are very ill people with a grave prognosis who need expert nursing care. Patients' families must learn cardiopulmonary resuscitation (CPR) and know how to access emergency care. The nurse should include family members and other support systems when planning a patient's care.

Home health and hospice nursing can provide the patient and the family with the continuous assessments and therapeutic interventions that are required to maximize and maintain functional status or prepare for a peaceful death. Observing for signs and symptoms of worsening HF, dysrhythmias, and embolic formation is paramount in this patient, as is monitoring drug responsiveness. The goal of therapy is to keep the patient at an optimal level of function and out of the hospital.

Hypertrophic Cardiomyopathy

Etiology and Pathophysiology

Hypertrophic cardiomyopathy (HCM)—formerly called *hypertrophic subaortic stenosis*, *asymmetrical septal hypertrophy (ASH)*, or *hypertrophic obstructive cardiomyopathy (HOCM)*—is asymmetrical left ventricular hypertrophy without ventricular dilation. (HOCM was a misleading term because one-third of all patients with HCM have a nonobstructive left ventricular outflow tract (LVOT) at rest or with exertion.) In one form of the disease, the septum between the two ventricles becomes enlarged and obstructs the blood flow from the left ventricle. HCM can be idiopathic, although about one-half of all cases have a genetic basis characterized by inappropriate myocardial hypertrophy (see Table 39-18). HCM occurs less commonly than DCM and is more common in men aged 30 to 40 than in women. In one study, HCM occurred more frequently in young Black male athletes than in young White male athletes. The four main characteristics of HCM are (a) massive ventricular hypertrophy; (b) rapid, forceful contraction of the left ventricle; (c) impaired relaxation (diastolic dysfunction); and (d) obstruction of LVOT (not present in all patients). Ventricular hypertrophy is associated with a thickened intraventricular septum and ventricular wall (Figure 39-12). The end result is impaired ventricular filling as the ventricle becomes noncompliant and unable to relax. The primary defect of HCM is diastolic dysfunction from left

ventricular stiffness. Decreased ventricular filling and obstruction to outflow can result in decreased CO, especially during exertion. HCM is the most common cause of SCD in otherwise healthy young people. It accounts for 3% of deaths in young competitive athletes (usually diagnosed in young adulthood) and is often seen in active, athletic individuals (Gersh, Maron, Bonow, et al., 2011; Wilson, Chandra, Papadakis, et al., 2011).

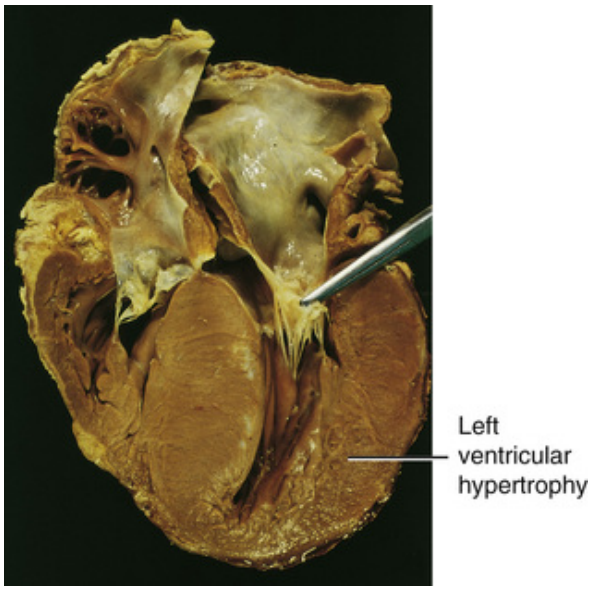

FIGURE 39-12 Hypertrophic cardiomyopathy. There is marked left ventricular hypertrophy, and the chamber size and volume are decreased. Source: Kumar, V., Abbas, A. K., & Aster, J. (2013). *Robbins basic pathology* (9th ed., p. 400). Philadelphia: Elsevier Saunders.

Clinical Manifestations

Patients with HCM may be asymptomatic or may have exertional dyspnea, fatigue, angina, and syncope. The most common symptom is dyspnea, which is caused by an elevated left ventricular diastolic pressure. Fatigue occurs because of the resultant decrease in CO and in exercise-induced flow obstruction. Angina can occur and is most often caused by the increased left ventricular muscle mass or compression of the small coronary arteries by the hypercontractile ventricular myocardium. The patient may also have syncope, especially during exertion. Syncope is most often caused by an increase in obstruction to aortic outflow during increased activity, resulting in decreased CO and cerebro-vascular

circulation. Syncope can also be caused by dysrhythmias. Common dysrhythmias include supraventricular tachycardia, atrial fibrillation, ventricular tachycardia, and ventricular fibrillation. Any of these dysrhythmias may lead to loss of consciousness or SCD (SCD is discussed in Chapter 36).

Diagnostic Studies

Clinical findings on examination may be unremarkable. However, on palpation of the chest, there may be a forced apical impulse that may be displaced laterally. Auscultation may reveal an S_4 and a systolic ejection murmur between the apex and the sternal border at the fourth intercostal space. ECG findings usually indicate ventricular hypertrophy, ST–T-wave abnormalities, prominent Q waves in the inferior or precordial leads, left-axis deviation, and ventricular and atrial dysrhythmias (see Chapter 38).

The echocardiogram is the primary diagnostic tool to confirm the classic feature of HCM, which is left ventricular hypertrophy. The echocardiogram may also demonstrate wall motion abnormalities and diastolic dysfunction. Cardiac catheterization may also be helpful in the diagnosis of HCM.

Nursing and Collaborative Management Hypertrophic Cardiomyopathy

Goals of intervention are to improve ventricular filling by reducing ventricular contractility and relieving LVOT obstruction. These can be accomplished with the use of β-adrenergic blockers, such as metoprolol (Lopresor), or calcium channel blockers, such as verapamil. Use of digitalis preparations is contraindicated unless they are used to treat atrial fibrillation. Antidysrhythmics, such as amiodarone or sotalol, are effective medications for dysrhythmias. However, their use has not been shown to prevent SCD. For patients at risk for SCD, the implantation of a cardioverter–defibrillator is recommended (see Chapter 38).

It has been found that AV pacing can be beneficial for patients with HCM and LVOT obstruction. By pacing the ventricles from the apex of the right ventricle, septal depolarization occurs first, allowing the septum to move away from the left ventricular wall and reducing the degree of obstruction of the LVOT.

Some patients may be candidates for surgical treatment of their hypertrophied septum. The indications for surgery include severe symptoms refractory to therapy with marked obstruction to aortic outflow (>50 mm Hg) while at rest. The surgery is termed a *ventriculomyotomy and myectomy.* It involves incision of the hypertrophied septal muscle and resection of some of the hypertrophied ventricular muscle. Most patients have good symptomatic improvement and improved exercise tolerance after surgery.

An alternative, nonsurgical procedure to reduce symptoms and the LVOT obstruction is alcohol-induced percutaneous transluminal septal myocardial ablation (PTSMA). Through this procedure, alcohol is administered into the first septal artery branching off the left anterior descending artery, causing ischemia and septal wall MI. Ablation of the septal wall decreases the flow obstruction, and the patient's symptoms decrease. The procedure improves HF symptoms and exercise capacity about 3 months after ablation. Mortality rates for the procedure are approximately 1% depending on the age and condition of the patient. Information on long-term effects of PTSMA in treated patients is lacking because the procedure is still new. Potential complications of PTSMA include conduction disturbances (e.g., heart block) and MI beyond the intended septum.

Nursing interventions for HCM focus on relieving symptoms, observing for and preventing complications, and providing emotional and psychological support. Teaching should focus on helping patients adjust their lifestyle to avoid strenuous activity and dehydration. Any activity, such as competitive sports, that causes an increase in systemic vascular resistance (thus increasing the obstruction to forward flow) is dangerous and should be avoided. HCM patients who experience chest pain need to rest and elevate their feet to improve venous return to the heart. Vasodilators such as nitroglycerin may worsen the chest pain by decreasing venous return to the heart, which can further obstruct blood flow from the heart.

Restrictive Cardiomyopathy

Etiology and Pathophysiology

Restrictive cardiomyopathy (RCM) is the least common of the cardiomyopathic conditions. It is a disease of the heart muscle that impairs diastolic filling and stretch (see Figure 39-11). Systolic function remains unaffected. Although the specific etiology of RCM is unknown, a number of pathological processes may be involved in its development. Myocardial fibrosis, hypertrophy, and infiltration produce stiffness of the ventricular wall with loss of ventricular compliance. Secondary causes of RCM include amyloidosis, endocardial fibrosis, sarcoidosis, fibrosis of different etiology, and radiation to the thorax. With RCM, the ventricles are resistant to filling and, therefore, demand high diastolic filling pressures to maintain CO.

Clinical Manifestations

Classic symptoms of RCM are fatigue, exercise intolerance, and dyspnea because the heart cannot increase CO by increasing the heart rate without further compromising ventricular filling. Additional symptoms may include angina, orthopnea, syncope, and palpitations. The patient may have signs of HF, including dyspnea, peripheral edema, ascites, hepatomegaly, and jugular venous distension.

Diagnostic Studies

The chest radiograph may be normal, or it may show cardiomegaly from right and left atrial enlargement. Pleural effusions and pulmonary

congestion may be evident in patients with progression to HF. The ECG may reveal a mild tachycardia at rest. The most common dysrhythmias are supraventricular (atrial fibrillation) and AV block. Echocardiography may reveal a left ventricle that is of normal size with a thickened wall, slightly dilated right ventricle, and dilated atria. EMB, CT, and nuclear imaging may be helpful in the diagnosis.

Nursing and Collaborative Management Restrictive Cardiomyopathy

Currently, no specific treatment for RCM exists. Interventions are aimed at improving diastolic filling and the underlying disease process. Treatment includes conventional therapy for HF and dysrhythmias. Heart transplantation may also be considered. Nursing care is similar to the care of a patient with HF. As in the treatment of patients with HCM, the patient should be taught to avoid situations that impair ventricular filling (e.g., strenuous activity, dehydration, and increases in systemic vascular resistance).

Nursing care of a patient with cardiomyopathy includes individualized teaching based on the patient's clinical manifestations. All patients with cardiomyopathy are at risk for IE from any procedure that may cause bacteremia and should be instructed on the need for prophylactic antibiotics (see Table 39-3). A general patient and caregiver teaching guide is presented in Table 39-21.

TABLE 39-21

PATIENT & CAREGIVER TEACHING GUIDE Cardiomyopathy

The following information should be included in the teaching plan for a patient with cardiomyopathy and the patient's caregiver.

- Take all medications as prescribed and follow up with health care provider.
- Use a low-sodium diet (if ordered) and read all product labels (food and over-the-counter drugs) for sodium content.
- Unless fluids are restricted, drink six to eight glasses of water a day.
- Achieve and maintain a reasonable weight, and avoid large meals.
- Avoid alcohol, caffeine, diet pills, and over-the-counter cold medicines that may contain stimulants.
- Balance activity and rest periods.
- Avoid heavy lifting or vigorous isometric exercises, and check with health care provider for exercise guidelines.
- Use stress-reduction activities: relaxation to relieve tension, guided imagery, diversional activities (see Chapter 8).
- Report to health care provider any signs of heart failure, including weight gain, edema, shortness of breath, and increased fatigue.
- Consider having family members learn CPR because of the potential for sudden cardiac arrest.
- Notify health care provider or dentist before any invasive medical or dental procedures since patients with cardiomyopathy are at risk for endocarditis (see Table 39-3).

CPR, cardiopulmonary resuscitation.

Case Study

Valvular Heart Disease

Source: travleview/Shutterstock.com.

Patient Profile

Ronald Balderson, a 50-year-old man, is admitted to the hospital for valvular heart disease.

Subjective Data

- Reports history of IV drug use
- Prior current regular alcohol intake of approximately 475 mL of whisky per day
- Complains of chest pain with minimal exertion
- Recently unemployed
- States he is short of breath and cannot sleep lying flat
- States he is tired and irritable all the time
- States he cannot afford medications
- Smokes a pack of cigarettes a day

Objective Data

Physical Examination

- Third heart sound (S_3)
- Loud holosystolic murmur of MR

- Wears dentures (teeth removed due to periodontal disease)
- Vital signs: temperature 37.2°C; pulse 110, irregular; respirations 24; BP 104/58

Diagnostic Studies

- ECG shows atrial fibrillation and a rapid ventricular response.
- Chest radiograph reveals pulmonary congestion and cardiomegaly.
- Transesophageal echocardiography shows left atrial and ventricular hypertrophy and mitral and aortic regurgitation.

Discussion Questions

1. Identify the cause and course of Mr. Balderson's disease based on his history and current examination.
2. Differentiate between mitral and aortic regurgitation.
3. What medical treatments or surgical procedures will Mr. Balderson probably require as his condition worsens?
4. ***Priority decision:*** On the basis of the assessment data provided, what are the priority nursing diagnoses?
5. ***Priority decision:*** Identify the priority nursing interventions for Mr. Balderson.
6. ***Evidence-informed practice:*** Mr. Balderson asks why he needs to be on "blood thinners" after his valves are replaced.

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. Assessment of an IV cocaine user with infective endocarditis should focus on which of the following signs and symptoms? *(Select all that apply)*
   a. Retinal hemorrhages
   b. Splinter hemorrhages
   c. Presence of Osler's nodes
   d. Painless nodules over bony prominences
   e. Painless erythematous macules on the palms and soles
2. Which of the following are nursing assessment findings for acute pericarditis?
   a. Wheezing and dull precordial pain
   b. Bradycardia, tachypnea, and murmur
   c. Chest pain, dyspnea, and pericardial friction rub
   d. Respiratory stridor, dull chest pain, and abdominal discomfort
3. Which of the following at-risk individuals need prophylactic antibiotics to prevent IE?
   a. Those with a history of IE.
   b. Those having a viral respiratory infection.
   c. Those entering the third trimester of pregnancy.
   d. Those exposed to human immunodeficiency virus.
4. A client is admitted with myocarditis. Which of the following clinical signs and symptoms might the nurse find while performing the initial assessment? *(Select all that apply)*
   a. Angina
   b. Pleuritic chest pain
   c. Splinter hemorrhages
   d. Pericardial friction rub
   e. Presence of Osler's nodes
5. When teaching a client about the long-term consequences of rheumatic fever, what possibilities should the nurse discuss?

a. Valvular heart disease
b. Pulmonary hypertension
c. Superior vena cava syndrome
d. Hypertrophy of the right ventricle

6. A client with rheumatic fever should be taught about the need for which of the following?
a. Regular exercise
b. Antibiotic therapy
c. A high-protein diet
d. Anticoagulant therapy

7. What is a common cause of aortic valve stenosis in older adults?
a. Rheumatic fever
b. Cardiomyopathy
c. Congenital heart disease
d. Acute infective endocarditis

8. Which of the following findings is indicative of left ventricular overload in a client with chronic aortic regurgitation?
a. Dehydration and a pericardial friction rub
b. An audible third heart sound and a midsystolic murmur
c. Exertional dyspnea and a diastolic high-pitched murmur
d. An audible third heart sound and a pansystolic or holosystolic murmur

9. A client hospitalized with aortic stenosis has a nursing diagnosis of *activity intolerance* related to *imbalance between oxygen supply/demand*. Which of the following is an appropriate nursing intervention for this client?
a. Monitoring electrocardiogram to assess cardiac output
b. Maintaining client on bed rest to reduce tissue oxygen demands
c. Progressively increasing activity to increase cardiac tolerance
d. Using semi-Fowler's position to decrease venous return and increase respiratory excursion.

10. What should the nurse caring for a client scheduled for a mitral valve replacement with a mechanical valve understand about this procedure?
a. It is similar to a commissurotomy.

b. It requires long-term anticoagulation therapy.

c. It is the treatment of choice for an older-adult client with a history of falling.

d. It involves the insertion of a transventricular dilator into the opening of the valve.

11. Which of the following assessment findings would the nurse expect in a client with dilated cardiomyopathy?

a. Dyspnea and fatigue

b. Wheezing and epigastric pain

c. Palpitations and left lower quadrant tenderness

d. Excessive sputum and lower abdominal cramping

12. The nurse plans care for a client with dilated cardiomyopathy based on what knowledge?

a. Family members may be at risk because of the infectious nature of the disease.

b. Medical management of the disorder focuses on treatment of the underlying cause.

c. The prognosis of the client is poor, and emotional support is a high priority of care.

d. The condition may be successfully treated with surgical ventriculomyotomy and septal ablation.

1. a, b, c, e; 2. c; 3. a; 4. a, b, d; 5. a; 6. b; 7. a; 8. c; 9. c; 10. b; 11. a; 12. c.

CHAPTER 40

Nursing Management

Vascular Disorders

Written by, Deidre D. Wipke-Tevis, Kathleen A. Rich

Adapted by, Phil Bourget

LEARNING OBJECTIVES

1. Relate the major risk factors to the etiology and pathophysiology of peripheral artery disease (PAD).
2. Describe the clinical manifestations, collaborative care and surgical and nursing management of PAD of the lower extremities.
3. Plan appropriate nursing interventions for the patient with acute arterial ischemic disorders of the lower extremities.
4. Differentiate the pathophysiology, clinical manifestations, and nursing management of thromboangiitis obliterans (Buerger's disease) and Raynaud's phenomenon.
5. Differentiate the pathophysiology, clinical manifestations, and collaborative care of different types of aortic aneurysms.
6. Select appropriate nursing interventions for a patient undergoing an aortic aneurysm repair.
7. Differentiate the pathophysiology, clinical manifestations, collaborative care, and nursing management of aortic dissection.
8. Evaluate the risk factors predisposing patients to the development of superficial vein thrombosis and venous thrombo-embolism (VTE).
9. Discriminate between the clinical characteristics of superficial vein thrombosis and VTE.

10. Compare and contrast the collaborative care and nursing management of patients with superficial vein thrombosis and VTE.
11. Prioritize the key aspects of nursing management of the patient receiving anticoagulant therapy.
12. Relate the pathophysiology and clinical manifestations to the collaborative care of patients with varicose veins, chronic venous insufficiency, and venous leg ulcers.

KEY TERMS

acute arterial ischemia, p. 921
aneurysm, p. 924
aortic dissection, p. 928
chronic venous insufficiency (CVI), p. 940
critical limb ischemia, p. 919
deep vein thrombosis (DVT), p. 930
intermittent claudication, p. 916
peripheral artery disease (PAD), p. 915
post-thrombotic syndrome, p. 933
Raynaud's phenomenon, p. 923
superficial vein thrombosis (SVT), p. 930
thromboangiitis obliterans (Buerger's disease), p. 922
varicose veins, p. 939
venous thrombo-embolism (VTE), p. 930
Virchow's triad, p. 930

Problems of the vascular system include disorders of the arteries, veins, and lymphatic vessels. Arterial disorders are classified as aneurysmal, atherosclerotic, and nonatherosclerotic vascular diseases. Atherosclerotic vascular disease is divided into coronary, cerebral, peripheral, mesenteric, and renal artery disease (Creager, Belkin, Bluth, et al., 2012). This chapter is a discussion of peripheral artery disease (PAD), aortic aneurysm and dissection, and venous diseases.

Peripheral Artery Disease

Peripheral artery disease (PAD) is a condition that involves thickening of artery walls, which results in a progressive narrowing of the arteries of the upper and lower extremities. The risk of developing PAD increases with age, increasing substantially after age 70. In people with diabetes mellitus, PAD occurs much earlier.

PAD is strongly related to other types of cardiovascular disease (CVD) and their risk factors. Patients with PAD are at significantly higher risk of premature mortality in general, death from CVD, major coronary events, and stroke (Mozaffarian, Benjamin, Go, et al., 2016). Thus PAD is a marker of advanced systemic atherosclerosis. Patients with PAD are more likely to have coronary artery disease, cerebral artery disease, or both. Many individuals are not familiar with or aware of PAD risk factors and complications (Hirsch, Allison, Gomes, et al., 2012).

Etiology and Pathophysiology of Peripheral Artery Disease

The leading cause of PAD is *atherosclerosis,* a gradual thickening of the *intima* (the innermost layer of the arterial wall) and the *media* (middle layer of the arterial wall) that leads to progressive narrowing of the artery lumen (see Figure 36-1 for diagrams of progression of atherosclerosis). Although the exact cause or causes of atherosclerosis are unknown, inflammation and endothelial injury play a major role (see Chapter 36).

Significant risk factors for PAD include tobacco use, diabetes, hyperlipidemia, elevated C-reactive protein levels, and uncontrolled hypertension. The use of tobacco is one of the main risk factors for PAD. Nicotine is a vasoconstrictor, and tobacco smoke impairs transport and cellular use of oxygen and increases blood viscosity and homocysteine levels. Other risk factors include family history, hypertriglyceridemia, increasing age, hyperhomocysteinemia, hyperuricemia, obesity, sedentary lifestyle, and stress (Ix, Biggs, Kizer, et al., 2011). Women with low lifetime recreational activity are at greater risk for PAD than are similarly sedentary men (Wilson, Sadrzadeh-Rafie, Myers, et al., 2011).

Atherosclerosis more commonly affects certain segments of the arterial tree. These include the coronary (see Chapter 36), carotid (see Chapter 60), common iliac, superficial femoral, popliteal, and tibial arteries (Figure 40-1). Clinical symptoms occur when vessels are 60% to 75% blocked.

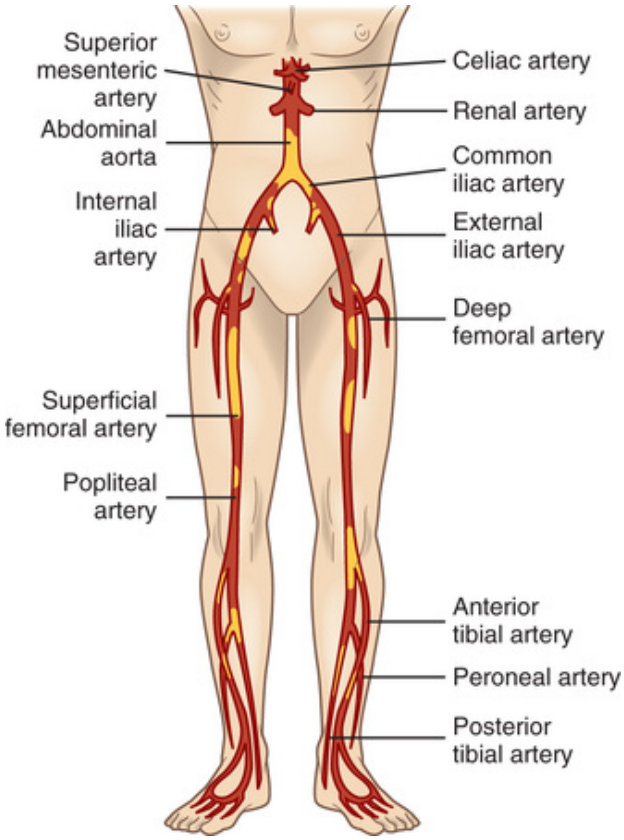

FIGURE 40-1 Common anatomical locations (shown in *yellow*) of atherosclerotic lesions of the abdominal aorta and lower extremities.

Peripheral Artery Disease of the Lower Extremities

Lower extremity PAD may affect the aortoiliac, femoral, popliteal, tibial, or peroneal arteries or any combination of these (see Figure 40-1). The femoral popliteal area is the site most commonly affected in nondiabetic patients. Patients with diabetes mellitus tend to develop PAD in the arteries below the knee. In advanced PAD, occlusions are found at multiple levels.

Clinical Manifestations

In general, the severity of the clinical manifestations depends on the site and extent of the obstruction and the amount of collateral circulation. The classic symptom of lower extremity PAD is **intermittent claudication,** an ischemic muscle ache or pain that is precipitated by a consistent level of exercise, resolves within 10 minutes or less with rest, and is reproducible (McDermott, Kibbe, Guralnik, et al., 2013). The ischemic pain is a result of

the accumulation of end products of anaerobic cellular metabolism, such as lactic acid. Once the patient stops exercising, the metabolites are cleared and the pain subsides. PAD of the aortoiliac arteries produces claudication in the buttocks and thighs, whereas calf claudication indicates femoral or popliteal artery involvement. Only about 10% of patients with PAD display the well-known symptom of intermittent claudication (McDermott, Kibbe, Guralnik, et al., 2013). If PAD involves the internal iliac (hypogastric) arteries, erectile dysfunction may result.

Paresthesia, manifested as numbness or tingling in the toes or feet, may result from nerve tissue ischemia. True peripheral neuropathy occurs more commonly in patients with diabetes (see Chapter 52) and in those with longstanding ischemia. Neuropathy produces excruciating shooting or burning pain in the extremity, does not follow particular nerve roots, and may be present near ulcerated areas. Gradually diminishing perfusion to neurons obviates sensations of both pressure and deep pain. Thus affected patients may not notice lower extremity injuries.

The physical appearance of the limb provides important information about blood flow. The skin becomes thin, shiny, and taut, and hair loss occurs on the lower legs. Pedal, popliteal, or femoral pulses are diminished or absent. Pallor (blanching of the foot) develops in response to leg elevation *(elevation pallor).* In dark-skinned patients with pallor, normal brown skin appears to be yellow-brown, and normal black skin often appears to be ashen grey. Assessment of limb pallor in the dark-skinned patient requires observation of less pigmented areas such as the nailbeds or sole of the foot. Conversely, *reactive hyperemia* (redness of the foot) develops when the limb is in a dependent position (*dependent rubour;* Table 40-1). It is difficult to observe erythema in the dark-skinned patient but the limb colour would be darker than other skin areas, often purple, blue or eggplant in colour.

TABLE 40-1

COMPARISON OF PERIPHERAL ARTERY AND VENOUS DISEASE

Characteristic	Peripheral Artery Disease	Venous Disease
Peripheral pulses	Decreased or absent	Present; may be difficult to palpate with edema
Capillary refill	>3 sec	<3 sec
Ankle–brachial index	≤0.90	>0.90
Edema	Absent unless leg is constantly in dependent position	Lower leg edema
Hair	Loss of hair on legs, feet, toes	Hair may be present or absent
Ulcer location	Tips of toes, foot, or lateral malleolus	Near medial malleolus
Ulcer margin	Rounded, smooth, looks "punched out"	Irregularly shaped
Ulcer drainage	Minimal	Moderate to large amount
Ulcer tissue	Black eschar or pale pink granulation	Yellow slough or dark red, "ruddy" granulation
Pain	Intermittent claudication or rest pain in foot; ulcer may or may not be painful	Dull ache or sensation of heaviness in calf or thigh; ulcer often painful
Nails	Thickened; brittle	Normal or thickened
Skin colour	Dependent rubour; elevation pallor	Bronze-brown pigmentation; varicose veins may be visible
Skin texture	Thin, shiny, taut	Skin thick, hardened, and indurated
Skin temperature	Cool, temperature gradient down the leg	Warm, no temperature gradient
Dermatitis	Rare	Frequent
Pruritus	Rare	Frequent

As PAD progresses and involves increasing numbers of arterial segments, continuous pain at rest develops. *Rest pain* most often occurs in the forefoot or toes and is aggravated by limb elevation. Rest pain occurs when blood flow is insufficient to meet basic metabolic requirements of the distal tissues. Rest pain occurs more often at night because cardiac output tends to drop during sleep and the limbs are at the level of the heart. Affected patients often try to partially relieve pain by dangling the leg over the side of the bed or sleeping in a chair to allow gravity to maximize blood flow.

Chronic rest pain, ulceration, or gangrene is characteristic of *critical limb ischemia*. Critical limb ischemia often necessitates amputation within 6 months if untreated (McDermott, Kibbe, Guralnik, et al., 2013). Every attempt is made to save the limb, and surgical or endovascular revascularization is indicated. If a patient is not a candidate for revascularization, or if revascularization is not technically possible, medical treatment is indicated (Jones, Dolor, Hasselblad, et al., 2014).

Complications

Lower extremity PAD progresses slowly. Prolonged ischemia leads to atrophy of the skin and underlying muscles. Because of the decreased arterial blood flow, even minor trauma to the feet (e.g., stubbing one's toe, blister from ill-fitting shoes) may result in delayed healing, wound infection, and tissue necrosis, especially in diabetic patients. Arterial (ischemic) ulcers most commonly occur over bony prominences on the toes, feet, and lower leg (see Table 40-1). Nonhealing arterial ulcers and gangrene are the most serious complications. Amputation may be needed if blood flow is not restored adequately or if severe infection occurs. If PAD has been present for an extended period, collateral circulation may prevent gangrene of the extremity. Uncontrolled pain and severe, spreading infection are indicators that an amputation is required in individuals who are not candidates for revascularization.

Diagnostic Studies

Various tests are used to assess blood flow and outline the vascular system (Table 40-2). In Doppler ultrasonography, a probe is used to direct high-frequency sound waves toward the vessel being examined. Duplex imaging involves a colour Doppler system to systematically map blood flow throughout the entire region of an artery. When palpation of a peripheral pulse is difficult because of severe PAD, the Doppler imaging can determine the degree of blood flow. A palpable pulse and a pulse acquired through the use of Doppler ultrasonography (Doppler pulse) are not equivalent, and the terms are not interchangeable. *Segmental blood pressures* are measured (with Doppler ultrasonography and a sphygmomanometer) at the thigh, below the knee, and at ankle level while the patient is supine. A drop in segmental BP of greater than 30 mm Hg suggests PAD. Angiography and magnetic resonance angiography delineate the location and extent of PAD. They also provide information on inflow and outflow vessels to plan for surgery (see Table 34-6).

TABLE 40-2

COLLABORATIVE CARE
Peripheral Artery Disease

Diagnostic
• Health history and physical examination, including palpation of peripheral pulses • Angiography • Ankle–brachial index (ABI) • Doppler ultrasound studies • Duplex imaging • Magnetic resonance angiography (MRA) • Segmental blood pressures
Collaborative Therapy
• Achieve/maintain ideal body weight • Angiotensin-converting enzyme inhibitors (see Table 35-8) • Antiplatelet agent (ASA [Aspirin] or clopidogrel [Plavix]) • Cardiovascular disease risk factor modification • Endarterectomy (for localized stenosis but rarely done) • Follow Dietary Approaches to Stop Hypertension (DASH) diet (see Table 35-7) • Nutritional therapy • Patch graft angioplasty, often in conjunction with bypass surgery • Pentoxifylline (Trental) • Percutaneous transluminal atherectomy • Percutaneous transluminal balloon angioplasty with or without stent • Percutaneous transluminal cryoplasty • Peripheral artery bypass surgery • Proper foot care (see Chapter 52, Table 52-20) • Regular physical exercise • Structured walking/exercise program • Sympathectomy (for pain management only) • Thrombolytic therapy (for acute ischemia only) • Tight blood pressure control • Tight glucose control in diabetic patients • Tobacco cessation • Treatment of claudication symptoms • Treatment of hyperlipidemia (see Table 36-5) and hypertriglyceridemia • Amputation

The *ankle–brachial index* (ABI) is a PAD screening tool. It is measured with a handheld Doppler probe. To calculate the ABI, the ankle systolic blood pressures (BPs) are divided by the higher of the left and right brachial systolic BP (Lin, Olson, Johnson, et al., 2013). A normal ABI is 1.00 to 1.40 and indicates adequate BP in the extremities. An ABI between 0.91 and 0.99 is considered borderline, a value of 0.90 or less is abnormal, and values greater than 1.40 indicate noncompressible arteries (Rooke, Hirsch, Misra, et al., 2011; Table 40-3). An ABI has limited usefulness when arteries are calcified and noncompressible, as occurs in patients with diabetes mellitus and PAD. In such patients, the ABI frequently is falsely elevated. ABI measurement is not recommended immediately after revascularization surgery or on distal bypass grafts because of the risk of graft thrombosis (Aboyans, Criqui, Abraham, et al., 2012).

TABLE 40-3
INTERPRETATION OF ANKLE–BRACHIAL INDEX RESULTS

Ankle–Brachial Index (ABI)	Clinical Significance
≥1.40	Noncompressible arteries
1.00–1.40	Normal ABI
0.91–0.99	Borderline ABI
≤0.90	Abnormal ABI
Classification of PAD Severity	
0.90–0.71	Mild PAD
0.71–0.41	Moderate PAD
≤40	Severe PAD

PAD, peripheral artery disease.

Collaborative Care

Table 40-2 summarizes the collaborative care for a patient with PAD.

Risk Factor Modification.

Patients who have diabetes and atherosclerotic vascular disease such as coronary artery disease or PAD are at the highest risk for cardiovascular events such as myocardial infarction (MI), ischemic stroke, and CVD-related death. The Clinical Practice Guidelines of the Canadian Diabetes Association Clinical Practice Guidelines Expert Committee (2013) stress the importance of lifestyle modifications such as achieving and maintaining a healthy body weight, regular physical activity, smoking cessation, optimal BP control, and optimal glycemic control to reduce CVD risk factors. Risk factors may be modified with drug therapy and lifestyle changes on the part of the patient and caregiver (see Tables 36-1 through 36-5). Tobacco cessation is essential in the management of patients with PAD to reduce the risk of CVD events, PAD progression, and death. Tobacco cessation is a complex and difficult process with a high incidence of relapse. All patients with PAD should have access to comprehensive smoking cessation interventions (see the Resources at the end of Chapter 11).

Canadian lipid guidelines recommend aggressive management with a low-density lipoprotein cholesterol level of 2.0 mmol/L or less, and a total cholesterol and high-density lipoprotein cholesterol ratio less than 4.0 mmol/L (Pike-MacDonald, 2013). Although dietary change is also recommended, this alone is unlikely to achieve these goals. Research indicates that in patients with PAD, treatment with a statin (e.g., simvastatin [Zocor]) not only lowers cholesterol levels but also reduces

risks of CVD-related morbidity and mortality. Table 36-5 lists medications to lower cholesterol.

Hypertension is a major risk factor for PAD progression, as well as for other CVD events (e.g., stroke, MI, heart failure). The Canadian Hypertension Education Program (2015) recommendations for the management of hypertension in patients with PAD and CVD include BP lower than 140/90 mm Hg. In such patients who also have diabetes mellitus, BP lower than 130/80 mm Hg is recommended. Initial antihypertensive drug therapy includes thiazides, angiotensin-converting enzyme inhibitors, and angiotensin II receptor blockers. Lifestyle changes are encouraged and include reducing dietary sodium and following the Dietary Approaches to Stop Hypertension (DASH) diet. (Hypertension is discussed in Chapter 35.)

Diabetes is a well-known risk factor for PAD and increases the risk of needing amputation in these patients. It is recommended that patients with diabetes maintain a glycosylated hemoglobin (hemoglobin A_{1c}) below 7.0% and, optimally, as close as possible to 6.0%. (Diabetes mellitus is discussed in Chapter 52.)

Drug Therapy.

Antiplatelet agents are considered crucial for reducing the risks of CVD events and death in patients with PAD. Guidelines for oral antiplatelet therapy recommend acetylsalicylic acid (ASA; Aspirin) (75–325 mg/day). For patients who are ASA (Aspirin) intolerant, clopidogrel (Plavix; 75 mg/day) is indicated. Combination antiplatelet therapy with ASA (Aspirin) and clopidogrel is not recommended. Likewise, anticoagulants (e.g., warfarin [Coumadin]) are not recommended for the prevention of CVD events in patients with PAD. The use of angiotensin-converting enzyme inhibitors (e.g., ramipril [Altace]) decreases risks of morbidity and mortality (Rooke, Hirsch, Misra, et al., 2011).

Pentoxifylline (Trental) is used to treat intermittent claudication. It improves peripheral blood flow by increasing red blood cell flexibility and reducing blood viscosity. Anticoagulants, oral vasodilator prostaglandins, and chelation are not recommended for the treatment of claudication symptoms (McDermott, Kibbe, Guralnik, et al., et al., 2013). One promising approach to claudication treatment under investigation is levocarnitine (Carnitor), a naturally occurring derivative of the amino acid lysine. Carnitine improves initial and maximal treadmill walking distance and quality of life (Delaney, Spark, Thomas, et al., 2013).

Drug Alert

Clopidogrel (Plavix) and Omeprazole (Losec)

- Antiplatelet effect of clopidogrel is reduced by about half when given with omeprazole.
- This increases the risk of myocardial infarction and stroke.

Exercise Therapy.

The primary nondrug treatment for intermittent claudication is tobacco cessation in combination with a formal, supervised exercise-training program. Lack of exercise in patients with PAD is related to low quality of life, particularly in men (Parmenter, Dieberg, Phipps, et al., 2015). Walking is the most effective exercise for patients with PAD. A supervised, hospital-based PAD rehabilitation program is an effective means of improving exercise performance. Such programs typically include exercise for 30 to 60 minutes a day, three to five times a week, for 3 to 6 months. Supervised, treadmill exercise training improves walking performance and quality of life in patients with PAD regardless of whether they have claudication (McDermott, Kibbe, Guralnik, et al., 2013). A home exercise program is an alternative to a formal program. The nurse should encourage slow, progressive physical activity after a warm-up period. The patient is instructed to walk until the point of discomfort, stop and rest, and then resume walking until the discomfort recurs. Walking should be done for 30 to 40 minutes a day, three to five times a week, for at least 6 months. An exercise therapy program should also be implemented in patients with PAD after surgical interventions (discussed later in this chapter).

Nutritional Therapy.

Patients with PAD should be taught to adjust their dietary intake so that their body mass index is less than 25 kg/m^2 and their waist circumference is less than 101.6 cm (40 inches) for men and less than 89 cm (35 inches) for women (Heart and Stroke Foundation of Canada, 2017). A diet high in fruits, vegetables, and whole grains and low in cholesterol, saturated fat, and salt is recommended. Dietary cholesterol intake should be less than 200 mg/day, saturated fat intake should be substantially reduced, and dietary sodium should be 2 g/day or less (see Chapter 37, Table 37-11).

Complementary and Alternative Therapies.

A number of vitamin, mineral, dietary, and herbal supplements have been investigated in the treatment of intermittent claudication. Currently data are insufficient to support the efficacy of supplemental fish oil, ginkgo biloba, L-arginine, or homocysteine-lowering vitamins (e.g., folate, vitamin B_6, cobalamin) in the treatment of claudication (Brass, 2013). Vitamin E is not recommended to treat claudication (McDermott, Kibbe, Guralnik, et al., 2013). Patients taking antiplatelet agents (e.g., ASA [Aspirin]), nonsteroidal anti-inflammatory agents (NSAIDs; e.g., ibuprofen [Motrin]), and anticoagulants (e.g., warfarin) should consult with their health care provider before taking any dietary or herbal supplements because of potential interactions and bleeding risks (see the "Complementary & Alternative Therapies: Natural Health Products That May Affect Clotting" box later in the chapter; Grant, Bin, Kiat, et al., 2012).

Care of the Leg With Critical Limb Ischemia.

Critical limb ischemia is a condition characterized by chronic ischemic rest pain lasting more than 2 weeks, arterial leg ulcers, or gangrene of the leg as a result of PAD (Rooke, Hirsch, Misra, et al., 2011). Optimal therapy is revascularization through surgery or endovascular procedure. Although aggressive CVD risk factor modification and antiplatelet therapy are palliative in nature, all patients with critical limb ischemia should undergo these to decrease the risk of a CVD event (Jones, Dolor, Hasselblad, et al., 2014).

Conservative management goals include protecting the extremity from trauma, decreasing ischemic pain, preventing and controlling infection, and maximizing perfusion. The patient should carefully inspect, cleanse, and lubricate both feet to prevent cracking of the skin and infection. The patient must avoid soaking feet to prevent skin *maceration* (or breakdown). If ulceration is present, the affected foot must be kept clean and dry. Any ulcers should be covered with a dry, sterile dressing to maintain cleanliness and protect the limb. Ulcers with significant depth may be treated with a variety of wound care products, but healing is unlikely without increased blood flow. The nurse should encourage the patient to select soft, roomy, and protective footwear and avoid extremes of heat and cold. The patient's heels should be kept free of pressure. This may be accomplished by placing a pillow under the calves so that the heels are off the bed. Commercially available devices can also provide heel protection. Opioid analgesia and placing the bed in the reverse Trendelenburg

position may control pain and facilitate perfusion to the lower extremities (Jones, Dolor, Hasselblad, et al., 2014).

Some evidence indicates that spinal cord stimulation or hyperbaric oxygen therapy may be helpful in preventing the need for amputation in patients with critical limb ischemia (Benoit, O'Donnell, Kitsios, et al., 2012). Another promising strategy under investigation is gene therapy to stimulate blood vessel growth (angiogenesis; Grochot-Przeczek, Dulak, & Jozkowicz, 2013).

Interventional Radiological Catheter-Based Procedures.

Interventional radiology catheter-based procedures are alternatives to open surgical approaches for treatment of PAD in the lower extremity. These procedures take place in a catheterization laboratory rather than an operating room. Determining which intervention to use depends on stenosis location, along with type and severity of the lesion. After the procedure, most patients can ambulate the same day and return to normal activity within 24 to 48 hours. All of these procedures are similar to angiography in that they involve the insertion of a specialized catheter into the femoral artery. The *percutaneous transluminal angioplasty* procedure involves the use of a catheter that contains a cylindrical balloon at the tip. The end of the catheter is advanced to the narrowed (stenotic) area of the artery. When in position, the balloon is inflated, compressing the confining atherosclerotic intimal lining while also stretching the underlying media.

Stents, expandable metallic devices, are positioned within the artery immediately after the balloon angioplasty is performed. The stent acts as a scaffold to keep the artery open and is used as a treatment for peripheral artery dissection (Deiter & Nanjundappa, 2012). Dissection is a tear in the inner arterial wall that causes blood to flow between the layers of the artery, separating or dissecting the layers and often causing a false lumen. Stents may be covered with Dacron or a drug-eluting agent (e.g., paclitaxel) to minimize re-stenosis by reducing the amount of new tissue growth in the stent.

Atherectomy is the removal of the obstructing plaque. In directional atherectomy, a high-speed cutting disc built into the catheter end cuts long strips of the atheroma. In laser atherectomy, ultraviolet energy is used to break the molecular bonds of the atheroma to reduce the stenosis (Ahmed, 2015). Orbital or rotational atherectomy catheters have a diamond-coated tip that rotates at high speed (similar to a dentist drill) to pulverize the calcium within the atheroma into particles smaller than a blood cell.

Cryoplasty is a combination of two procedures: balloon angioplasty and cold therapy. The specialized balloon is inflated with liquid nitrous oxide that changes from liquid to gas as it enters the balloon. Expansion of the gas results in cooling to −10°C. The cold minimizes re-stenosis through reduction of smooth muscle cell activity (Dominguez, Bahadorani, Reeves, et al., 2015). Preprocedure and post-procedure nursing care are the same as those for diagnostic angiography. Antiplatelet agents are necessary after the procedure to reduce the risk of re-stenosis. Long-term, low-dose ASA (Aspirin) therapy is recommended after the procedure (Brass, 2013). Re-stenosis rates depend on the procedure performed, lesion type and length, and characteristics of the target vessel. Immediate post-procedure success rates are high (>95%) for iliac and femoral interventions (Ahmed, 2015).

Surgical Therapy.

Various surgical approaches can be used to improve blood flow beyond a stenotic or occluded artery. The most common is a peripheral artery bypass operation with autogenous (native) vein or synthetic graft material to bypass or carry blood around the lesion (Figure 40-2). Synthetic grafts (expanded polytetrafluoroethylene or Dacron) typically are used for long bypasses such as axillary–femoral or axillary–popliteal bypasses. When a patient's own vein is not available, human umbilical vein, cryopreserved vein, or a composite sequential bypass graft is an alternative. Percutaneous transluminal angioplasty with stenting also may be used in combination with bypass surgery. Other surgical options include *endarterectomy* (opening the artery and removing the obstructing plaque) and *patch graft angioplasty* (opening the artery, removing plaque, and sewing a patch to the opening to widen the lumen).

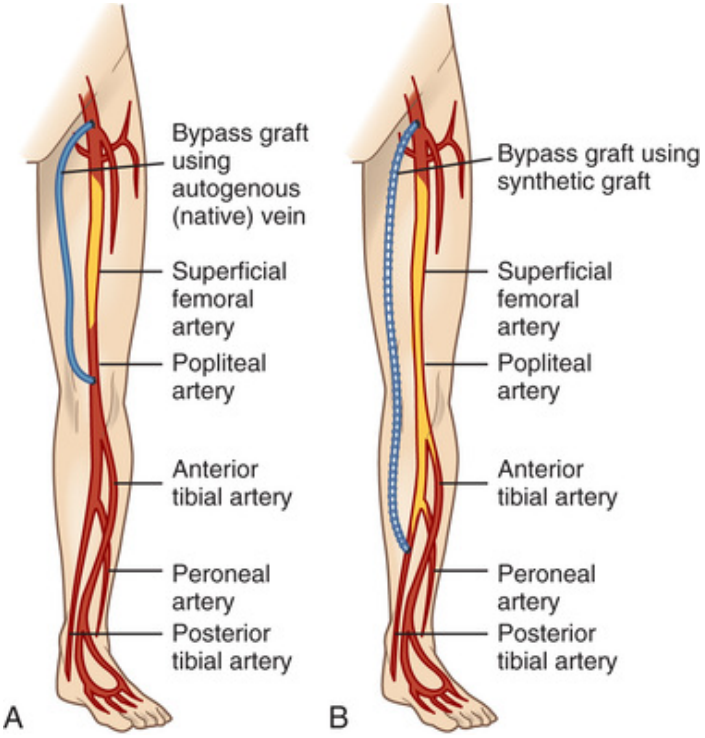

FIGURE 40-2 **A,** Femoral–popliteal bypass graft around an occluded superficial femoral artery. **B,** Femoral–posterior tibial bypass graft around occluded superficial femoral, popliteal, and proximal tibial arteries.

Amputation may be required if tissue necrosis is extensive, if infectious gangrene or osteomyelitis (infection in the bone) develops, or if all major arteries in the limb are occluded, all of which preclude the possibility of successful reparative surgery (Benoit, O'Donnell, Kitsios, et al., 2012). Every effort is made to preserve as much of the limb as possible so that the potential for rehabilitation is optimized. Implementation of an amputee mobility protocol after surgery can increase functional mobility of patients with a lower limb amputation and maximize their rehabilitation potential (Benoit, O'Donnell, Kitsios, et al., 2012). (Amputation is discussed in Chapter 65.)

Complementary & Alternative Therapies

Natural Health Products That May Affect Clotting

Anticoagulant Effects

Increased

Angelica, anise, bilberry, bromelain, celery, chamomile, devil's claw, dong quai, fenugreek, feverfew, garlic, ginger, *Ginkgo biloba,* goldenseal, horse chestnut, licorice root, lovage root, meadowsweet, motherwort, parsley, passionflower, red clover, rue, turmeric, willow bark

Decreased

Coenzyme Q_{10}, ginseng, green tea, St. John's wort

Nursing Implications

- In general, these natural products should be used with caution or not at all by patients with bleeding or clotting disorders or those taking anticoagulant and antiplatelet drugs (e.g., warfarin [Coumadin], heparin, low-molecular-weight heparin, ASA [Aspirin], ticlopidine, or clopidogrel [Plavix]). These patients should consult with a health care provider before using any of these natural products.
- These natural health products should be discontinued at least 2 to 3 wk before surgery to avoid potential complications. If this is not possible, the herbal product in its original container should be brought to the health care provider or the surgery site so the anaesthesia care provider knows exactly what the patient is taking.
- One common mechanism of these products is to inhibit platelet aggregation.

Nursing Management Lower Extremity Peripheral Artery Disease

Nursing Assessment

Table 40-4 lists subjective and objective data that the nurse should obtain from a patient with PAD.

TABLE 40-4

NURSING ASSESSMENT
Peripheral Artery Disease

Subjective Data
Important Health Information
Past health history: Diabetes mellitus, tobacco use, hypertension, hyperlipidemia, hypertriglyceridemia, hyperuricemia, impaired renal function, obesity; ↑ high-sensitivity C-reactive protein, homocysteine or lipoprotein (a) levels; positive family history; exposure to environmental smoke; sedentary lifestyle; stress High intake of sodium, saturated fat, and cholesterol; elevated hemoglobin A_{1c} level Exercise intolerance
Symptoms
• Buttock, thigh, or calf pain that is precipitated by exercise and that subsides with rest (intermittent claudication) or progresses to pain at rest; burning pain in feet and toes at rest; numbness, tingling, sensation of cold in legs or feet; progressive loss of sensation and deep pain in extremities • Erectile dysfunction
Objective Data
Integumentary
Loss of hair on legs and feet; thick toenails; pallor with elevation; dependent rubour; thin, cool, shiny skin with muscle atrophy; skin breakdown and arterial ulcers, especially over bony areas; gangrene
Cardiovascular
Decreased or absent peripheral pulses; feet cool to touch; capillary refill >3 sec; possible presence of bruits at pulse sites
Neurological
Mobility or sensation impairment
Possible Diagnostic Findings
Arterial stenosis evident with duplex imaging, ↓ segmental limb pressures (Doppler ultrasound pressures combined with blood pressure measurements), ↓ ankle–brachial index (ABI), angiogram indicative of peripheral atherosclerosis

Nursing Diagnoses

Nursing diagnoses for a patient with PAD of the lower extremities (who has not undergone surgery) may include, but are not limited to, the following:

- *Ineffective peripheral tissue perfusion* related to *insufficient knowledge of disease process*
- *Activity intolerance* related to *imbalance between oxygen supply/demand*
- *Chronic pain* related to *injury agent* (ischemia, inflammation, and swelling)
- *Ineffective health management* related to *insufficient knowledge of therapeutic regimen, difficulty managing complex treatment regimen*

Additional information on nursing diagnoses for the patient with PAD of the lower extremities is presented in Nursing Care Plan (NCP) 40-1, available on the Evolve website for this chapter.

Planning

The overall goals for a patient who has lower extremity PAD include (a) adequate tissue perfusion; (b) relief of pain; (c) increased exercise tolerance; and (d) intact, healthy skin on extremities.

Nursing Implementation

Health Promotion.

The nurse assesses the patient for CVD risk factors and provides instructions on how to control them (see Chapter 36, Tables 36-1 and 36-2). The nurse also teaches diet modification to reduce the intake of cholesterol, saturated fat, and refined sugars; proper care of the feet; and the avoidance of injury to the extremities. Patients with positive family histories of cardiac, diabetic, or vascular disease are encouraged to obtain regular follow-up care.

Acute Intervention.

After surgical or radiological intervention, the patient is moved to a recovery area for observation. The nurse checks the operative extremity every 15 minutes initially and then hourly for colour, temperature, capillary refill, presence of peripheral pulses, and sensation and movement. If the nurse observes loss of palpable pulses or a change in the

Doppler sound over a pulse, or both, the physician or radiologist must be notified immediately and prompt intervention undertaken. ABI measurements may be ordered, and the indexes should be higher than the patient's baseline and should remain stable if the bypass (or stent) remains patent. The nurse compares all assessment findings with the patient's baseline and with findings in the opposite limb (Jarvis, Browne, Macdonald-Jenkins, et al., 2014). Many patients with PAD have a history of chronic ischemic rest pain and may have developed a tolerance to opioids. Therefore, aggressive pain management may be needed postoperatively.

After the patient leaves the recovery area, the nurse continues to monitor perfusion to the extremities and to assess for potential complications such as bleeding, hematoma, thrombosis, embolization, and compartment syndrome. A dramatic increase in pain, loss of previously palpable pulses, extremity pallor or cyanosis, decreasing ABIs, numbness or tingling, or a cold extremity suggests occlusion of the graft or stent. The nurse must report these findings to the physician immediately.

The patient should not be placed in a knee-flexed position except for exercise. The patient should be turned and repositioned frequently with pillows to avoid strain on the incision. On postoperative day 1, the nurse assists the patient out of bed several times daily. Short periods of different leg and body positions will not impair postoperative skin oxygen levels. Prolonged sitting with leg dependency should be discouraged because it may cause pain and edema, increase the risk of venous thrombosis, and place stress on the suture lines. If edema develops, the nurse positions the patient supine and elevates the edematous leg above heart level. On occasion, graduated compression stockings are used to help control leg edema. Walking even short distances is desirable. The use of a walker may be helpful, especially in frail older adult patients. Although graft patency and mortality rates are equivalent for men and women after lower extremity revascularization, women are more likely to develop wound complications than are men (Lo, Bensley, Hamdan, et al., 2013).

Surgical site infection after lower extremity revascularization occurs in about 11% of cases. Women develop such infections more often than do men. Careful postoperative assessment and wound care are important. Surgical site infections are associated with early graft loss, reoperation, and sepsis (Greenblatt, Rajamanickam, & Mell, 2011). If no complications are present, discharge from the hospital can be anticipated 3 to 5 days postoperatively.

Ambulatory and Home Care.

The nurse should assess for CVD risk factors and be alert for opportunities to teach health promotion strategies to patients and their caregivers (see Chapters 4 and 36). Tobacco use in any form (including environmental smoke) is contraindicated. Nicotine exerts vasoconstrictive effects, and tobacco smoke impairs transport and cellular utilization of oxygen and increases blood viscosity and homocysteine levels. Continued tobacco use dramatically decreases the long-term patency rates of grafts and stents and increases the risk of an MI or stroke. The nurse should encourage physical activity and explain that it improves a number of CVD risk factors, including hypertension, hyperlipidemia, obesity, and glucose levels. Physical activity also improves peripheral circulation and increases walking distance (Parmenter, Dieberg, Phipps, et al., 2015).

The nurse should teach foot care to all patients with PAD. Meticulous foot care is especially important in diabetic patients with PAD (see Table 52-20). Diabetic neuropathy increases the patient's susceptibility to traumatic injury and results in delay in seeking treatment. Patients are instructed to inspect their legs and feet daily for mottling, changes in skin colour, skin texture, amount of subcutaneous fat, and reduction in hair growth. The nurse can also teach patients to check skin temperature and capillary refill and to palpate pulses. The nurse should emphasize that patients must report any changes in these findings or the development of any ulceration or inflammation to their health care provider. Thick or overgrown toenails and calluses are potentially serious and require regular attention by a skilled health care provider (e.g., podiatrist). Patients who have poor eyesight, back problems, obesity, or arthritis may need assistance with foot care. Patients are encouraged to wear clean, all-cotton or all-wool socks and comfortable shoes with rounded (not pointed) toes and soft insoles. Shoes should be laced loosely, and patients should break in new shoes gradually (Table 40-5).

TABLE 40-5

PATIENT & CAREGIVER TEACHING GUIDE
Peripheral Artery Bypass Surgery

The following information should be included in the teaching plan for a patient undergoing peripheral artery bypass surgery and the patient's caregiver:
1. Patients can reduce risk factors by stopping the use of tobacco products, by controlling blood pressure and blood glucose levels (if diabetic), by lowering cholesterol and triglyceride levels, by achieving/maintaining ideal body weight, and by exercising regularly. 2. Patients should be provided rationales, basic mechanism of action, and anticipated duration of medications such as antiplatelets, antihypertensives, anticholesterol therapy, and pain medication. 3. Diet must be healthy—it is essential to recovery. Patients should drink plenty of fluids, follow a well-balanced diet (e.g., foods high in protein, vitamins C and A, and zinc; high-fibre foods; fresh fruits and vegetables), eat fewer high-fat foods, and reduce salt intake. 4. Patients should participate in a supervised exercise program, take a daily walk, or both. In the beginning, patients may take several short walks a day and rest between activities. Walking is gradually increased to 30–40 min/day, 3–5 days/wk. 5. Patients should care for their feet and legs; inspect feet and wash them daily; wear clean cotton or wool socks and well-fitting shoes; file toenails straight across; and avoid sitting with legs crossed, extreme hot and cold temperatures, and prolonged standing. 6. Routine postoperative wound care includes keeping incision clean and dry; Steri-Strips (if present) should not be disturbed. 7. Patients should monitor for signs and symptoms of impaired healing and infection of the leg incision, and they should notify the health care provider if any of the following occur: • Prolonged drainage or pus from the incision • Increased redness, warmth, pain, or hardness along incision • Separation of wound edges • Body temperature greater than 37.8°C 8. Patients must keep all follow-up appointments with their health care provider. 9. The health care provider should be notified if the patient experiences increased leg or foot pain or a change in the colour or temperature of the foot and leg.

Evaluation

NCP 40-1, available on the Evolve website, addresses the expected outcomes for the patient with PAD of the lower extremities.

Acute Arterial Ischemic Disorders

Etiology and Pathophysiology

Acute arterial ischemia is a sudden interruption in the arterial blood supply to a tissue, organ, or extremity that, if left untreated, can result in tissue death. It is caused by embolism, thrombosis of a pre-existing atherosclerotic artery, or trauma. Embolization of a thrombus (clot) from the heart is the most frequent cause of acute arterial occlusion. Heart conditions in which thrombi can develop include infective endocarditis, MI, mitral valve disease, chronic atrial fibrillation, and cardiomyopathies; thrombi can also develop in prosthetic heart valves. Noncardiac sources of

emboli include aneurysms, ulcerated atherosclerotic plaque, and venous thrombi. Emboli can also develop as a result of recent endovascular procedures, and, in rare cases, arteritis.

Thrombi become dislodged and may travel anywhere in the systemic circulation if they originate in the left side of the heart. The majority of emboli obstruct an artery of the lower extremity (e.g., iliofemoral, popliteal, tibial) (Anderson, Halperin, Albert, et al., 2013).

Arterial emboli tend to lodge at sites of arterial branching or in areas of atherosclerotic narrowing. An acute arterial occlusion causes the oxygen and blood supply distal to the embolus to decrease suddenly, producing ischemia. The amount of tissue and muscle at risk, degree of the ischemia, and extent of the symptoms depend on several factors, including (a) the location and size of the occlusion, (b) the occurrence of clot fragmentation with embolism to smaller vessels, (c) the degree of PAD already present, and (d) the presence of collateral vessels around the acute obstruction.

Sudden local thrombosis may occur at the site of an atherosclerotic plaque. States of hypovolemia (e.g., resulting from shock), hyperviscosity (e.g., resulting from polycythemia), and hypercoagulability (e.g., resulting from chemotherapy) predispose an individual to thrombotic arterial occlusion (Ouriel & Kasyap, 2011).

Traumatic injury to the extremity itself may cause partial or total occlusion. Acute arterial occlusion may also develop as a result of arterial dissection in the carotid artery or aorta or as a result of iatrogenic arterial injury (e.g., after angiography).

Clinical Manifestations

Clinical manifestations of acute arterial ischemia include the "six *P*s": **p**ain, **p**allor, **p**aralysis, **p**ulselessness, **p**aresthesia, and **p**oikilothermia (adaptation of the limb to the environmental temperature, most often cool). Without immediate intervention, ischemia may progress quickly to tissue necrosis and gangrene within a few hours. If the nurse detects these signs, the nurse should immediately notify the physician. Paralysis is a very late sign of acute arterial ischemia and signals the death of nerves supplying the extremity. Footdrop occurs as a result of nerve damage. Because nerve tissue is extremely sensitive to hypoxia, limb paralysis or ischemic neuropathy may be permanent even after revascularization.

Collaborative Care

Early treatment is essential to keep the affected limb viable during acute arterial ischemia. Anticoagulant therapy with continuous intravenous (IV) unfractionated heparin is started to prevent thrombus enlargement and inhibit further embolization (Schulman, 2014). In patients undergoing embolectomy, unfractionated heparin should be followed by long-term anticoagulation with warfarin (see discussion of other anticoagulant options later in this chapter). To restore blood flow, the embolus/thrombus is removed as soon as possible. Options for embolus/thrombus removal include percutaneous catheter-directed thrombolytic therapy, percutaneous mechanical thrombectomy with or without thrombolytic therapy, surgical thrombectomy, or surgical bypass (Jones, Dolor, Hasselblad, et al., 2014). Catheter-directed intra-arterial thrombolytic therapy (e.g., tissue plasminogen activator [tPA], or alteplase) is recommended for patients with short-term (<14 days) thrombo-embolic disease (Schulman, 2014). A percutaneous catheter is inserted into the femoral artery and threaded to the site of the clot, and the thrombolytic drug is infused. Thrombolytic agents work by directly dissolving the clot over a period of 24 to 48 hours. (Thrombolytic therapy is discussed in Chapter 36.) The catheter may act as a mechanical thrombectomy device; that is, it is also designed to remove or fragment the thrombus (Jones, Dolor, Hasselblad, et al., 2014).

Surgical intervention is recommended for some patients (e.g., those with ischemia for more than 14 days when catheter-based interventions are not possible, as with inability of the guide wire to transverse the thrombus) (Jones, Dolor, Hasselblad, et al., 2014). Direct arteriotomy may be necessary to remove the clot. Surgical revascularization may be used in a patient with trauma (e.g., laceration of the artery) or with significant arterial occlusion. Amputation is reserved for patients with ischemic rest pain and tissue loss, for whom limb salvage is not possible. If the patient remains at risk for further embolization from a persistent source (e.g., chronic atrial fibrillation), long-term oral anticoagulation is recommended to prevent further acute arterial ischemic episodes (see Table 40-10 later in this chapter) (Jones, Dolor, Hasselblad, et al., 2014).

Thromboangiitis Obliterans

Thromboangiitis obliterans (Buerger's disease) is a nonatherosclerotic, segmental, recurrent inflammatory disorder of the small and medium-sized arteries and veins of the upper and lower extremities. In rare cases, systemic manifestations of the disease may involve cerebral, mesenteric, or

coronary arteries. The disorder occurs predominantly in young men (<45 yr) with a long history of tobacco or marihuana use (or both), but without other CVD risk factors (e.g., hypertension, hyperlipidemia, diabetes mellitus) (Vijayakumar, Tiwari, & Prabhuswamy, 2013).

In Buerger's disease, an inflammatory process damages the blood vessel wall. Lymphocytes and giant cells infiltrate the vessel wall, and fibroblasts proliferate (Vijayakumar, Tiwari, & Prabhuswamy, 2013). Ultimately, thrombosis and fibrosis occur in the vessel, causing tissue ischemia. Patients with Buerger's disease have a high rate of periodontitis and the presence of *Porphyromonas gingivalis* (a periodontal pathogen) in the occluded blood vessels (Vijayakumar, Tiwari, & Prabhuswamy, 2013). This suggests that bacterial infection plays a role in the pathogenesis of Buerger's disease. Researchers are examining genetic factors in susceptible individuals (Vijayakumar, Tiwari, & Prabhuswamy, 2013). The symptom complex of Buerger's disease often is confused with PAD and other inflammatory or autoimmune diseases (e.g., scleroderma). Patients may have intermittent claudication of the feet, hands, or arms. As the disease progresses, rest pain and ischemic ulcerations develop. Other signs and symptoms may include colour and temperature changes of the limbs, paresthesia, superficial vein thrombosis, and cold sensitivity. There are no laboratory or diagnostic tests specific to Buerger's disease. Diagnosis is based on age at onset; history of tobacco use; clinical symptoms; involvement of distal vessels; presence of ischemic ulcerations; and exclusion of diabetes mellitus, autoimmune disease, thrombophilia (inherited tendency to clot), and proximal source of emboli (Vijayakumar, Tiwari, & Prabhuswamy, 2013).

Patients with Buerger's disease have red blood cell rigidity, elevated hematocrit, and increased blood viscosity (Vijayakumar, Tiwari, & Prabhuswamy, 2013). The mainstay of treatment for Buerger's disease is the complete cessation of tobacco and marihuana use in any form. Use of nicotine replacement products is contraindicated. Conservative management includes the use of antibiotics to treat any infected ulcers and analgesics to manage the ischemic pain. Patients must avoid trauma to the extremities. A variety of novel drug therapies to treat Buerger's disease have been studied, but the results have been marginal; one therapy with modest effectiveness in Europe has been IV iloprost (a prostaglandin analogue). Another promising area of research is the intramuscular gene transfer of vascular growth factors.

Surgical options include *sympathectomy* (transection of a nerve, ganglion, or plexus of the sympathetic nervous system, or a combination of these),

implantation of a spinal cord stimulator, and bypass surgery. Sympathectomy and implantation of a spinal cord stimulator are useful in improving distal blood flow and reducing pain, but neither alters the inflammatory process. Bypass surgery typically is not an option, owing to the involvement of smaller, distal vessels, but may be used in selected patients with severe ischemia (Vijayakumar, Tiwari, & Prabhuswamy, 2013).

Painful ulcerations may necessitate finger or toe amputations. Amputation below the knee may be necessary in severe cases. The rate of amputation in patients who continue tobacco or marihuana use after diagnosis is much higher than in those who stop (Vijayakumar, Tiwari, & Prabhuswamy, 2013).

Raynaud's Phenomenon

Raynaud's phenomenon is an episodic vasospastic disorder of small cutaneous arteries, most frequently involving the fingers and toes. It occurs primarily in young women (typically between 15 and 40 years of age) and it is more common in women than in men (Prete, Fatone, Favoino, et al., 2014). The exact etiology of Raynaud's phenomenon remains unknown. One theory is that the vasospasm results from an exaggerated response to sympathetic nervous system stimulation. Other contributing factors include occupation-related trauma and pressure to the fingertips, as noted in typists, pianists, and people who use handheld vibrating equipment. Exposure to heavy metals (e.g., lead) may also be a contributing factor.

Primary Raynaud's phenomenon, the more common form of the disease, is associated with significantly poorer physical and mental health–related quality of life (Prete, Fatone, Favoino, et al., 2014). When symptoms occur in association with autoimmune diseases (e.g., rheumatoid arthritis, systemic lupus erythematosus), the disorder is called *secondary Raynaud's phenomenon.*

Raynaud's phenomenon is characterized by vasospasm-induced colour changes of the fingers, toes, ears, and nose (white, blue, and red). Decreased perfusion results in pallor (white). The digits then appear cyanotic (bluish-purple) (Figure 40-3). These changes are followed by rubour (redness), caused by the hyperemic response that occurs when perfusion is restored. The patient usually describes coldness and numbness in the vasoconstrictive phase, followed by throbbing, aching pain; tingling; and swelling in the hyperemic phase. An episode usually

lasts only minutes but, in severe cases, may persist for several hours. Exposure to cold, emotional upset, tobacco use, and caffeine usually precipitate symptoms. After frequent, prolonged attacks, the skin may become thickened and the nails brittle. On occasion, complications include punctate (small hole) lesions of the fingertips and superficial gangrenous ulcers in advanced stages. Diagnosis is based on persistence of symptoms for at least 2 years. The primary focus of nursing management of Raynaud's phenomenon is patient education.

FIGURE 40-3 Raynaud's phenomenon. Source: Kamal, A., & Brockelhurst, J. C. (1991). *Color atlas of geriatric medicine* (2nd ed.). St. Louis: Mosby–Year Book.

Instructions should focus on preventing recurrent episodes. Patients should wear loose, warm clothing as protection from the cold, including gloves when using the refrigerator or freezer or when handling cold objects. At all times, patients should avoid temperature extremes. Immersing hands in warm water often decreases the vasospasm. Patients should stop using all tobacco products and avoid caffeine and other drugs that have vasoconstrictive effects (e.g., amphetamines, cocaine, ergotamine, pseudoephedrine).

Patients with Raynaud's phenomenon often describe themselves as anxious or depressed, or both (Prete, Fatone, Favoino, et al., 2014). Biofeedback, relaxation training, and stress management may be useful. If these options are appropriate, the nurse should encourage patients to explore them. When a patient's episodes are severe and other therapies are ineffective, drug therapy is considered. Calcium channel blockers (e.g., diltiazem [Cardizem]) are the first-line drug therapy (Herrick, 2012).

Calcium channel blockers relax smooth muscles of the arterioles by blocking the influx of calcium into the cells, thus reducing the frequency and severity of vasospastic attacks.

Sympathectomy is considered only in advanced cases. Patients with Raynaud's phenomenon should receive routine follow-up to monitor for development of connective tissue or autoimmune diseases because Raynaud's phenomenon may be an early sign of scleroderma (Merritt, 2015).

Aortic Aneurysms

The aorta is the largest artery and supplies oxygen and blood to all vital organs. One of the most common problems affecting the aorta is an **aneurysm,** a permanent, localized outpouching or dilation of the vessel wall (either congenital or acquired). Aneurysms occur in men more often than in women, and their incidence increases with age. Peripheral artery aneurysms also develop but are less common.

Etiology and Pathophysiology

Aortic aneurysms may involve the aortic arch, thoracic aorta, abdominal aorta, or a combination. Most aneurysms, however, are found in the abdominal aorta below the level of the renal arteries. The growth rate of aneurysms is unpredictable, but the larger the aneurysm, the greater the risk of rupture. The dilated aortic wall becomes lined with thrombi that can embolize, leading to acute ischemic symptoms to distal (downstream) branches. Of true aortic aneurysms, 75% occur in the abdomen (Figure 40-4) and 25% in the thoracic aorta. Popliteal artery aneurysms rank third in frequency. Patients may have more than one aneurysm, in different locations.

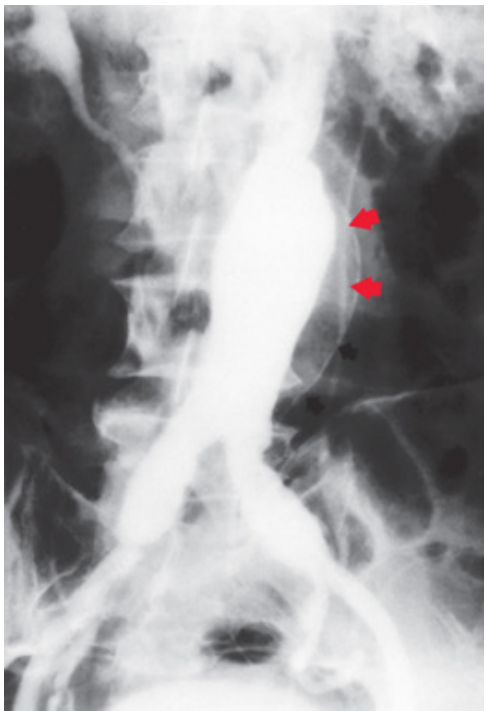

FIGURE 40-4 Angiogram demonstrates a fusiform abdominal aortic aneurysm. Note calcification of the aortic wall *(arrows)* and extension of the aneurysm into the common iliac arteries. Source: Courtesy James O. Menzoian, Boston.

Although various disorders are associated with aortic aneurysms, the primary cause may be classified as degenerative, congenital, mechanical, inflammatory, or infectious. The most common etiology of aneurysms of the aorta is atherosclerosis (Copstead & Banasik, 2013). It is known that atherosclerotic plaques are deposited beneath the *intima* (the innermost layer of the arterial wall). This plaque formation is thought to cause degenerative changes in the *media* (middle layer of the arterial wall), leading to loss of elasticity, weakening, and eventual dilation of the aorta.

Male sex, age of 65 years or older, and tobacco use are the major risk factors for abdominal aortic aneurysms (AAAs) of atherosclerotic origin. Other risk factors include the presence of coronary artery disease or PAD, hypertension, and high cholesterol levels (Copstead & Banasik, 2013). Studies have shown a strong genetic component in AAA development. The familial tendency is related to a number of congenital anomalies, including specific collagen defects (e.g., Ehlers-Danlos syndrome) and premature breakdown of vascular elastic tissue (Marfan syndrome; Copstead & Banasik, 2013). Less common causes of AAAs include penetrating or blunt trauma from motor vehicle collisions, inflammatory

aortitis (e.g., Takayasu's or giant cell arteritis), and infectious aortitis (e.g., from syphilis or *Salmonella* or human immunodeficiency virus infection).

Classification

Aneurysms are classified as true or false (Figure 40-5, *A* to *D*). A *true aneurysm* is one in which the wall of the artery forms the aneurysm, with at least one vessel layer still intact. True aneurysms can be further subdivided into fusiform and saccular dilations. A *fusiform aneurysm* is circumferential and relatively uniform in shape. A *saccular aneurysm* is pouchlike with a narrow neck connecting the bulge to one side of the arterial wall.

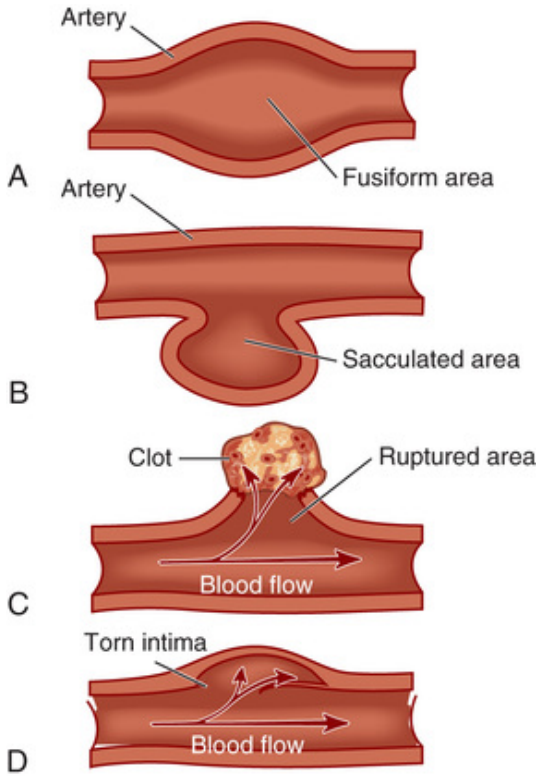

FIGURE 40-5 **A,** True fusiform abdominal aortic aneurysm. **B,** True saccular aortic aneurysm. **C,** False aneurysm, or pseudoaneurysm. **D,** Aortic dissection.

A *false aneurysm,* or *pseudoaneurysm,* is not an aneurysm but a disruption of all layers of the arterial wall, resulting in bleeding that is contained by surrounding structures. False aneurysms may result from trauma or infection or occur after peripheral artery bypass graft surgery at the site of

the graft-to-artery anastomosis. They may also result from arterial leakage after removal of cannulas such as lower extremity arterial catheters and intra-aortic balloon pump devices.

Clinical Manifestations

Thoracic aortic aneurysms are often asymptomatic. When they are symptomatic, the most common symptom is deep, diffuse chest pain extending to the interscapular area. Aneurysms located in the ascending aorta and the aortic arch can produce hoarseness in the patient as a result of pressure on the recurrent laryngeal nerve. Pressure on the esophagus can cause dysphagia. If the aneurysm presses on the superior vena cava, it can cause a decrease in venous drainage, resulting in jugular venous distension (distended neck veins) and edema of the head and the arms.

AAAs are often asymptomatic and frequently detected on routine physical examination or when the patient is examined for an unrelated problem (e.g., on abdominal radiographic examination, ultrasound study, computed tomography [CT] scan, or IV pyelography, or during abdominal surgery). On physical examination, a pulsatile mass in the periumbilical area slightly to the left of the midline may be detected. Bruits may be audible through a stethoscope placed over the aneurysm. These physical findings may be more difficult to detect in obese individuals.

Symptoms of an AAA may mimic pain associated with any abdominal or back disorder. Symptoms may result from compression of nearby anatomical structures. These include back pain caused by lumbar nerve compression and epigastric discomfort with or without alteration in bowel elimination, as a result of compression on the bowel. On occasion, embolization is caused by plaque released by an aneurysm, even a small one. This can cause the "blue toe syndrome," in which patchy mottling of the feet and toes occurs in the presence of palpable pedal pulses.

Complications

The most serious complication is rupture of the aneurysm. If blood from a rupture leaks into the retroperitoneal space, bleeding may be controlled by surrounding anatomical structures, preventing exsanguination and death. In such cases, many patients have severe back pain and may or may not have back or flank ecchymosis *(Grey Turner's sign).* In cases in which blood from a rupture leaks into the thoracic or abdominal cavity, more than 90% of patients die from massive hemorrhage (Go, Mozaffarian, Roger, et al., 2013). Such a patient who reaches the hospital is in hypovolemic shock

with tachycardia, hypotension, pale clammy skin, decreased urine output, altered level of consciousness, and abdominal tenderness. (Shock is discussed in Chapter 69.) In this situation, simultaneous resuscitation and immediate surgical repair are necessary.

Diagnostic Studies

Chest radiographs reveal abnormal widening of the thoracic aorta. An abdominal radiograph may show calcification within the aortic wall. Because symptoms of thoracic aneurysm can mimic angina, electrocardiography is performed to rule out evidence of MI. Echocardiography is performed to assess the function of the aortic valve. Ultrasonography is useful for aneurysm screening and monitoring aneurysm size. A CT scan is the most accurate test for determining the length and cross-sectional diameter and the presence of thrombus in the aneurysm. Three-dimensional CT scans can assist in determining what type of surgical repair should be done. Magnetic resonance imaging (MRI) also may be used to diagnose and assess the location and severity of aneurysms.

Angiography, anatomical mapping of the aortic system by contrast imaging, provides information about the involvement of intestinal, renal, or distal vessels. Angiography is also useful if a suprarenal or thoraco-abdominal aneurysm is suspected. (Angiography is discussed in Chapter 34 and Table 34-6.)

Collaborative Care

The goal of management is to prevent aneurysm rupture and extension of dissection. Early detection and prompt treatment are essential. A careful review of body systems is necessary to identify any comorbid conditions, especially of the lungs, heart, or kidneys, because they may influence the patient's risk for surgical complications. Existing carotid and coronary artery obstructions may need to be corrected before the aneurysm is repaired. Conservative therapy of small, asymptomatic AAAs (4.0–5.5 cm) is the best practice (Filardo, Powell, Martinez, et al., 2012). This consists of risk factor modification (ceasing tobacco use, decreasing BP, optimizing lipid profile) and annual monitoring of aneurysm size with ultrasonography, CT, or MRI (Copstead & Banasik, 2013). Surgical intervention may be undertaken sooner if (a) the patient is a younger patient at low risk for surgical complications, (b) the aneurysm expands rapidly (i.e., >1-cm diameter increase per year), (c) the patient develops

symptoms, or (d) the risk of rupture is high (Anderson, Halperin, Albert, et al., 2013).

Surgical Therapy.

Before elective surgery, the patient is hydrated, and any electrolyte, coagulation, and hematocrit abnormalities are corrected. If the aneurysm has ruptured, emergency surgical intervention is required. With ruptured AAAs, the mortality rate is as high as 90%; the rate of survival is lowest in women and older adult patients (Lo, Bensley, Hamdan, et al., 2013).

The open aneurysm repair involves a large abdominal incision through which the surgeon (a) incises the diseased aortic segment, (b) removes any thrombus or plaque, (c) sutures a synthetic graft to the aorta proximal and distal to the aneurysm, and (d) sutures the native aortic wall around the graft to act as a protective cover (Figure 40-6). If the iliac arteries are also aneurysmal, a bifurcated graft replaces the entire diseased segment. With saccular aneurysms, it may be possible to excise only the bulbous lesion, the artery being repaired by primary closure (suturing the artery together) or by application of an autogenous or synthetic patch graft. *Autotransfusion,* which recycles the patient's own blood, reduces the need for blood transfusions during AAA surgery. (Autotransfusion is discussed in Chapter 33.)

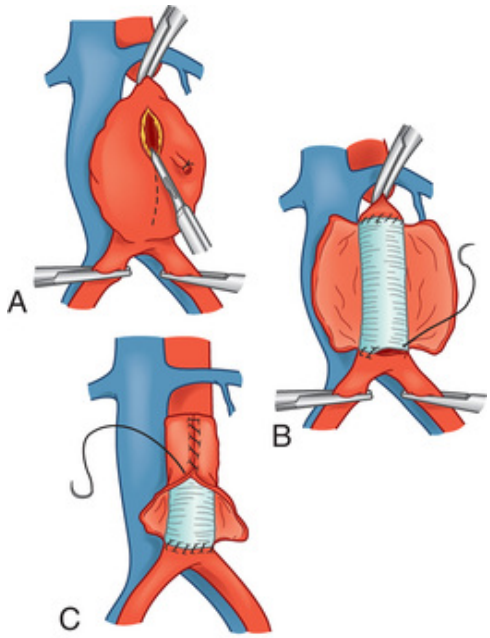

FIGURE 40-6 Surgical repair of an abdominal aortic aneurysm. **A,** Incising the aneurysmal sac. **B,** Insertion of synthetic graft. **C,** Suturing native aortic wall over synthetic graft.

All AAA resections necessitate aortic cross-clamping proximal and distal to the aneurysm. Most resections are performed in 30 to 45 minutes, after which time the clamps are removed and blood flow is restored. If the cross-clamp must be applied above the renal arteries, adequate renal perfusion after clamp removal should be ensured before the abdominal incision is closed. The risk of postoperative renal complications such as acute renal failure increases significantly when surgical repair of AAAs is above the level of the renal arteries.

Endovascular Graft Procedure.

Minimally invasive endovascular aneurysm repair (EVAR) is an alternative to open aneurysm repair. EVAR involves the placement of a sutureless aortic graft into the abdominal aorta inside the aneurysm via femoral artery cutdowns. The graft, a Dacron cylinder consisting of several sections, is supported with multiple rings of flexible wire (Figure 40-7).

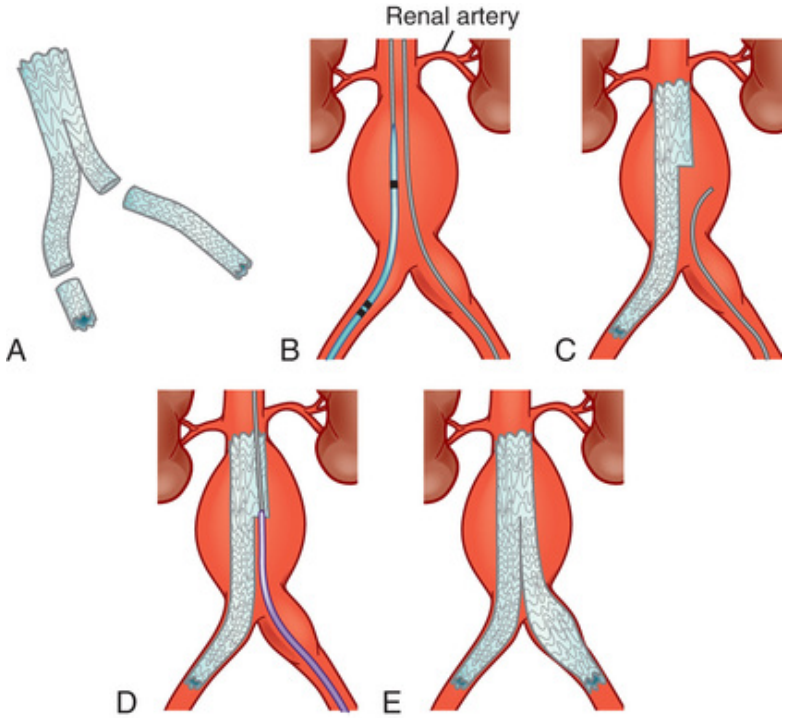

FIGURE 40-7 Bifurcated (two-branched) endovascular stent grafting of an aneurysm. **A,** Insertion of a woven polyester tube (graft) covered by a tubular metal web (stent). **B,** The stent graft is inserted through a large blood vessel (e.g., femoral artery) by a delivery catheter. The catheter is positioned below the renal arteries in the area of the aneurysm. **C,** The stent graft is slowly released (deployed) into the blood vessel. When the stent comes in contact with the blood vessel, it expands to a preset size. **D,** A second stent graft can be inserted in the contralateral (opposite) vessel if necessary. **E,** Fully deployed bifurcated stent graft.

The main section of the graft is bifurcated and delivered through a femoral artery catheter. The second part of the graft is inserted through the opposite femoral artery. When all graft components are in place, they are released (deployed) against the vessel wall by balloon inflation (which creates a circumferential seal). The blood then flows through the endovascular graft, thus preventing further expansion of the aneurysm (Nienaber, Kische, Rousseau, et al., 2013). The aneurysmal wall shrinks over time because the blood is now being diverted through the endograft.

Patients must meet certain eligibility criteria to be candidates for EVAR. These include iliofemoral vessels that will allow for safe graft insertion and vessels of sufficient length and width to support the graft (Park, Azefor, Huang, et al., 2013). The benefits of EVAR include decreased anaesthesia and operative time, limited blood loss, decreased morbidity

and mortality risks, small bilateral groin incisions, more rapid resumption of physical activity, shortened length of hospital stays, quicker recovery, higher patient satisfaction, and reduction in overall costs (Di Minno, Sparadella, Petitto, et al., 2014).

Complications.

EVAR is less invasive than open aneurysm repair. EVAR also has fewer complications, and reports from non-randomized studies suggest that it may reduce early negative outcomes such as long hospital stays, paraplegia, and death (Abraha, Romagnoli, Montedori, et al., 2016). Women have a higher rate of complications after EVAR than do men; however, there are no sex differences in mortality rates (Gloviczki, Huang, Oderich, et al., 2015).

The most common complication is *endoleak,* the seepage of blood back into the old aneurysm. This may result from inadequacy of the seal at either graft end, a tear through the graft fabric, or leakage between overlapping graft segments, and coil embolization (insertion of beads) may be necessary for hemostasis (Park, Azefor, Huang, et al., 2013). Other potential complications include aneurysm growth above or below the graft aneurysm rupture, aortic dissection, bleeding, stent migration, renal artery occlusion caused by stent migration, graft thrombosis, incisional site hematoma, and incisional infection.

Graft dysfunction may necessitate conversion to an open surgical repair. Patients must have regular follow-up visits with their health care provider and routine CT scans for the rest of their lives to monitor for complications (e.g., stent migration, aneurysm recurrence).

A potentially lethal complication in an emergency repair of a ruptured AAA is the development of *intra-abdominal hypertension* with associated *abdominal compartment syndrome.* Persistent intra-abdominal hypertension reduces blood flow to the viscera. Abdominal compartment syndrome is the condition of impaired organ perfusion caused by intra-abdominal hypertension and resulting multisystem organ failure (Rubenstein, Bietz, Davenport, et al., 2015). Intra-abdominal hypertension is confirmed by measurement of the patient's intra-abdominal pressure indirectly through a catheter and transducer system, typically with an indwelling urinary catheter.

Treatment goals include control of situations that lead to intra-abdominal hypertension. Interventions include open (surgical) decompression, percutaneous drainage, and percutaneous drainage combined with infusion of tissue plasminogen activator. Conservative

measures such as intubation, ventilation, patient positioning, gastric decompression, cautious fluid resuscitation, pain management, and temporary hemofiltration are also used.

Nursing Management Aortic Aneurysms and Aortoiliac Disease

Nursing Assessment

The nurse should obtain a thorough history and perform a thorough physical assessment. Because atherosclerosis is a systemic disease, the nurse should look for signs of coexisting cardiac, pulmonary, cerebral, and lower extremity vascular problems. The patient is monitored for signs of aneurysm rupture, such as diaphoresis; pallor; weakness; tachycardia; hypotension; abdominal, back, groin, or periumbilical pain; changes in level of consciousness; or a pulsating abdominal mass.

Establishing baseline data is critical for comparison with later postoperative assessments. The nurse must pay special attention to the character and quality of the patient's peripheral pulses and renal and neurological status. Before surgery, the nurse should mark and document pedal pulse sites (dorsalis pedis and posterior tibial) and any skin lesions on the lower extremities.

Planning

The overall goals for a patient undergoing aortic surgery include (a) normal tissue perfusion, (b) intact motor and sensory function, and (c) no complications related to surgical repair, such as thrombosis, infection, or rupture.

Nursing Implementation

Health Promotion.

To promote overall health, the nurse encourages the patient to reduce CVD risk factors (see Table 36-2), including BP control, tobacco cessation (see Chapter 11), increasing physical activity, and maintaining normal body weight and serum lipid levels. These measures also help ensure continued graft patency after surgical repair.

Acute Intervention.

During the preoperative period, the nurse should provide emotional support and education to the patient and caregiver and thoroughly assess

all body systems. Preoperative teaching includes a brief explanation of the disease process, the planned surgical procedures, preoperative routines, what to expect immediately after surgery (e.g., recovery room, the presence of tubes and drains), and usual postoperative timelines. Specific preoperative routines vary by institution and surgeon. In general, patients undergoing aortic surgery have a bowel preparation (e.g., laxatives, enemas) and skin cleansing with an antimicrobial agent the day before surgery, receive nothing by mouth (NPO status) after midnight the day of surgery, and receive IV antibiotics immediately before the incision is made. If appropriate, a preoperative visit to the intensive care unit may be helpful to the patient and caregiver. Patients with a history of CVD should receive a beta blocker (e.g., metoprolol [Lopressor]) preoperatively to reduce the risk of morbidity and mortality.

After aortic surgery, patients typically go to an intensive care unit for 24 to 48 hours for close monitoring. When the patient arrives in the intensive care unit, various devices are in place, including an endotracheal tube for mechanical ventilation; an arterial line; a central venous pressure (CVP) or pulmonary artery catheter; peripheral IV lines; an indwelling urinary catheter; and, depending on the approach and the surgeon's preference, a nasogastric tube. If the thorax is opened during surgery, chest tubes are in place. The patient needs continuous electrocardiographic and pulse oximetry monitoring. Pain medication is administered via epidural catheter or patient-controlled analgesia. In addition to the usual goals of care for a postoperative patient (e.g., maintaining adequate respiratory function, fluid and electrolyte balance, and pain control; see Chapter 22), the nurse should monitor graft patency and renal perfusion. The nurse should also monitor for and intervene to limit or treat dysrhythmias, infections, and neurological complications. See NCP 40-2, available on the Evolve website for this chapter, for care of the patient with an aneurysm repair or other aortic surgery.

Graft Patency.

An adequate BP is important for maintaining graft patency. Prolonged hypotension may result in graft thrombosis. Administration of IV fluids and blood components (as indicated) is essential for adequate blood flow. CVP readings or pulmonary artery pressures and urinary output are monitored hourly in the immediate postoperative period to help assess the patient's hydration and perfusion status.

Severe hypertension must be prevented because it may cause undue stress on the arterial anastomoses, resulting in leakage of blood or rupture

at the suture lines. Drug therapy with IV diuretics (e.g., furosemide [Lasix]) or IV antihypertensive agents (e.g., nitroprusside [Nipride], esmolol [Brevibloc], and labetalol [Trandate]) may be indicated (Dasgupta, Quinn, Zarnke, et al., 2014).

Cardiovascular Status.

Myocardial ischemia or infarction may occur in the perioperative period because of decreased myocardial oxygen supply or increased myocardial oxygen demands. Cardiac dysrhythmias may occur because of electrolyte imbalances, hypoxemia, hypothermia, or myocardial ischemia. Nursing interventions include continuous electrocardiographic monitoring; frequent electrolyte and arterial blood gas determinations; administration of oxygen, IV antidysrhythmic and antihypertensive medications, and electrolytes as needed; adequate pain control; and resumption of cardiac medications.

Infection.

A prosthetic vascular graft infection is a relatively rare but potentially life-threatening complication. Nursing interventions to prevent infection should include ensuring that the patient receives a broad-spectrum antibiotic as prescribed. The nurse should assess body temperature regularly and report elevations promptly. Laboratory data should be monitored for an elevated white blood cell (WBC) count, which may be the first indication of an infection. The nurse should ensure adequate nutrition and assess the surgical incision for signs of infection (e.g., redness, swelling, drainage). All IV, arterial, and CVP or pulmonary artery catheter insertion sites should be cared for with strict aseptic technique because they are ports of entry for bacteria. Meticulous perineal care for the patient with an in-dwelling urinary catheter is essential to minimize the risk of urinary tract infection. Surgical incisions must be kept clean and dry.

Gastrointestinal Status.

After open abdominal aortic surgery, paralytic ileus may develop as a result of anaesthesia and the handling of the bowel during surgery. The intestines may become swollen and bruised, and peristalsis ceases for variable intervals. A retroperitoneal surgical approach can be used to decrease the risk of bowel complications.

An nasogastric tube may be placed during surgery and arranged with low, intermittent suction to decompress the stomach, prevent aspiration of stomach contents, and decrease pressure on suture lines. The nurse

records the amount and character of the nasogastric output. While the patient is NPO, oral care should be provided frequently. Ice chips or lozenges may be used to soothe a dry or irritated throat. The nurse assesses for bowel sounds; the passing of flatus signals returning bowel function and should be noted. Early ambulation should be encouraged because this promotes the return of bowel functioning. A paralytic ileus rarely lasts beyond the fourth postoperative day.

If the blood supply to the bowel is disrupted during surgery, temporary ischemia or infarction (leading to death) of intestinal tissue may result. Clinical manifestations of this rare but serious complication include absence of bowel sounds, fever, abdominal distension, diarrhea, and bloody stools. If bowel infarction occurs, immediate reoperation is necessary to restore blood flow, with probable resection of the infarcted bowel.

Neurological Status.

Neurological complications can occur after aortic surgery. When the ascending aorta and the aortic arch are involved, the nurse assesses the patient's level of consciousness, pupil size and response to light, facial symmetry, tongue deviation, speech, ability to move upper extremities, and quality of hand grasps (see Chapter 58). When the descending aorta is involved, neuro-vascular assessment of the lower extremities is important. The nurse must record all assessments and report changes from baseline to the physician immediately.

Peripheral Perfusion Status.

The aneurysm's anatomical location indicates the areas of interest related to peripheral perfusion. The nurse should check and record all peripheral pulses hourly for several hours and then routinely, according to institutional policy. When the ascending aorta and aortic arch are involved, the nurse assesses the carotid, radial, and temporal artery pulses. For surgery of the descending aorta, the nurse assesses the femoral, popliteal, posterior tibial, and dorsalis pedis pulses (see Chapter 34, Figure 34-6).

When checking pulses, the nurse should mark the locations with a felt-tip pen so that other medical staff can locate them easily. In some cases, a Doppler ultrasound study may be needed to assess peripheral pulses. The nurse checks skin temperature and colour, capillary refill time, and sensation and movement of the extremities (see Chapter 34).

On occasion, lower extremity pulses may be absent for a short time after surgery because of vasospasm and hypothermia. Decrease in or absence of the pulse accompanied by coolness, pallor, or mottling of the extremity or pain in the extremity may indicate embolization or graft occlusion. The nurse must report these findings to the physician immediately. Graft occlusion necessitates reoperation if identified early. Thrombolytic therapy may also be considered. In some patients, pulses may have been absent before surgery owing to coexistent PAD. It is essential to compare findings with those of the preoperative status to determine the cause of a decrease in or absence of pulse and the proper treatment.

Renal Perfusion Status.

Postoperatively, the patient has an indwelling urinary catheter. In the immediate postoperative period, the nurse records urine output hourly, and urinary output is maintained at 0.5 to 1 mL/kg/hr. The nurse maintains accurate fluid intake and output and records daily weights until the patient resumes a regular diet. CVP and pulmonary artery pressures also provide important information about hydration status. The nurse evaluates renal function by monitoring daily blood urea nitrogen and serum creatinine levels. (For signs and symptoms of acute kidney injury, see Chapter 49.) Irreversible renal failure may occur after aortic surgery, particularly in individuals at high risk for complications (e.g., patients with diabetes). Renal perfusion can decrease as a result of embolization of the aortic thrombus/plaque to one or both renal arteries. This causes ischemia of one or both kidneys. Hypotension, dehydration, prolonged aortic clamping during surgery, or blood loss also can lead to a decrease in renal perfusion.

Ambulatory and Home Care.

The nurse instructs the patient and caregiver to increase activities gradually after the patient returns home. Fatigue, poor appetite, and irregular bowel habits are common. The patient should avoid heavy lifting for 6 weeks after surgery. Any redness, swelling, increased pain, drainage from incisions, or fever greater than 37.8°C should be reported to a health care provider.

The nurse teaches the patient and caregiver to look for changes in colour or warmth of the extremities. Patients and caregivers can learn to palpate peripheral pulses to assess changes in their quality.

Sexual dysfunction in male patients is common after aortic surgery. Preoperatively, the nurse should document baseline sexual function and recommend counselling as appropriate. A referral to an urologist may be useful if erectile dysfunction occurs.

Evaluation

Expected outcomes for the patient who undergoes aortic surgery include the following:

- Patent arterial graft with adequate distal perfusion
- Adequate urine output
- No signs of infection

Aortic Dissection

Aortic dissection, often misnamed "dissecting aneurysm," is not a type of aneurysm. Rather, dissection (tearing of the inner layer of the vessel) results from the creation of a false lumen (between the intima and the media) through which blood flows (see Figure 40-5). Classification is based on anatomical location (ascending versus descending aorta) and duration of onset (acute versus chronic). Approximately 60% to 70% of aortic dissections involve the ascending aorta and are acute in onset (Copstead & Banasik, 2013). Acute aortic dissections (i.e., diagnosed within 14 days of symptom onset) carry a mortality rate as high as 1% per hour (Estrera, Azam, Shalhub, et al., 2015). Chronic dissections almost exclusively involve the descending aorta.

Etiology and Pathophysiology

Most experts attribute nontraumatic aortic dissection to the degeneration of the elastic fibres in the medial layer. Chronic hypertension accelerates the degradation process. Aortic dissection is believed to arise from an intimal tear. Intimal tears typically occur in areas with the greatest rate of rise of BP: for example, immediately above the aortic valve and just distal to the left subclavian artery. As the heart contracts, each systolic pulsation causes increased pressure on the damaged area, which further increases the dissection. Extension of the dissection may cut off blood supply to critical areas such as the brain, kidneys, spinal cord, and extremities. The

false lumen may remain patent, become thrombosed (clotted), rejoin the true lumen by way of a distal tear, or rupture.

Aortic dissection affects two to five times more men than women and occurs mostly in the sixth and seventh decades of life (Conrad & Cambria, 2014). Approximately half of all dissections in women younger than 40 years occur during pregnancy (Lo, Bensley, Hamdan, et al., 2013). Predisposing factors include age, aortic diseases (e.g., aortitis, coarctation, arch hypoplasia), atherosclerosis, blunt or iatrogenic trauma, tobacco use, cocaine or methamphetamine use, congenital heart disease (e.g., bicuspid aortic valve), connective tissue disorders (e.g., Marfan or Ehlers-Danlos syndrome), family history, history of heart surgery, male sex, pregnancy, and poorly controlled hypertension (Erbel, Aboyans, Boileau, et al., 2014). Younger patients are more likely to have a bicuspid aortic valve or Marfan syndrome, to have undergone prior aortic valve surgery, or to have suffered recent trauma (Wojnarski, Svensson, Roselli, et al., 2015).

Clinical Manifestations

The majority of patients with an acute ascending aortic dissection report sudden, severe onset of excruciating chest pain, back pain, or both, radiating to the neck or shoulders. The pain is frequently described as "sharp" and "worst ever" followed less frequently by "tearing" or "ripping." Patients with acute descending aortic dissection are more likely to report pain in their back, abdomen, or legs. Dissection pain can be differentiated from MI pain, whose onset is more gradual and of increasing intensity. As the dissection progresses, pain may migrate. Older patients are less likely to have abrupt onset of chest or back pain (in their back, abdomen, or legs) and more likely to have hypotension and vague symptoms. Some patients have a painless aortic dissection, which emphasizes the importance of the physical examination (Wojnarski, Svensson, Roselli, et al., 2015).

If the aortic arch is involved, the patient may exhibit neurological deficits, such as altered level of consciousness, weakened or absence of carotid and temporal pulses, and dizziness or syncope. An ascending aortic dissection usually produces some degree of disruption in blood flow in the coronary arteries and aortic valve insufficiency. The patient may develop angina, MI, and a new high-pitched, diastolic heart murmur. If severe enough, these complications can result in left ventricular failure with the development of dyspnea, orthopnea, and pulmonary edema. When either subclavian artery is involved, radial, ulnar, and brachial pulse

quality and BP readings may be different between the left and the right arms. As the dissection progresses down the aorta, the abdominal organs and lower extremities demonstrate evidence of decreased tissue perfusion.

Complications

A severe and life-threatening complication of an acute ascending aortic dissection is cardiac tamponade, which occurs when blood from the dissection leaks into the pericardial sac. Clinical manifestations of tamponade include hypotension, narrowed pulse pressure, jugular venous distension, muffled heart sounds, and pulsus paradoxus (see Chapter 39). The aorta may rupture because it is weakened by the dissection. Hemorrhage may occur into the mediastinal, pleural, or abdominal cavities. Aortic rupture typically results in exsanguination and death. Dissection can lead to occlusion of the blood supply to vital organs. Symptoms of spinal cord ischemia range from weakness and decreased sensation to complete lower extremity paralysis. Renal ischemia can lead to renal failure. Manifestations of abdominal (mesenteric) ischemia include abdominal pain, decreased bowel sounds, altered bowel function, and bowel necrosis.

Diagnostic Studies

Diagnostic studies to detect aortic dissection are similar to those performed for suspected aneurysms (Table 40-6). A chest radiograph may show a widening of the mediastinum and pleural effusion. Three-dimensional CT scanning, MRI, and transesophageal echocardiography are equally reliable for the diagnosis of acute aortic dissection (Copstead & Banasik, 2013). A CT scan or MRI can provide more detailed information on the presence and severity of the dissection. Transesophageal echocardiography is preferred in very unstable patients or those with contraindications to CT or MRI (e.g., those with metal implants, allergies to contrast material) (Erbel, Aboyans, Boileau, et al., 2014).

COLLABORATIVE CARE
Aortic Dissection

Diagnostic	Collaborative Therapy
• Health history and physical examination • Chest radiography • CT scan with three-dimensional reconstruction • Electrocardiography • Magnetic resonance imaging • Transesophageal echocardiography	• Bed rest • Blood transfusion (if necessary) • Pain relief with opioids
	Drug Therapy (see Table 35-8)
	• ACE inhibitors • IV β-blockers (e.g., esmolol [Brevibloc]) • IV calcium channel blockers • Sodium nitroprusside (Nipride)
	Surgical Therapy
	• Surgical aortic resection and repair • Endovascular aortic dissection repair

ACE, angiotensin-converting enzyme; *CT,* computed tomography; *IV,* intravenous.

Collaborative Care

Patients with acute aortic dissection are managed in the intensive care unit. The initial goals of therapy for acute aortic dissection without complications are heart rate and BP control and pain management. Heart rate and BP control reduces stress on the aortic wall by reducing systolic BP and myocardial contractility (see Table 40-6). An IV beta-adrenergic blocker (e.g., esmolol [Brevibloc]) is titrated to effect a target heart rate of 60 beats/minute or less. A calcium channel blocker (e.g., diltiazem [Cardizem], verapamil [Calan]) can be used to lower heart rate if a beta-adrenergic blocker is contraindicated. An IV angiotensin-converting enzyme inhibitor (e.g., enalapril [Vasotec]) may also be used. Reducing the heart rate, BP, and myocardial contractility limits extension of the dissection. Morphine is the preferred analgesic because it decreases sympathetic nervous system stimulation and relieves pain. Supportive treatment for an acute aortic dissection serves as a bridge to surgery.

Conservative Therapy.

A patient with an acute descending aortic dissection without complications can be treated conservatively. Supportive treatment includes pain relief and BP control. Conservative treatment includes pain relief, heart rate and BP control, and CVD risk factor modification.

Endovascular Dissection Repair.

Endovascular repair of chronic descending aortic dissection is an effective treatment option (Antoniou, Georgiadis, Antoniou et al., 2013; Park, Azefor, Huang, et al., 2013). Endovascular repair is the standard modality to treat acute descending aortic dissections with complications (e.g., hemodynamic instability, peripheral ischemia) (Park, Azefor, Huang, et al., 2013). Endovascular dissection repair is similar to EVAR. However, a temporary lumbar drain may be inserted for cerebro-spinal fluid removal to reduce spinal cord edema and help prevent paralysis (Nienaber, Kische, Rousseau, et al., 2013).

Surgical Therapy.

An acute ascending aortic dissection is considered a surgical emergency. Otherwise, surgery is indicated when drug therapy is ineffective or when complications (e.g., heart failure) occur. Because the aorta is fragile after dissection, surgery is delayed for as long as possible to allow time for edema to decrease and to enable clotting of the blood in the false lumen. Surgery involves resection of the aortic segment containing the intimal tear and replacement with a synthetic graft. Even with prompt surgical intervention, the in-hospital rate of mortality from acute aortic dissection remains high. Women experience poorer surgical outcomes and higher mortality rates than do men (Lo, Bensley, Hamdan, et al., 2013). Causes of in-hospital mortality include aortic rupture, mesenteric ischemia, sepsis, and multiorgan failure.

Nursing Management Aortic Dissection

Preoperatively, nursing management includes keeping the patient in bed in a semi-Fowler's position and maintaining a quiet environment. These measures help to keep the systolic BP at the lowest possible level that maintains vital organ perfusion (typically between 110 and 120 mm Hg); the desired outcome is to maintain a mean arterial pressure of greater than 65 mm Hg. In order to maintain the mean arterial pressure, the minimal diastolic pressure ought to be approximately 44 mm Hg (Dasgupta, Quinn, Zarnke, et al., 2014). Opioids and sedatives are administered as ordered. The nurse must manage pain and anxiety for patient comfort and because these symptoms can cause elevations in the systolic BP.

Administration of IV antihypertensive agents requires careful supervision. This entails continuous electrocardiographic and intra-arterial BP monitoring (see Chapters 35 and 68). The nurse should monitor vital signs frequently, sometimes as often as every 2 to 3 minutes, until target BP is reached. The nurse should observe for changes in peripheral pulses and signs of increasing pain, restlessness, and anxiety. If the arteries branching off the aortic arch are involved, decreased cerebral blood flow may alter the patient's level of consciousness. Postoperative care is similar to that after aortic aneurysm repair (see the "Nursing Management: Aortic Aneurysms and Aortoiliac Disease" section earlier in this chapter, and NCP 40-1 on the Evolve website).

In preparation for discharge, the nurse should focus on patient and caregiver teaching. All patients with a history of aortic dissection, regardless of anatomic location or treatment modality, require long-term medical therapy to control BP. Patients need to understand that antihypertensive drugs must be taken daily for the rest of their lives. Beta-adrenergic blockers (e.g., metoprolol [Lopressor]) are used to control BP and decrease myocardial contractility. It is important that patients understand the drug regimen and potential adverse effects (e.g., dizziness, depression, fatigue, erectile dysfunction). The nurse must tell the patient to discuss any adverse effects with the health care provider before discontinuing the drug. Follow-up with regularly scheduled MRI or CT is essential. The most common cause of death in long-term survivors is aortic rupture from redissection or aneurysm formation. The nurse must instruct patients that, if the pain or other symptoms return, they should contact emergency medical services for immediate care.

Venous Disorders

Phlebitis

Phlebitis is the inflammation (e.g., redness, tenderness, warmth, mild edema) of a superficial vein without the presence of a thrombus (Mackman, 2012). It occurs in about 65% of all patients receiving IV therapy. It is rarely infectious and usually resolves quickly with removal of the IV catheter.

Venous Thrombo-embolism

Venous thrombo-embolism (VTE), also known as *venous thrombosis,* is a condition in which a thrombus forms in association with inflammation of the vein. It is the most common disorder of the veins and is classified as either superficial vein thrombosis or deep vein thrombosis. **Superficial vein thrombosis (SVT)** is the formation of a thrombus in a superficial vein, usually the greater or lesser saphenous vein. **Deep vein thrombosis (DVT)** is a disorder involving a thrombus in a deep vein, most commonly the iliac and femoral veins (Copstead & Banasik, 2013). VTE represents the spectrum of pathology from DVT to pulmonary embolism (Cosmi, 2015; Table 40-7). (Pulmonary embolism is discussed in Chapter 30.)

TABLE 40-7

COMPARISON OF SUPERFICIAL VEIN THROMBOSIS AND VENOUS THROMBO-EMBOLISM

Characteristic	Superficial Vein Thrombosis	Venous Thrombo-embolism
Usual location	Typically, superficial leg veins (e.g., varicosities); occasionally, superficial arm veins.	Deep veins of arms (e.g., axillary, subclavian), legs (e.g., femoral), and pelvis (e.g., iliac or inferior or superior vena cava) and pulmonary system.
Clinical findings	Tenderness, rubour, warmth, pain, inflammation and induration along the course of the superficial vein. Vein appears as palpable cord. Edema rarely occurs.	Tenderness to pressure over involved vein, induration of overlying muscle, venous distension. Edema. Mild to moderate pain possible. Deep rubour in area caused by venous congestion. Systemic temperature possibly greater than 38°C. Note: Some patients may have no obvious physical changes in the affected extremity.
Sequelae	If left untreated, clot may extend to deeper veins and VTE may occur.	Embolization to lungs (pulmonary embolism) may occur and may result in death.* Pulmonary hypertension and post-thrombotic syndrome with or without venous leg ulceration may develop.

*See Chapter 30 for clinical findings related to pulmonary embolism.

IV, intravenous; *VTE*, venous thrombo-embolism.

SVT is generally a benign disorder. However, nearly 25% of patients with SVT also have VTE at the time of diagnosis. There is a risk for extension of the clot to deeper veins if the thrombus involves the superficial femoral vein or is near the saphenofemoral junction (Mackman, 2012).

Etiology

Three important factors (called **Virchow's triad**) in the etiology of venous thrombosis are (a) venous stasis, (b) damage of the endothelium (inner lining of the vein), and (c) hypercoagulability of the blood (Figure 40-8). The patient at risk for the development of venous thrombosis usually has conditions predisposing to these three disorders (Table 40-8).

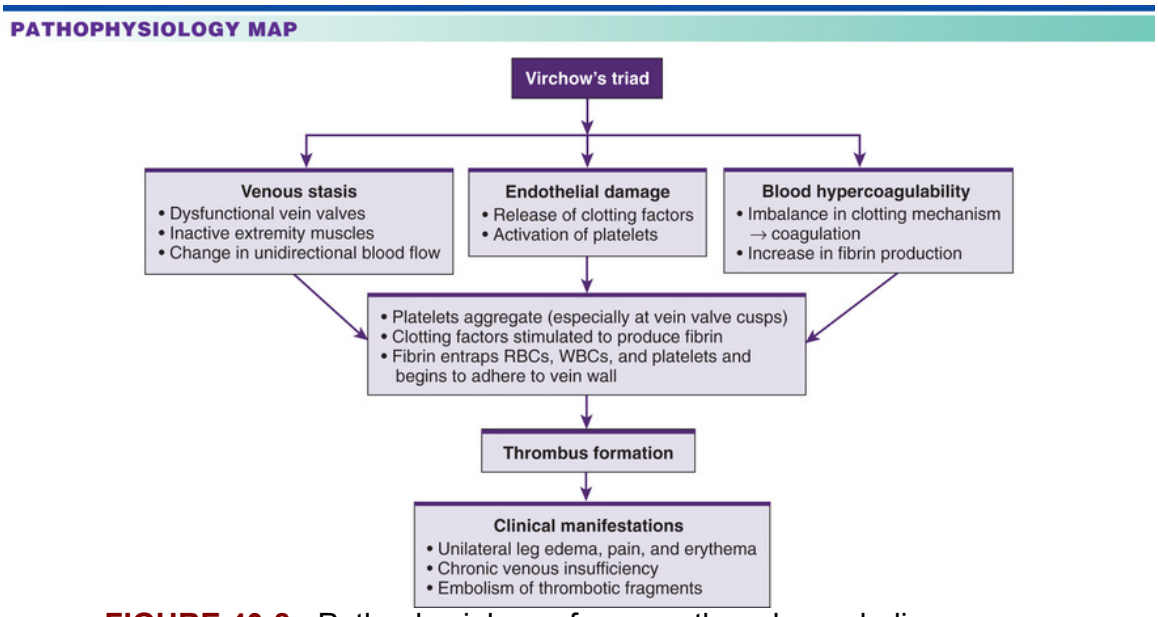

FIGURE 40-8 Pathophysiology of venous thrombo-embolism. *RBCs,* red blood cells; *WBCs,* white blood cells.

TABLE 40-8
RISK FACTORS FOR VENOUS THROMBO-EMBOLISM

Venous Stasis • Advanced age • Atrial fibrillation • Bed rest • Chronic heart failure • Fractured leg or hip • Long trips without adequate exercise • Obesity • Orthopedic surgery (especially lower extremity) • Pregnancy and postpartum period • Prolonged immobility • Spinal cord injury or limb paralysis • Stroke • Varicose veins **Hypercoagulability of Blood** • Antiphospholipid antibody syndrome • Antithrombin III deficiency • Dehydration or malnutrition • Elevated (clotting) factor VIII or lipoprotein (a) level • Erythropoiesis-stimulating drugs (e.g., epoetin alfa [Eprex]) • Factor V Leiden or prothrombin gene mutation • High altitudes • Hormone replacement therapy	• Hyperhomocysteinemia • Malignancies (especially breast, brain, hepatic, pancreatic, and gastro-intestinal) • Nephrotic syndrome • Oral contraceptives, especially in women >35 yr of age who use tobacco • Polycythemia vera • Pregnancy and postpartum period • Protein C deficiency • Protein S deficiency • Sepsis • Severe anemia • Tobacco use **Endothelial Damage** • Abdominal and pelvic surgery (e.g., gynecological or urological surgery) • Caustic or hypertonic intravenous medications • Fractures of pelvis, hip, or leg • History of previous venous thrombo-embolism (VTE) • In-dwelling, peripherally inserted central vein catheter • Intravenous drug abuse • Trauma

Venous Stasis.

Normal blood flow in the venous system depends on the action of muscles in the extremities and the functional adequacy of venous valves, which allow unidirectional flow. *Venous stasis* occurs when the valves are dysfunctional or the muscles of the extremities are inactive. Venous stasis occurs more frequently in people who are obese or pregnant, have heart failure or atrial fibrillation, have been on long trips without regular exercise, have a prolonged surgical procedure, or are immobile for long periods (e.g., with spinal cord injury, fractured hip, limb paralysis) (Reitsma, Versteeg, & Middeldorp, 2012).

Endothelial Damage.

Damage to the endothelium of the vein may be caused by direct (e.g., surgery, intravascular catheterization, trauma, fracture, burns) or indirect (chemotherapy, vasculitis, sepsis, hyperhomocysteinemia, diabetes) injury to the vessel (Anderson, Halperin, Albert, et al., 2013). Damaged endothelium stimulates platelet activation and initiates the coagulation cascade. This results in decreased fibrinolytic capabilities and predisposes the patient to thrombus development.

Hypercoagulability of Blood.

Hypercoagulability of blood occurs in many hematological disorders, particularly polycythemia, severe anemias, malignancies (e.g., cancers of the breast, brain, pancreas, and gastro-intestinal tract), nephrotic syndrome, antithrombin III deficiency, elevated lipoprotein (a) levels, elevated (clotting) factor VIII levels, hyperhomocysteinemia, protein C deficiency, and protein S deficiency (Rattan, Jones, & Namias, 2015). A patient with sepsis is predisposed to hypercoagulability because of endotoxins that are released. Some medications (e.g., corticosteroids, estrogens) predispose a patient to thrombus formation.

Women of child-bearing age who take estrogen-based oral contraceptives, as well as postmenopausal women receiving oral hormone replacement therapy are at increased risk for VTE (Reitsma, Versteeg, & Middeldorp, 2012). Women who use oral contraceptives and tobacco double their risk because of the vasoconstricting effects of nicotine. Smoking causes hypercoagulability by increasing plasma fibrinogen and homocysteine levels and activating the intrinsic coagulation pathway. Women who use tobacco and oral contraceptives, are older than 35 years, and have a family history of VTE are at extremely high risk for VTE. In women with known thrombophilia, the benefits of hormone replacement

therapy, tamoxifen (Nolvadex-D), or raloxifene (Evista) must be weighed against the risk for VTE (Rattan, Jones, & Namias, 2015). Transdermal or intranasal hormone replacement therapy may be safer than oral hormone replacement therapy with respect to risk for VTE (Rockman, Maldinado, Jacobowitz, et al., 2012).

Pathophysiology

Localized platelet aggregation and fibrin entrap RBCs, WBCs, and more platelets to form a thrombus. A frequent site of thrombus formation is the valve cusps of veins, where venous stasis occurs. As the thrombus enlarges, increased numbers of blood cells and fibrin collect behind it, producing a larger clot with a "tail" that eventually occludes the lumen of the vein.

If a thrombus only partially occludes the vein, endothelial cells cover the thrombus and stop the thrombotic process. If the thrombus does not become detached, it undergoes lysis or becomes firmly organized and adherent within 5 to 7 days. Organized thrombi may detach and result in emboli. Turbulence of blood flow is a major factor contributing to embolization. A thrombus can become an embolus that flows through the venous circulation to the heart and lodges in the pulmonary circulation, becoming a pulmonary embolism (see Chapter 30, Figure 30-11).

Superficial Vein Thrombosis

Clinical Manifestations.

The patient with SVT may have a palpable, firm, subcutaneous cordlike vein (see Table 40-7). The area surrounding the vein may be tender to the touch, reddened, and warm (Figure 40-9). A mild systemic temperature elevation and leukocytosis may be present. Extremity edema may or may not occur. The most common cause of upper extremity SVT is vein trauma caused by cannulation of a vein or IV therapy. It is more likely to occur if the catheter is located in a small vein or is left in place for more than 48 hours or if the IV solutions administered are caustic or hyperosmolar (Scott, Mahdi, & Alikhan, 2015).

FIGURE 40-9 Superficial vein thrombosis of the hand following intravenous therapy. Source: Grieg, J. D., & Garden, O. J. (1996). *Color atlas of surgical diagnosis.* London: Times Mirror International.

In rare cases, infectious or suppurative SVT occurs at an IV site. Unfortunately, there may not be any local signs or symptoms. A high-grade fever or pulmonary embolism may be the first indication of infectious SVT (Cosmi, 2015). An elevated WBC count, positive blood cultures, or both, may also be present. The most common causative organism is *Staphylococcus aureus.*

Risk factors for SVT include increased age; pregnancy; obesity; malignancy; thrombophilia; estrogen therapy; recent sclerotherapy (e.g., treatment for varicose veins); long-distance travel; and a history of CVI, SVT, or VTE (van Langevelde, Lijfering, Rosendaal, et al., 2011). SVT also can occur in persons with endothelial alterations (e.g., Buerger's disease). It also may be unprovoked.

Collaborative Care.

The initial treatment of infusion-related SVT involves the immediate removal of the IV catheter. If edema is present, the extremity should be elevated to promote reabsorption of fluid from the interstitial space into the vasculature. The application of warm, moist heat may help relieve pain and inflammation. Oral NSAIDs (e.g., diclofenac [Voltaren]), topical NSAIDs (e.g., diclofenac gel), or topical heparin gels are used to treat symptoms for a maximum of 2 weeks (Di Nisio & Middeldorp, 2014). Suppurative infusion-related SVT typically necessitates drainage of the abscess, excision of the affected tissue, and administration of systemic antibiotics (Di Nisio & Middeldorp, 2014). Systemic anticoagulants are not recommended for infusion-related SVT (Scott, Mahdi, & Alikhan, 2015).

Duplex ultrasonography is used to confirm the diagnosis (clot with a 5-cm diameter or larger) and to rule out clot extension to a deep vein

(Kearon, Akl, Comerota, et al., 2012). For patients with a lower extremity SVT involving the greater saphenous vein or the sapheno-femoral junction, initial treatment consists of low-molecular-weight heparin (LMWH) or unfractionated heparin, followed by warfarin (Scott, Mahdi, & Alikhan, et al., 2015). Use of oral NSAIDs in combination with anticoagulants is not recommended. If the SVT affects a very short vein segment and is not near the sapheno-femoral junction, anticoagulants are not necessary, and oral or topical NSAIDs are appropriate. Additional interventions for SVT include educating the patient to wear graduated compression stockings and perform mild exercise such as walking.

Compression helps reduce edema, and walking increases endogenous fibrinolysis (Pavon, Adam, Razouki, et al. 2016; Rattan, Jones, & Namias. 2015).

Venous Thrombo-embolism

Clinical Manifestations.

Patients with lower extremity VTE may or may not have unilateral leg edema, pain, tenderness with palpation, dilated superficial veins, a sense of fullness in the thigh or the calf, paresthesias, warm skin, erythema, or a systemic temperature greater than 38°C (see Table 40-7). A positive Homans sign (pain on forced dorsiflexion of the foot when the leg is raised) is a classic sign but very unreliable because false positive findings are common (Whitehead, Stephen, & Stansby, 2015). If the inferior vena cava is involved, the legs may be edematous and cyanotic. About 5% to 10% of VTEs involve the upper extremity veins and may extend into the internal jugular vein or superior vena cava (Kearon, Akl, Comerota, et al., 2012). If the superior vena cava is involved, symptoms may occur in the arms, neck, back, and face. Diagnosis of an initial VTE is based on clinical assessment combined with D-dimer testing and duplex ultrasonography (Bates, Jaeschke, Stevens, et al., 2012).

Complications.

The most serious complications of VTE are pulmonary embolism, post-thrombotic syndrome, and phlegmasia cerulea dolens (described later in this chapter). Pulmonary embolism is a potentially life-threatening complication of VTE (see Chapter 30).

Post-thrombotic syndrome occurs in 20% to 50% of patients with VTE despite adequate anticoagulant therapy. It results from chronic venous hypertension caused by valvular destruction (from inflammation and

scarring), stiffness and noncompliance of vein walls, and persistent venous obstruction. Symptoms include pain, aching, sensation of heaviness, swelling, cramps, itching, and tingling (Crumley, 2011; Henke & Comerota, 2011). Clinical signs include persistent edema, increased pigmentation, eczema, secondary varicosities, and *lipodermatosclerosis* (Figure 40-10). Venous ulceration can occur with severe post-thrombotic syndrome. Manifestations of post-thrombotic syndrome typically begin within 2 years of a VTE (Crumley, 2011; Henke & Comerota, 2011). Risk factors include persistent leg symptoms 1 month after VTE, location of VTE near the iliofemoral junction, extensive VTE, recurrent VTE, obesity, older age, and female sex. Sequential compression devices may be used for patients with severe post-thrombotic syndrome (Cohen, Akl, & Kahn, 2012).

FIGURE 40-10 Lipodermatosclerosis. Skin on lower leg becomes scarred, and the leg becomes tapered like an "inverted bottle." Hallmark signs of lipodermatosclerosis are leathery skin, brown discoloration, hyperpigmentation and hypopigmentation, and circumferential or near-circumferential scarring and shrinking of the extremity. Source: From Etufugh, C. N., & Phillips, T. J. (2007). Venous ulcers. *Clinics in Dermatology, 25*(1), 125. doi:10.1016/j.clindermatol.2006.09.004.

Phlegmasia cerulea dolens (swollen, blue, painful leg), a very rare complication, may develop in the advanced stages of cancer. It results from one or more severe lower extremity VTEs that involve the major leg veins, causing near-total occlusion of venous outflow. Patients typically experience sudden, massive swelling, deep pain, and intense cyanosis of the extremity. If untreated, the venous obstruction causes arterial occlusion and gangrene and necessitates amputation.

Diagnostic Studies.

Table 40-9 lists the various diagnostic studies used to determine the site or location and extent of a VTE.

TABLE 40-9
DIAGNOSTIC STUDIES
Venous Thrombo-embolism*

Study	Description and Abnormal Findings
Blood Laboratory Studies	
ACT, aPTT, INR, bleeding time, Hb, Hct, platelet count	Alterations if patient has underlying blood dyscrasia (e.g., increased Hb and Hct in patient with polycythemia).
D-dimer	Fragment of fibrin formed as result of fibrin degradation and clot lysis. Elevated results suggest venous thrombo-embolism (VTE). *Normal results:* 3.0 mmol/L (<50 ng/mL)
Fibrin monomer complex	Forms when concentration of thrombin exceeds that of antithrombin. Presence is evidence of thrombus formation and suggests VTE. *Normal results:* <10 mg/dL (<10 mcg/mL)
Noninvasive Venous Studies	
Venous compression ultrasonography	Evaluation of deep femoral, popliteal, and posterior tibial veins. *Normal finding:* Veins collapse with application of external pressure *Abnormal finding:* Veins fail to collapse with application of external pressure; failure to collapse suggests a thrombus
Duplex ultrasonography	Combination of compression ultrasonography with spectral and colour flow Doppler study. Veins are examined for respiratory variation, compressibility, and intraluminal filling defects to help determine location and extent of thrombus (most widely used test to diagnose VTE).
Invasive Venous Studies	
Computed tomography venography (CTV)	Spiral CT used to evaluate veins in the pelvis, thighs, and calves after injection of venous phase contrast material; involves less contrast material than does traditional venography; may be performed simultaneously with CT angiography of pulmonary vessels for patients being evaluated for VTE.
Magnetic resonance venography	MRI with specialized software to evaluate blood flow through veins; can be performed with or without contrast material; highly accurate for pelvic and proximal veins; less accurate for calf veins; can distinguish acute and chronic thrombus.
Contrast venography (phlebography)	Radiographic determination of location and extent of clot with contrast media to outline filling defects; identifies the presence of collateral circulation; once the "gold standard" of invasive venous studies but currently rarely performed

*See Table 30-25 for diagnostic studies for pulmonary embolism.

ACT, activated clotting time; *aPTT,* activated partial thromboplastin time; *CT,* computed tomography; *Hb,* hemoglobin; *Hct,* hematocrit; *INR,* international normalized ratio; *MRI,* magnetic resonance imaging.

Collaborative Care

Prevention and Prophylaxis.

VTE prophylaxis is a core measure of quality health care in hospitalized patients undergoing surgery. In addition, it is recommended that hospitals

have a formal, hospital-wide thromboprophylaxis policy that addresses VTE prevention on admission of all adult patients.

In patients at risk for VTE, various interventions are used. Their use is based on such factors as bleeding and thrombosis risk, past medical history, current medications, medical diagnoses, scheduled procedures, and patient preferences (Kahn, Lim, Dunn, et al., 2012). Early and aggressive mobilization based on the patient's condition is the easiest and most cost-effective method to decrease VTE risk (Christakou & Zakyntinos, 2014). Patients on bed rest need to change position every 2 hours. Unless it is contraindicated, the nurse should teach patients to flex and extend their feet, knees, and hips every 2 to 4 hours while awake. Patients who are able to get out of bed need to be in a chair for meals and ambulate at least four to six times per day as tolerated. The nurse must reinforce the importance of these measures to the patient and caregiver. Research has shown that patients want additional information on VTE and prevention of VTE (Christakou & Zakyntinos, 2014). Early and frequent ambulation is sufficient prophylaxis for low-risk patients who are undergoing minor surgical procedures and have no additional VTE risk factors (Parmenter, Dieberg, Phipps, et al., 2015).

Graduated compression (antiembolism) stockings (e.g., thrombo-embolic deterrent hose) are a part of VTE prevention in hospitalized patients. When fitted and worn properly, these stockings increase venous blood flow velocity, prevent venous wall dilation, improve venous valve function, and stimulate endothelial fibrinolytic activity (Pavon, Adam, Razouki, et al., 2016). The patient's legs must be measured accurately, the stocking size and length (thigh-high or knee-high) must be the correct size, the stockings should be applied properly, and the patient and caregiver need to be educated regarding proper use (Pavon, Adam, Razouki, et al., 2016). “Correct use” means the toe hole is under the toes, the heel patch is over the heel, the thigh gusset is on the inner thigh (thigh length only), and there are no wrinkles. The stockings are not to be rolled down, cut, or otherwise altered. Venous return is impeded by the stockings if the top elastic band is too tight or the stockings are rolled down. This actually increases the risk of VTE and skin damage (Li, Yuan, & Qi, 2012). The nurse should monitor patients regularly to ensure that the stockings are being worn properly, the size is still appropriate, and peripheral perfusion is adequate (Pavon, Adam, Razouki, et al., 2016). If the patient's legs are swollen after surgery, remeasurement is necessary, and a larger stocking size may be needed. The nurse must thoroughly assess the skin with the

stockings off at least once a day or more frequently, depending on the patient's condition.

Sequential compression devices (SCDs) are inflatable garments wrapped around the legs that apply intermittent external pressure to the lower extremities. They are often used in combination with graduated compression stockings (Li, Yuan, & Qi, 2012). Benefits are similar to those provided by stockings. As with graduated compression stockings, the nurse must accurately measure the extremities to ensure correct fit. SCDs do not provide effective VTE prophylaxis if they are not applied correctly, if the fit is incorrect, or if the patient does not wear the device continuously except during bathing, skin assessment, and ambulation (Li, Yuan, & Qi, 2012). SCDs are not to be worn when a patient has an active VTE because of the risk of pulmonary embolism. Preventive anticoagulation is recommended for many patients; the recommendation depends on the patient's risk for VTE (Schulman, 2014). VTE prevention is enhanced if SCDs are used along with anticoagulation.

Drug Therapy.

Anticoagulants are used routinely for VTE prevention and treatment. The regimen depends on the patient's VTE risk. The goal of anticoagulant therapy for VTE prophylaxis is to prevent clot formation. The goals for treatment of a confirmed VTE are to prevent new clot development, prevent spread of the clot, and prevent embolization.

Three major classes of anticoagulants are available: (a) vitamin K antagonists, (b) thrombin inhibitors (both indirect and direct), and (c) factor Xa inhibitors (Ageno, Gallus, Wittkowsky, et al., 2012; Table 40-10). The use of ASA (Aspirin) alone for VTE thromboprophylaxis is not recommended for any patient group (Brotons, Benamouzig, Filipiak et al., 2015). Anticoagulant therapy does not dissolve the clot. Lysis of the clot begins spontaneously through the body's intrinsic fibrinolytic system (see Chapter 32).

TABLE 40-10

DRUG THERAPY
Anticoagulant Therapy

Anticoagulant	Drug	Route of Administration	Comments
Vitamin K antagonists	Warfarin (Coumadin)	PO	INR is used for monitoring therapeutic levels. Drugs are administered at the same time each day. Variations of certain genes (e.g., *CYP2CP, VKORC1*) may influence response to the drug. Antidote: Vitamin K
Thrombin Inhibitors: Indirect			
Unfractionated heparin	Heparin sodium	Continuous IV Intermittent IV Subcut	Therapeutic effects measured at regular intervals by the aPTT or ACT. CBC is monitored at regular intervals. If administered subcutaneously, drug should be injected deep into subcutaneous tissue (preferably into the abdominal fatty tissue or above the iliac crest), inserting the entire length of the needle. Skinfold is held during injection but released before needle is removed. The nurse should not aspirate, not inject intramuscularly, and not rub site after injection. Sites should be rotated. Antidote: Protamine
Low-molecular-weight heparin (LMWH)	Enoxaparin (Lovenox) Tinzaparin (Innohep) Dalteparin (Fragmin) Nadroparin (Fraxiparine)	Subcut	Routine coagulation tests typically not required. CBC is monitored at regular intervals. Air bubble should not be expelled before drug is administered subcutaneously. The nurse should follow remaining administration guidelines as described for unfractionated heparin. Dosage should be reduced in patients with renal impairment. Extreme caution should be used in patients with a history of HIT. *Antidote*: Protamine
Thrombin Inhibitors: Direct			
Hirudin derivatives	Lepirudin (Refludan)	IV or subcut IV	Therapeutic effect measured by ACT or aPTT. Used in patients with HIT when anticoagulation is still required. *Antidote*: None
	Bivalirudin (Angiomax)	IV or subcut	
Synthetic thrombin inhibitors	Argatroban	IV	Therapeutic effect measured by aPTT. Used in patients at risk for or with HIT. *Antidote:* None
	Dabigatran (Pradaxa)	Subcut	
Factor Xa Inhibitors			
	Fondaparinux (Arixtra)	Subcut and IV	Routine coagulation tests not required. CBC and creatinine are monitored at regular intervals. Air bubble should not be expelled before drug is administered. The nurse should follow remaining administration guidelines as described for unfractionated heparin. Approved for VTE prophylaxis and treatment. For patients undergoing surgery, initial dose should be given no earlier than 6 hr postoperatively. Should be administered with caution in elderly patients and patients with impaired renal function. May cause thrombo-cytopenia. If uncontrollable bleeding occurs, treatment with recombinant factor

Anticoagulant	Drug	Route of Administration	Comments
	Rivaroxaban (Xarelto)	PO	VIIa may be effective. *Antidote*: None

ACT, activated clotting time; *aPTT,* activated partial thromboplastin time; *CBC,* complete blood count; *HIT,* heparin-induced thrombo-cytopenia; *INR,* international normalized ratio; *IV,* intravenous; *PO*, oral; *Subcut,* subcutaneous*; VTE,* venous thrombo-embolism.

Vitamin K Antagonists.

The oral anticoagulant for long-term or extended anticoagulation is warfarin, a vitamin K antagonist. Warfarin inhibits activation of the vitamin K–dependent coagulation factors II, VII, IX, and X, as well as the anticoagulant proteins C and S (Schulman, 2014). (Figure 32-4 displays the clotting pathways, and clotting factors are listed in Table 32-3.) Warfarin begins to take effect in 48 to 72 hours. It then takes several more days to achieve a maximum effect. Thus an overlap of a parenteral anticoagulant (e.g., unfractionated heparin or LMWH) and warfarin typically is required for 5 days. The level of anticoagulation is monitored daily with the international normalized ratio (INR). The INR is a standardized system of reporting prothrombin time (Table 40-11).

TABLE 40-11
TESTS OF BLOOD COAGULATION

Drugs Monitored	Normal Value	Therapeutic Value
International normalized ratio (INR) • Vitamin K antagonists (e.g., warfarin [Coumadin])	0.75–1.25	2–3
Activated partial thromboplastin time (aPTT) • Unfractionated heparin (e.g., heparin) • Hirudin derivatives (e.g., bivalirudin [Angiomax]) • Synthetic thrombin inhibitors (e.g., argatroban; dabigatran (Pradaxa)	25–35 sec	46–70 sec
Activated clotting time (ACT) • Unfractionated heparin • Hirudin derivatives • Synthetic thrombin inhibitors	70–120 sec*	>300 sec
Anti–factor Xa		
• Low-molecular-weight heparin (e.g., enoxaparin [Lovenox])	0 U/mL	U/mL
• Factor Xa inhibitors (e.g., fondaparinux [Arixtra])	0 U/mL	0.2–1.5 U/mL

*Varies based on type of system and test reagent or activator used.

The nurse should carefully document the patient's history before warfarin therapy is started. Antiplatelet agents (e.g., ASA [Aspirin]) generally are not given with warfarin because they increase bleeding risk (Schulman, 2014). Other drugs that interact with warfarin include NSAIDs; phenytoin (Dilantin); barbiturates; and many vitamin, mineral, dietary,

and herbal supplements (see the "Complementary & Alternative Therapies: Natural Health Products That May Affect Clotting" box). A diet that frequently varies in vitamin K intake (e.g., green leafy vegetables) can make it difficult to achieve and maintain a therapeutic INR level.

Genetic variants in the genes *VKORC1* and *CYP2C9* (cytochrome P450 2C9) may influence how some people respond to warfarin. Although genetic testing is available, pharmacogenetic-based dosing is currently not recommended in clinical practice (Guyatt, Akl, Crowther, et al., 2012).

Thrombin Inhibitors: Indirect.

Indirect thrombin inhibitors are divided into two major classes: unfractionated heparin and LMWHs. Unfractionated heparin (e.g., heparin) affects both the intrinsic and the common pathways of blood coagulation by way of antithrombin found in blood plasma. Antithrombin is a natural anticoagulant that inhibits the activated coagulation factors II (prothrombin), IX, X, XI, and XII (see Figure 32-4). Heparin increases the inhibition rate significantly.

Heparin can be given subcutaneously for VTE prophylaxis or by continuous IV infusion for VTE treatment. When heparin is given intravenously, clotting status, as measured by activated partial thromboplastin time (aPTT), must be monitored frequently (see Table 40-11). One serious adverse effect of heparin is *heparin-induced thrombocytopenia* (HIT). HIT is an immune reaction to heparin in which the platelet count diminishes severely and suddenly, along with a paradoxical increase in venous or arterial thrombosis (Sartori, Favaretto, Migliaccio, et al., 2016). HIT is diagnosed by measurements for the presence of heparin antibodies in the blood. Treatment requires immediately stopping heparin therapy and, if further anticoagulation is required, using a nonheparin anticoagulant (Schulman, 2014). Another adverse effect of long-term heparin therapy is osteoporosis (Tufano, Coppola, Contaldi, et al., 2015).

LMWHs (e.g., enoxaparin [Lovenox] and dalteparin [Fragmin]) are derived from heparin, but the molecule size is about one-third that of unfractionated heparin (Schulman, 2014). They have more bioavailability, more predictable dose effects, longer half-life, and fewer bleeding complications than does unfractionated heparin. LMWHs also are less likely than heparin to cause HIT and osteoporosis. LMWHs typically do not necessitate anticoagulant monitoring and dose adjustment. Protamine neutralizes the effect of LMWH.

Thrombin Inhibitors: Direct.

Direct thrombin inhibitors are classified as hirudin derivatives or synthetic thrombin inhibitors. Hirudin is manufactured through recombinant DNA technology. It binds specifically with thrombin and directly inhibits its function without causing plasma protein and platelet interactions. Hirudin derivatives (e.g., lepirudin [Refludan] and bivalirudin [Angiomax]) are administered by continuous IV infusion. Lepirudin is approved for prophylaxis or treatment of HIT, whereas bivalirudin is approved for patients with HIT who undergo percutaneous coronary angioplasty. Anticoagulant activity is monitored according to aPTT or activated clotting time (see Table 40-11). There is no antidote for hirudin derivatives if bleeding occurs.

Argatroban, a synthetic direct thrombin inhibitor, inhibits thrombin. It is used as an alternative to heparin for the prevention and treatment of HIT and for patients known to have HIT who require percutaneous coronary interventions. Dabigatran (Pradaxa), an oral direct thrombin inhibitor, is used for VTE prevention after elective joint replacement, for stroke prevention in nonvalvular atrial fibrillation, and as a treatment option for VTE. The effects of argatroban and dabigatran are not reversible. Anticoagulant effect is monitored for both medications according to aPTT or activated clotting time.

Factor Xa Inhibitors.

Factor Xa inhibitors (e.g., fondaparinux [Arixtra]) inhibit factor Xa directly or indirectly, producing rapid anticoagulation. Fondaparinux is recommended for both treatment and prophylaxis of VTE. It is given subcutaneously. Coagulation monitoring or dose adjustment is not needed, although its anticoagulant activity can be measured with anti–factor Xa assays (see Table 40-11). If uncontrollable bleeding occurs, recombinant factor VIIa may be useful. Fondaparinux is contraindicated in patients with renal insufficiency. Rivaroxaban (Xarelto) is an oral factor Xa inhibitor used for VTE prevention.

Anticoagulation Therapy for VTE Prophylaxis.

For VTE prophylaxis in hospitalized patients at risk for thrombosis who are not bleeding, low-dose unfractionated heparin, LMWH, or fondaparinux is prescribed. Patients with moderate VTE risk (e.g., those undergoing general, gynecological, or urological surgery; those with acute medical problems) should receive unfractionated heparin, LMWH, or fondaparinux (Khan, 2015). Patients with high VTE risk (e.g., those who have sustained trauma) should receive VTE prophylaxis with LMWH,

fondaparinux, or warfarin until discharge (Khan, 2015). It is recommended that patients undergoing high-risk gynecological surgery (e.g., for cancer) and major orthopedic surgery (e.g., total knee or hip replacement) be prescribed VTE prophylaxis up to 35 days after discharge. Similarly, all critically ill patients (e.g., those who have sustained trauma) should receive VTE prophylaxis while hospitalized (Rattan, Jones, & Namias, 2015).

Anticoagulation Therapy for Venous Thrombo-embolism Treatment.

Patients with confirmed VTE should receive initial treatment with LMWH, unfractionated heparin, or fondaparinux, as well as warfarin, for at least 5 days or until the INR is 2.0 or higher for 24 hours. Patients with one or more of multiple comorbid conditions, complex medical issues, or a very large VTE usually are hospitalized for treatment and typically receive IV unfractionated heparin LMWH is recommended over unfractionated heparin for most patients with acute VTE. Depending on clinical presentation, many of these patients can be managed safely and effectively as outpatients (Whayne, 2012). Fondaparinux may be particularly useful for VTE treatment in patients with a history of HIT.

Thrombolytic Therapy for Venous Thrombo-embolism.

Another treatment option for patients with a thrombus is catheter-directed administration of a thrombolytic drug (e.g., urokinase, recombinant tissue plasminogen activator [recombinant alteplase]) (Kearon, Akl, Comerota, et al., 2012). Catheter-directed thrombolytic drugs directly dissolve clots, reduce the acute symptoms, and decrease the incidence of postphlebitic vein problems. Additional catheter-based interventions such as angioplasty, stents, or mechanical thrombectomy with a high-speed impeller to fragment the thrombus can be used in conjunction with the thrombolytic drug (Kearon, Akl, Comerota, et al., 2012). (Thrombolytic therapy is discussed in Chapter 36.)

Surgical Therapy.

Although most cases of VTE are managed medically, a small number of patients undergo surgery. Surgical options include open venous thrombectomy and inferior vena cava interruption. Venous thrombectomy involves the removal of a thrombus through an incision in the vein (Panico, Jafferani, Shah, et al., 2015). Vena cava interruption devices (e.g., Greenfield, VenaTech, or TrapEase filters) can be inserted percutaneously through the right femoral or right internal jugular veins. The filter device

is opened, and the spokes penetrate the vessel walls (Figure 40-11). This results in "sieve-type" obstruction, allowing filtration of clots without interruption of blood flow. Complications after the insertion of the device are rare but include air embolism, improper placement, migration of the filter, and perforation of the vena cava with retroperitoneal bleeding (Dominguez, Bahadorani, Reeves, et al., 2015). Over time, venous congestion can occur from accumulation of trapped clots. These can clog the filter and completely occlude the vena cava, necessitating filter removal and replacement. A filter device is recommended if anticoagulant therapy is contraindicated because of an increased risk of bleeding.

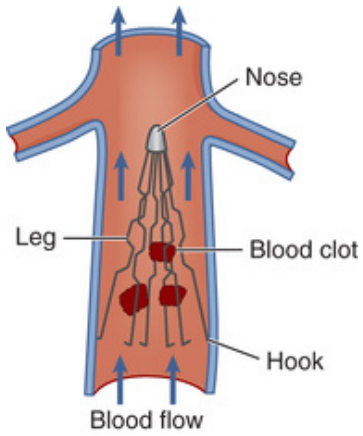

FIGURE 40-11 Inferior vena caval interruption technique with a Greenfield stainless steel filter to prevent pulmonary embolism. As blood travels up the vena cava, clots are trapped in the filter.

Evidence-Informed Practice

Translating Research Into Practice

The nurse is caring for Hana Bercier, a 78-year-old woman who is being discharged with a prescription for enoxaparin (Lovenox) after a knee replacement. Her granddaughter will be her primary caregiver. Because arthritis limits dexterity in Ms. Bercier's hands, the nurse is preparing to teach her granddaughter how to inject the medication. Her granddaughter tells the nurse that Ms. Bercier is a modest woman and will not permit her abdomen to be exposed. She asks if the injection can be given in her arm.

Best Available Evidence	Clinician Expertise	Patient Preferences and Values
Enoxaparin (per the package literature) should be administered by deep subcutaneous injection in the abdomen. Injection sites should be rotated.	Some patients have told the nurse that they used alternate sites for injection of enoxaparin, specifically the thighs and upper arms. The nurse has no evidence about the efficacy of the drug when alternate sites are used.	Ms. Bercier states she does not want to expose herself to her granddaughter. The granddaughter expresses a desire to support her grandmother's need for modesty.

Decision and Action

The nurse discusses the importance of following the drug manufacturer's recommendations regarding site selection with Ms. Bercier and her granddaughter. The nurse further explains that there is no evidence on whether alternate sites are equally effective. Ms. Bercier's granddaughter states that she is the only one available to do this and she needs to respect her grandmother's wishes. The nurse teaches the granddaughter how to inject enoxaparin in Ms. Bercier's upper arms and to alternate the sites and arms. The nurse informs the physician of Ms. Bercier's decision and documents the teaching and related conversation.

Nursing Management Venous Thrombo-embolism

Nursing Assessment

Table 40-12 lists the subjective and objective data to obtain from a patient with VTE.

TABLE 40-12
NURSING ASSESSMENT
Venous Thrombo-embolism

Subjective Data
Important Health Information
Past health history: Trauma to vein, intravascular catheter (e.g., peripherally inserted central catheter), varicose veins, pregnancy or recent childbirth, bacteremia, obesity, prolonged bed rest, irregular heartbeat (e.g., atrial fibrillation), COPD, HF, cancer, coagulation disorders and hypercoagulable states, systemic lupus erythematosus, MI, spinal cord injury, stroke, prolonged air travel, recent bone fracture, dehydration *Medications:* Use of estrogens (including oral contraceptives, hormone replacement therapy), tamoxifen (Nolvadex-D), raloxifene (Evista), corticosteroids, excessive amounts of vitamin E, IV use of recreational drugs *Surgery or other treatments:* Any recent surgery, especially orthopedic, gynecological, gastric, or urological; previous surgery involving veins; central venous catheter
Symptoms
• Pain in area on palpation or ambulation
Objective Data
General
Fever, anxiety, pain
Integumentary
Increased size of affected extremity in comparison with opposite extremity; taut, shiny, warm skin; erythematous skin; tenderness to palpation. Some patients may have no physical changes in the affected extremity.
Cardiovascular
Distension and warmth of superficial veins in affected area; edema and cyanosis of extremities, neck, back, and face (if superior vena cava involvement)
Possible Findings
Leukocytosis, abnormal coagulation, anemia or ↑ hematocrit and RBC count, ↑ D-dimer level, positive venous compression on duplex ultrasound study; positive findings on CTV, magnetic resonance venography, or contrast venography.

COPD, chronic obstructive pulmonary disease; *CTV*, computed tomography venography; *HF*, heart failure; *IV*, intravenous; *MI*, myocardial infarction; *RBC*, red blood cell.

Nursing Diagnoses

Nursing diagnoses and collaborative problems for a patient with VTE include, but are not limited to, the following:

- *Acute pain* related to *physical injury agent* (venous congestion, impaired venous return, and inflammation)
- *Ineffective health maintenance* related to *insufficient resources* (lack of knowledge about disorder and its treatment)
- *Risk for impaired skin integrity* related to *alteration in fluid volume* (altered peripheral tissue perfusion)
- Potential complication: bleeding related to anticoagulant therapy
- Potential complication: pulmonary embolism related to embolization of thrombus, dehydration, and immobility

Planning

The overall goals for the patient with VTE include (a) pain relief, (b) decreased edema, (c) no skin ulceration, (d) no bleeding complications, and (e) no evidence of pulmonary embolism.

Nursing Implementation

Acute Intervention.

Nursing care for the patient with VTE is directed toward the prevention of emboli formation and the reduction of inflammation. Because effective anticoagulation is essential, the nurse should review with the patient any medications, vitamins, minerals, and dietary and natural health products being taken that may interfere with anticoagulation therapy (Grant, Bin, Kiat, et al., 2012) (see the "Complementary and Alternative Therapies: Natural Health Products That May Affect Clotting" box). Depending on the anticoagulant ordered, the nurse should monitor INR, aPTT, activated clotting time, anti–factor Xa levels, complete blood cell count, creatinine, factor X levels, hemoglobin, hematocrit, platelet levels, and liver enzyme levels (Holbrook, Schulman, Witt, et al., 2012). Platelet counts in patients receiving unfractionated heparin or LMWH should be monitored to assess for HIT. Doses of unfractionated heparin, warfarin, and direct thrombin

inhibitors should be titrated on the basis of results of clotting studies and physician-established parameters. Dosages of direct thrombin inhibitors may need adjustment for patients with impaired renal or liver function. The nurse should always check the results of appropriate tests before initiating, administering, or adjusting anticoagulant therapy.

Drug Alert

Anticoagulant Therapy

- Patients taking coagulants should avoid taking ASA (Aspirin), nonsteroidal anti-inflammatory drugs (NSAIDs), fish oil supplements, garlic supplements, ginkgo biloba, and certain antibiotics (e.g., sulfamethoxazole and trimethoprim [Bactrim]).
- Patients should be instructed to report any signs of bleeding (e.g., black or bloody stools, bloody urine, coffee-ground or bloody vomit, nosebleeds).
- The nurse should assess for signs of bleeding (e.g., hypotension, tachycardia, hematuria, melena, hematemesis, petechiae, ecchymosis).

The nurse should monitor for bleeding and reduce the risk of bleeding that may rise with anticoagulant therapy (Table 40-13). The nurse must be aware that the risk of bleeding is greater in persons receiving LMWH or unfractionated heparin who have an active gastro-duodenal ulcer, prior bleeding history, low platelet count, hepatic or renal failure, rheumatic disease, and cancer and those older than 85 years (Decousus, Tapson, Bergmann, et al., 2011). Patients receiving warfarin with an INR of 5.0 or more are also at increased risk for bleeding. In the event of anticoagulation above target goals, the nurse should give reversal agents (e.g., protamine, vitamin K) or make dosage adjustments as ordered. In the event of major vitamin K antagonist–related bleeding, rapid treatment with four-factor prothrombin complex concentrate and IV vitamin K is recommended over fresh-frozen plasma.

TABLE 40-13

NURSING INTERVENTIONS FOR PATIENTS RECEIVING ANTICOAGULANTS

Assessment
• Evaluating appropriate laboratory coagulation tests for target therapeutic levels • Evaluating lower extremity for ecchymosis/hematoma development if intermittent compression device is used • Evaluating platelet count for signs of heparin-induced thrombo-cytopenia (HIT) • Examining urine and stool for overt signs of blood • Inspecting skin frequently, especially under any splinting devices • Monitoring vital signs as indicated • Notifying the health care provider of any abnormalities in assessments, vital signs, or laboratory values • Performing assessment of risk for falling per institutional policy, and implementing safety measures as needed • Performing assessments frequently to observe for signs and symptoms of bleeding (e.g., hypotension, tachycardia), clotting, or both
Injections
• Applying manual pressure for at least 10 min (or longer if needed) on venipuncture sites • Avoiding intramuscular injections • Minimizing venipunctures • Using small-gauge needles for venipunctures unless ordered therapy necessitates the use of a larger gauge
Routine Care and Patient Education
• Administering stool softeners to avoid hard stools and straining • Applying graduated compression stockings or sequential compression devices as ordered and with attention to proper size, application, and use • Applying moisturizing lotion to skin • Avoiding removal or disruption of established clots • Avoiding restraints if possible; using only soft, padded restraints if needed • Instructing patient not to forcefully blow nose • Instructing patient to avoid restrictive clothing • Instructing patient to use electric razors, not straight razors • Instructing patient to use soft toothbrushes or foam swabs for oral care • Limiting tape application; using paper tape as appropriate • Lubricating tubes (e.g., suction catheter) adequately before insertion • Performing physical care in a gentle manner • Repositioning the patient carefully at regular intervals • Using humidified O_2 source • Using support pads, mattresses, bed cradles, and therapeutic beds as indicated

Safety Alert

- The nurse should observe the patient closely for the following events:
  - Any overt or occult bleeding
  - Epistaxis and bleeding gingivae
  - Blood (visible or occult) in emesis, urine, stool, and sputum
  - Oozing or visible bleeding from trauma site or surgical incision
  - Excessive menstrual bleeding

- The nurse should monitor vital signs for changes: decreased blood pressure, increased heart rate
- Intramuscular injections should be avoided
- The patient should be assessed for mental status changes, especially in the older patient, because they may indicate cerebral bleeding.

Early exercise, in comparison with bed rest, does not increase the short-term risk of a pulmonary embolism in patients with VTE (Hillegass, Puthoff, Frese, et al., 2015). In addition, early exercise after VTE results in a more rapid decrease in edema and limb pain (McDermott, Kibbe, Guralnik, et al., 2013). The nurse should emphasize to the patient and caregiver the importance of exercise and assist the patient to ambulate several times a day. For patients who have acute VTE with severe edema and limb pain, bed rest with limb elevation may initially be prescribed.

Ambulatory and Home Care.

The nurse should focus discharge teaching on modification of VTE risk factors, use of graduated compression stockings, importance of monitoring laboratory values, medication instructions, and guidelines for follow-up. Once the edema is resolved, the patient should be measured for custom-fit, graduated compression stockings. Stocking use (or sleeves in the case of an upper extremity VTE) is recommended for at least 2 years after a VTE to support the vein walls and valves and decrease swelling and pain (Bernstein, Kristianson, Akl, et al., 2016; Pavon, Adam, Razouki, et al., 2016). Regular use of graduated compression stockings reduces the occurrence of post-thrombotic syndrome (which leads to chronic venous insufficiency) (Pavon, Adam, Razouki, et al., 2016).

If appropriate, patients should be instructed to stop smoking, to avoid all nicotine products, and to avoid constrictive clothing. If appropriate, women with a history of VTE should be instructed to stop using birth control pills or oral hormone replacement therapy (Rockman, Maldinado, Jacobowitz, et al., 2012). Patients need to avoid standing or sitting in a motionless, leg-dependent position. Frequent knee flexion, ankle rotation, and active walking during long periods of sitting or standing, as on car or airplane trips, should be encouraged. For patients at high risk for VTE who are planning a long trip, knee-high graduated compression stockings or one dose of LMWH before departure should be recommended (Schulman, 2014).

The patient and caregiver should be taught the signs and symptoms of pulmonary embolism such as sudden onset of dyspnea, tachypnea, and pleuritic chest pain. (Pulmonary embolism is discussed in Chapter 30.) They should contact emergency medical services if these symptoms occur. However, adults older than 70 years are less likely to have calf or thigh swelling or pleuritic pain, two of the classic symptoms of VTE (Copstead & Banasik, 2013).

The patient and caregiver need thorough education regarding medication dosage, actions, and adverse effects, the need for routine blood tests, and what symptoms to report to the health care provider (Table 40-14). Devices are available for home monitoring of INR. Patients taking LMWH or fondaparinux or their caregivers should be taught how to administer the medication subcutaneously. Active or young patients need to avoid contact sports and activities with high risk for trauma (e.g., skiing). Older patients need to know to take safety precautions to prevent falls (e.g., avoid use of throw rugs). The nurse must instruct the patient and caregiver to apply pressure for 10 to 15 minutes if bleeding occurs (e.g. nosebleeds). If the bleeding persists, they should contact emergency medical services.

TABLE 40-14

PATIENT & CAREGIVER TEACHING GUIDE
Anticoagulant Therapy

The following information should be included in the teaching plan for a patient receiving anticoagulant therapy and for the patient's caregiver.
1. Reasons for and basic mechanism of action of anticoagulant therapy and how long the anticipated therapy will last 2. The need to take medication at same time each day (preferably in afternoon or evening) 3. Depending on medication prescribed, the need for frequent follow-up with blood tests to assess therapeutic effect of the drug and whether change in drug dosages is required 4. Adverse effects of drug therapy that necessitate medical attention: • Any bleeding that does not stop after a reasonable amount of time (usually 10–15 min) • Blood in urine or stool, or black, tarry stools • Chest pain, shortness of breath, palpitations (heart racing) • Cold, blue, or painful feet • Severe headaches or stomach pains • Unusual bleeding from gums, throat, skin, or nose, or heavy menstrual bleeding • Vomiting blood or coffee-ground emesis • Weakness, dizziness, mental status changes 5. Avoidance of any trauma or injury that might cause bleeding (e.g., vigorous brushing of teeth, contact sports, in-line roller skating, use of straight razor) 6. Avoidance of all ASA (Aspirin)-containing drugs or nonsteroidal anti-inflammatory drugs 7. Limiting alcohol intake to small to moderate amount (341 mL [12 oz] of beer, 118 mL [4 oz] of wine, or 30 mL [1 oz of hard liquor per day) 8. Wearing a MedicAlert bracelet or necklace indicating what anticoagulant is being taken 9. Avoiding frequent changes in eating habits, such as dramatically increasing foods high in vitamin K (e.g., broccoli, spinach, kale, greens); avoiding supplemental vitamin K 10. Consulting with health care provider before beginning or discontinuing any medication, vitamin, mineral, or dietary or herbal supplement (see the "Complementary and Alternative Therapies: Natural Health Products That May Affect Clotting" box) 11. Informing all health care providers, including dentist, of anticoagulant therapy 12. The necessity of correct dosing; supervision may be required (e.g., patients experiencing confusion or cognitive impairment; Whayne, 2012)

A well-balanced diet, including calcium and vitamin E, is important because these affect coagulation. Patients taking warfarin should be taught to follow a consistent diet of foods containing vitamin K, to avoid taking any supplements containing vitamin K, and to avoid excessive amounts of vitamin E and alcohol. Proper hydration to prevent additional hypercoagulability of the blood, which may occur with dehydration, should be encouraged.

Patients who are overweight not only need to limit caloric intake but also must increase physical activity to achieve and maintain desired weight. A balanced program of rest and exercise also improves venous return. The nurse should assist the patient to develop an exercise program with an emphasis on walking and swimming. Water exercise is particularly beneficial because of the gentle, even pressure of the water. A 6-month exercise program of daily walking improves calf muscle

flexibility, strength, and pump function and reduces post-thrombotic syndrome (Christakou & Zakyntinos, 2014).

Evaluation

The expected outcomes for the patient with VTE include the following:

- Minimal to no pain
- Intact skin
- No signs of hemorrhage or occult bleeding
- No signs of respiratory distress

Varicose Veins

Varicose veins, or *varicosities,* are dilated, tortuous subcutaneous veins most commonly found in the saphenous vein system. Varicosities may be small and innocuous or large and bulging. *Primary varicose veins* (idiopathic) are caused by a congenital weakness of the veins and are more common in women. *Secondary varicose veins* typically result from a previous VTE. Secondary varicose veins also may occur in the esophagus (esophageal varices), vulva, spermatic cords (varicoceles), and anorectal area (hemorrhoids), and as abnormal arteriovenous connections. Reticular veins are smaller varicose veins that appear flat, less tortuous, and bluish green. Telangiectasias (often referred to as *spider veins*) are very small visible vessels (generally <1 mm in diameter) that appear bluish-black, purple, or red.

Etiology and Pathophysiology

The etiology of varicose veins is multifactorial in nature. Superficial veins in the lower extremities become dilated and tortuous in response to increased venous pressure. Risk factors include family history of chronic venous disease, weakness of the vein structure, female sex, Latin American ethnicity, tobacco use, increasing age, obesity, multiparity, history of VTE, venous obstruction resulting from extrinsic pressure by tumours, thrombophilia, phlebitis, previous leg injury, and occupations that require prolonged standing or sitting (Wittens, Davies, Baekgaard, et al., 2015). Although the exact etiology remains unknown, it is thought that the vein valve leaflets are stretched and become incompetent (do not fit together properly). Incompetent vein valves allow retrograde blood flow,

particularly when the patient is standing, which results in increased venous pressure and further venous distension.

Clinical Manifestations and Complications

Discomfort from varicose veins varies among people and tends to be worse after episodes of SVT. Many patients are concerned about cosmetic disfigurement. The most common varicose vein symptom is a heavy, achy feeling or pain after prolonged standing, which is relieved by walking or limb elevation. Some patients feel pressure or complain of an itchy, burning, or cramplike sensation in the affected leg. Swelling or nocturnal leg cramps also may occur. SVT is the most frequent complication of varicose veins and may occur spontaneously or after trauma, surgical procedures, or pregnancy. Rare complications include rupture of the varicose veins, resulting in external bleeding and skin ulcerations.

Diagnostic Studies and Collaborative Care

Superficial varicose veins can be diagnosed by appearance. Duplex ultrasonography can reveal obstruction and reflux in the venous system with considerable accuracy. It is the test most widely used to diagnose deep varicose veins.

Treatment usually is not indicated if varicose veins are only a cosmetic problem. If venous insufficiency develops, collaborative care involves rest with limb elevation, graduated compression stockings and exercise, such as walking. Two herbal therapies used for varicose vein treatment are horse chestnut seed extract *(Aesculus hippocastanum)* and butcher's broom (*Ruscus aculeatus;* Grant, Bin, Kiat, et al., 2012). (See the "Chronic Venous Insufficiency and Venous Leg Ulcers" section later in this chapter.)

Sclerotherapy involves the injection of a substance that obliterates venous telangiectasias, reticular veins, and small, superficial varicose veins 5 mm or larger in diameter (Marsden, Perry, Kelley, et al., 2013) (Figure 40-12). Commonly used sclerosing agents include hypertonic saline, polidocanol, and glycerine. Direct IV injection of a sclerosing agent induces inflammation and results in eventual thrombosis of the vein. This procedure is performed in an office setting and causes minimal discomfort. Potential complications include itching, pain, blistering, edema, hyperpigmentation, necrosis, recurrence of varicosities, SVT, visual disturbances, and VTE (Marsden, Perry, Kelley, et al., 2013). After injection, a thigh-high graduated compression stocking is worn or an elastic bandage is applied to the leg for several days to maintain pressure

over the vein. Long-term compression therapy is advised to help prevent the development of further varicosities.

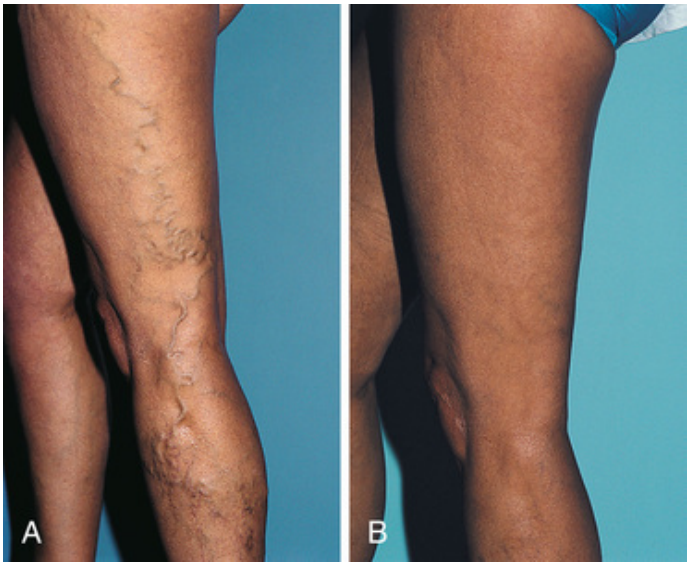

FIGURE 40-12 **A,** Lateral aspect of varicose veins before treatment. **B,** Lateral aspect of varicose veins 2 years after initial treatment with sclerotherapy. Source: Goldman, M. P., Guex, J. J., & Weiss, R.A. (2011). *Sclerotherapy: Treatment of varicose and telangiectatic leg veins* (5th ed.). Philadelphia: Mosby.

Newer, more costly, but noninvasive options for the treatment of venous telangiectasias include laser therapy and high-intensity pulsed-light therapy (Marsden, Perry, Kelley, et al., 2013). Laser or light therapy is indicated for isolated small telangiectasias or for patients in whom sclerotherapy is contraindicated or has been previously ineffective. Laser treatment typically requires more than one session, scheduled at 6- to 12-week intervals. Vascular lasers work by heating the hemoglobin in the vessels, which leads to thermocoagulation and results in vessel sclerosis (Marsden, Perry, Kelley, et al., 2013). Pulsed-light therapy is similar to laser therapy, but a spectrum of light, rather than a single wavelength, is used. Potential complications of these therapies include pain, blistering, hyperpigmentation, and superficial erosions.

Surgical intervention is indicated for recurrent superficial venous thrombosis or when chronic venous insufficiency cannot be controlled with conservative therapy. The traditional surgical intervention involves ligation of the entire vein (usually the greater saphenous vein) and dissection and removal of its incompetent tributaries. An alternative but

time-consuming technique is ambulatory phlebectomy. This procedure involves pulling the varicosity through a stab incision followed by excision of the vein. Potential complications include bleeding, bruising, and infection. In up to 30% of patients, a new vein forms to replace the one removed (Marsden, Perry, Kelley, et al., 2013).

A newer, less invasive procedure is endovenous ablation of the saphenous vein. Ablation involves the insertion of a catheter that emits energy. This causes collapse and sclerosis of the vein (Rasmussen, Lawaetz, Bjoern, et al., 2013). Potential complications include bruising, tightness along the vein, recanalization (reopening of the vein), and paresthesia (Rasmussen, Lawaetz, Bjoern, et al., 2013). Endovenous ablation also may be done in combination with saphenofemoral ligation or phlebectomy.

Nursing Management Varicose Veins

Prevention is a key factor related to varicose veins. The patient should be instructed to avoid sitting or standing for long periods, maintain ideal body weight, take precautions against injury to the extremities, avoid wearing constrictive clothing, and walk daily.

After vein ligation surgery, the patient should be encouraged to practise deep breathing, which promotes venous return. It is important to check the extremities regularly for colour, movement, sensation, temperature, edema, and quality of pedal pulses. Bruising and discoloration are considered normal. Postoperatively, the legs should be elevated 15 degrees to limit edema. Graduated compression stockings should be applied, removed every 8 hours for short periods, and then reapplied.

Long-term management of varicose veins is directed toward improving circulation and cosmetic appearance, relieving discomfort, and avoiding complications and ulceration. Varicose veins can recur in other locations after vein ligation. The patient needs to learn the proper use and care of custom-fitted graduated compression stockings. The patient should apply stockings in bed, before rising in the morning. In some instances, patients also use SCDs at home to control edema (Pavon, Adam, Razouki, et al., 2016). The importance of periodic positioning of the legs above the heart should be stressed. An overweight patient may need assistance with weight loss. A patient with a job that requires long periods of standing or sitting needs to frequently flex and extend her or his hips, legs, and ankles and change positions.

Chronic Venous Insufficiency and Venous Leg Ulcers

Chronic venous insufficiency (CVI), a common problem in women and older adults, is a condition in which leg veins and valves fail to keep blood moving forward. This results in *ambulatory venous hypertension.* CVI can lead to *venous leg ulcers* (formerly called *venous stasis ulcers* or *varicose ulcers*). Although CVI and venous leg ulcers are not life-threatening diseases, they are painful, debilitating, and costly chronic conditions that adversely affect the quality of patients' lives (O'Donnell, Passman, Marsten, et al., 2014).

Etiology and Pathophysiology

Both long-standing primary varicose veins and post-thrombotic syndrome can progress to CVI. The causes of CVI include vein valve incompetence, deep vein obstruction, congenital venous malformation, and arteriovenous fistula (Copstead & Banasik, 2013). The basic problem is incompetent valves of the deep veins. As a result, hydrostatic pressure in the veins increases and serous fluid and RBCs leak from the capillaries and venules into the tissue, which results in edema. Enzymes in the tissue eventually break down RBCs, causing the release of *hemosiderin,* which causes a brownish skin discoloration. Over time, the skin and subcutaneous tissue around the ankle are replaced by fibrous tissue, which results in thick, hardened, contracted skin. Although the causes of CVI are known, the exact pathophysiology of venous leg ulcers is not known

Clinical Manifestations and Complications

In individuals with CVI, the skin of the lower leg is leathery, with a characteristic brownish or "brawny" appearance from the hemosiderin deposition. Edema usually has been persistent for a prolonged period. Eczema, or "stasis dermatitis," is often present, and itching is a common complaint (see Table 40-1).

Venous ulcers classically are located above the medial malleolus (Figure 40-13; see Table 40-1). Many such ulcers are quite painful, particularly when edema or infection is present (Maddox, 2012). Pain may be worse when the leg is in a dependent position. If the venous ulcer is untreated, the wound becomes more extensive, eroding wider and deeper and increasing the likelihood of wound infection and cellulitis. Recurrent episodes of cellulitis may lead to destruction of the superficial lymphatic vessels, causing a secondary lymphedema to develop (Maddox, 2012). On very rare occasions, severe CVI with longstanding nonhealing venous ulcers may result in the need for amputation.

FIGURE 40-13 Venous leg ulcer. Source: Kamal, A., & Brocklehurst, J. C. (1991). *Color atlas of geriatric medicine* (2nd ed.). St. Louis: Mosby–Year Book.

Collaborative Care

Compression is essential for CVI treatment, venous ulcer healing, and prevention of ulcer recurrence. A variety of options are available for compression therapy, including elastic wraps, custom-fitted graduated compression stockings, elastic tubular support bandages, a Velcro wrap (CircAid), SCDs, a paste bandage (Unna boot) with an elastic wrap, and multilayer (three or four) bandage systems (e.g., Profore) (Woo, Alavi, Evans, et al., 2013). There are benefits to each type of compression therapy. Each patient should be evaluated individually when an extrinsic compression method is chosen. Before instituting compression therapy, the nurse should assess the arterial status to make sure that coexistent PAD is not present. An ABI of less than 0.9 suggests PAD, and levels of compression should not be high.

Moist environment dressings are the basis of wound care. A variety of these dressings are available and include transparent film dressings, hydrocolloids, hydrogels, foams, calcium alginates, impregnated gauze, gauze moistened with saline, and combination dressings. When used in conjunction with compression, moist environment dressings are more effective than dry dressings in hastening the healing of venous leg ulcers.

(Hydrocolloid and other dressings are discussed in Chapter 14 and Table 14-11.)

The nurse should evaluate the nutritional status of a patient with a venous ulcer. A balanced diet with adequate protein, calories, and micronutrients is essential for healing. Nutrients most important for healing include protein, vitamins A and C, and zinc. Foods high in protein (e.g., meat, beans, cheese, tofu), vitamin A (green leafy vegetables), vitamin C (citrus fruits, tomatoes, cantaloupe), and zinc (meat, seafood) must be provided.

For patients with diabetes mellitus, maintaining normal blood glucose levels assists the healing process. For overweight individuals with CVI and no active venous ulcer, a weight loss diet should be considered (O'Donnell, Passman, Marsten, et al., 2014). Routine antibiotic therapy is not indicated. Clinical signs of infection in a venous ulcer include change in quantity, colour, or odour of the drainage; presence of pus; erythema of the wound edges; change in sensation around the wound; warmth around the wound; increased local pain or edema, or both; dark-coloured granulation tissue; induration around the wound; delayed healing; and cellulitis. If signs of infection are present, the nurse should obtain a wound culture before instituting antibiotic therapy. The usual treatment for infection is debridement, wound excision, and systemic antibiotics. A number of antimicrobial dressings (e.g., cadexomer iodine, silver) are available for use on contaminated or infected venous ulcers.

If the ulcer does not heal with conservative therapy, drug therapy should be considered. Pentoxifylline or micronized purified flavonoid fraction (Daflon) is recommended with compression therapy to improve healing (Kahn, Comerota, Cushman, et al., 2014). Pentoxifylline minimizes WBC activation and adhesion to capillary endothelium and decreases oxidative stress. Micronized purified flavonoid fraction acts on WBCs to decrease inflammation and edema (Raffetto & Eberhardt, 2014).

Alternative treatments include coverage with a split-thickness skin graft, cultured epithelial autograft, allograft, or bioengineered skin such as Dermagraft (O'Donnell, Passman, Marsten, et al., 2014). Before the graft is applied, the ulcer is debrided, varicosities in the area are removed, and veins are ligated. (Skin grafting is discussed in Chapter 27.) Although grafts may assist with healing, they do not replace the need for lifelong compression therapy.

A natural health product used for CVI treatment is horse chestnut seed extract (HCSE). Escin (the active ingredient) reduces leg pain, itching, and swelling (Pittler & Ernst, 2012). Minor adverse effects associated with

HCSE include dizziness, gastro-intestinal complaints, headache, and pruritus. The efficacy of HCSE in venous ulcer healing and recurrence has not been determined.

Nursing Management Chronic Venous Insufficiency and Venous Leg Ulcers

Long-term management of venous leg ulcers should focus on teaching the patient about self-care measures because the ulcers often recur (Weller & Evans, 2012). The nurse should instruct the patient and caregiver to avoid trauma to the limbs and should teach them proper skin care. The nurse should also demonstrate the correct application of graduated compression stockings and stress the importance of regular replacement.

It is important to discuss activity guidelines and proper limb positioning. Proper foot and leg care is essential to avoid additional skin trauma. In patients with CVI, the skin is dry, flaky, and itchy as a result of stasis dermatitis. Daily moisturizing decreases itching and prevents cracking of the skin. Venous dermatitis may result from contact with sensitizing products such as antibacterial agents (e.g., gentamicin, neomycin); additives in bandages or dressings (e.g., adhesives); ointments containing lanolin, alcohols, benzocaine, or balsam of Peru; and over-the-counter creams or lotions with fragrance or preservatives (Weller & Evans, 2012). With each dressing change, the nurse must assess the wound for signs of infection.

Patients with CVI with or without a venous ulcer should be instructed to avoid standing or sitting for long periods. Standing or sitting with the legs in a dependent position decreases periulcer skin blood perfusion and oxygen levels. Patients with venous ulcers should elevate their legs above the level of the heart to reduce edema. Patients should begin a daily walking program once an ulcer heals. Prescription graduated compression stockings should be worn daily and replaced every 4 to 6 months to reduce the occurrence of CVI (Nelson & Bell-Syer, 2014).

Case Study

Peripheral Artery Disease

Patient Profile

Leo Ducharme, a 76-year-old man, was admitted to the hospital with rest pain in both legs and a nonhealing ulcer of the big toe on the right foot.

Subjective Data

- History of a myocardial infarction, stroke, hypertension, arthritis, and type 1 diabetes mellitus
- Underwent a left femoral–popliteal bypass 5 years ago
- Has a 45-pack-yr history of tobacco use
- Has been using insulin for 30 years
- Complains of sudden, intense increase in right foot pain for past 2 hr
- Has slept in recliner with right leg in dependent position for several months

Current Medications

- Furosemide (Lasix), 40 mg/day PO
- Enalapril (Vasotec), 5 mg/day PO
- Aspart (NovoRapid) insulin with meals
- Glargine insulin (Lantus), 50 units daily subcutaneously
- Diltiazem sustained-release (Tiazac), 240 mg/day PO
- ASA (Aspirin), 325 mg/day PO
- Fish oil daily (self-prescribed)

Objective Data

Physical Examination

- BP, 148/92 mm Hg; irregular apical heart rate, 90/min; respiratory rate, 22/min; temperature, 36.6°C
- Alert and oriented but anxious, no apparent physical or mental deficits from previous stroke
- Diminished right femoral pulse, popliteal pulse detected only with use of a Doppler probe, posterior tibial pulse detected with use of Doppler probe, and dorsalis pedis pulse absent (not palpable or visible on Doppler study); left leg pulses are weakly palpable
- Right leg ABI: 0.20; left leg ABI: 0.68
- Has a 2-cm necrotic ulcer on tip of right big toe
- Has thickened toenails; shiny, thin skin on legs; and hair absent on both lower legs
- Right foot is very cool, pale, and mottled in colour with decreased sensation
- No peripheral edema present
- Bedside glucose measurement 16 mmol/L (last meal 4 hr before admission)

Discussion Questions

1. What are Mr. Ducharme's risk factors for peripheral artery disease (PAD)?
2. Differentiate Mr. Ducharme's signs and symptoms of chronic PAD from those of acute arterial ischemia.
3. Identify the possible cause or causes for the sudden, intense increase in right foot pain.
4. How would the nurse interpret Mr. Ducharme's ABI findings?
5. What additional diagnostic tests can be performed to assess the extent of Mr. Ducharme's PAD?
6. Given the physical examination data, what initial medications might the physician prescribe?
7. What treatment modalities are possible for Mr. Ducharme?
8. ***Priority decision:*** What are the priority nursing responsibilities in caring for Mr. Ducharme?
9. ***Priority decision:*** On the basis of the assessment data presented, what are the priority nursing diagnoses? Are there any collaborative problems?

10. ***Evidence-informed practice:*** In patient education for Mr. Ducharme, what evidence-informed advice should the nurse give him regarding the use of dietary supplements such as fish oil?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. A 50-year-old woman weighs 95 kg and has a history of tobacco use, high blood pressure, high sodium intake, and sedentary lifestyle. When an individualized care plan is developed for this client, which of the following risk factors related to PAD would the nurse determine need to be modified?
   a. Weight and diet
   b. Activity level and diet
   c. Tobacco use and high blood pressure
   d. Sedentary lifestyle and high blood pressure
2. Rest pain is a manifestation of PAD that results from which chronic condition?
   a. Vasospasm of small cutaneous arteries in the feet
   b. Increase in retrograde venous blood flow in the legs
   c. Decrease in arterial blood flow to the nerves of the feet
   d. Decrease in arterial blood flow to the leg muscles during exercise
3. A client with infective endocarditis develops sudden left leg pain with pallor, paresthesia, and a loss of peripheral pulses. What should the nurse's initial action be?
   a. To elevate the leg to promote venous return
   b. To start anticoagulant therapy with IV heparin
   c. To notify the physician of the change in peripheral perfusion
   d. To place the bed in reverse Trendelenburg position to promote perfusion
4. Which clinical manifestations are seen in clients with either Buerger's disease or Raynaud's phenomenon? *(Select all that apply)*
   a. Intermittent fevers
   b. Sensitivity to cold temperatures
   c. Gangrenous ulcers on fingertips
   d. Colour changes of fingers and toes
   e. Episodes of superficial vein thrombosis

5. A client is admitted to the hospital with a diagnosis of abdominal aortic aneurysm. Which signs and symptoms would suggest that his aneurysm has ruptured?
   a. Sudden shortness of breath and hemoptysis
   b. Sudden, severe low back pain and bruising along his flank
   c. Gradually increasing substernal chest pain and diaphoresis
   d. Sudden, patchy blue mottling on feet and toes and rest pain
6. Which of the following are priority nursing measures after an abdominal aortic aneurysm repair?
   a. Assessment of cranial nerves and mental status
   b. Administration of IV heparin and monitoring of aPTT
   c. Administration of IV fluids and monitoring of kidney function
   d. Elevation of the legs and application of graduated compression stockings
7. What is the first priority of collaborative care of a client with a suspected acute aortic dissection?
   a. To reduce anxiety
   b. To control blood pressure
   c. To monitor for chest pain
   d. To increase myocardial contractility
8. Which of the following clients has the highest risk for venous thrombo-embolism (VTE)?
   a. A 62-year-old man with spider veins who is having arthroscopic knee surgery.
   b. A 32-year-old woman who smokes, takes oral contraceptives, and is planning a trip to Europe.
   c. A 26-year-old woman who is 3 days postpartum and received maintenance IV fluids for 12 hours during her labour.
   d. An active 72-year-old man at home recovering from transurethral resection of the prostate for benign prostatic hyperplasia.
9. Which of the following are probable clinical findings in a person with an acute lower extremity VTE? *(Select all that apply)*
   a. Pallor and coolness of foot and calf
   b. Mild to moderate calf pain and tenderness

c. Grossly diminished or absent pedal pulses

d. Unilateral edema and induration of the thigh

e. Palpable cord along a superficial varicose vein

10. The recommended treatment for an initial VTE in an otherwise healthy person with no significant comorbid conditions would include which of the following?

a. IV argatroban while the person is an inpatient

b. IV unfractionated heparin while the person is an inpatient

c. Subcutaneous unfractionated heparin while the person is an outpatient

d. Subcutaneous low-molecular-weight heparin while the person is an outpatient

11. Which of the following is a key teaching instruction for the client who is receiving anticoagulant therapy?

a. Monitor for and report any signs of bleeding.

b. Do not take acetaminophen (Tylenol) for a headache.

c. Decrease your dietary intake of foods containing vitamin K.

d. Arrange to have blood drawn routinely to check drug levels.

12. Which of the following is the most important intervention in healing and control of venous leg ulcers?

a. Sclerotherapy

b. Using moist environment dressings

c. Taking horse chestnut seed extract daily

d. Applying elastic compression stockings

1. c; 2. c; 3. c; 4. b, c, d; 5. b; 6. c; 7. b; 8. b; 9. b, c; 10. d; 11. a; 12. d.

CHAPTER 41

Nursing Assessment

Gastro-Intestinal System

Written by, Paula Cox-North

Adapted by, Shohreh Abrouie

LEARNING OBJECTIVES

1. Describe the structures and functions of the organs of the gastro-intestinal tract.
2. Describe the structures and functions of the liver, the gallbladder, the biliary tract, and the pancreas.
3. Differentiate between the processes of ingestion, digestion, absorption, and elimination.
4. Relate the age-related changes in the gastro-intestinal system to differences in assessment findings.
5. Select the significant subjective and objective data related to the gastro-intestinal system that should be obtained from a patient.
6. Describe the appropriate techniques used in the physical assessment of the gastro-intestinal system.
7. Differentiate normal from abnormal findings of a physical assessment of the gastro-intestinal system.
8. Describe the purpose, significance of results, and nursing responsibilities related to diagnostic studies of the gastro-intestinal system.

villi, p. 950

The main function of the gastro-intestinal (GI) system is to supply nutrients to body cells. This function is accomplished through the processes of *ingestion* (taking in food), *digestion* (breakdown of food), and *absorption* (transfer of food products into circulation). *Elimination* is the process of excreting the waste products of digestion.

The GI system (also called the *digestive system*) consists of the GI tract and its associated organs and glands. Included in the GI tract are the mouth, the esophagus, the stomach, the small intestine, the large intestine, the rectum, and the anus. The associated organs are the liver, the pancreas, and the gallbladder (Figure 41-1).

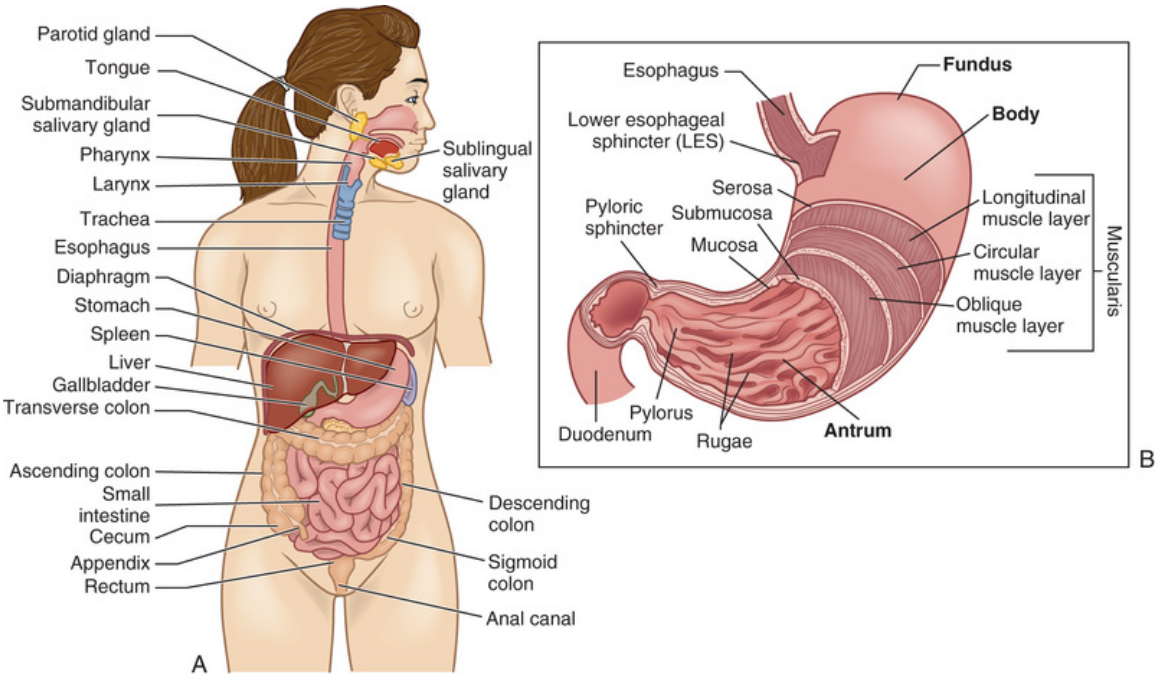

FIGURE 41-1 Location of organs of the gastro-intestinal system.

Factors outside the GI tract can influence its functioning. Both psychological and emotional factors, such as stress and anxiety, influence GI functioning in many people. Stress may be manifested as anorexia, nausea, epigastric and abdominal pain, or diarrhea. However, GI problems should never be attributed solely to psychological factors. Organic and psychologically based problems can exist independently or concurrently. Physical factors such as dietary intake, ingestion of alcohol and caffeine-containing products, cigarette smoking, and fatigue may also affect GI function. Some organic diseases of the GI system, such as peptic ulcer disease and ulcerative colitis, may be aggravated by stress.

Structures and Functions of the Gastro-Intestinal System

The GI tract is a tube approximately 9 m long, extending from the mouth to the anus. The entire tract is composed of four common layers. From the inside to the outside, these layers are (a) mucosa, (b) submucosa, (c) muscle, and (d) serosa (see Figure 41-1). In the esophagus, the outer coat is fibrous tissue rather than serosa. The muscular coat consists of two layers: the circular (inner) and the longitudinal (outer).

The GI tract is innervated by the parasympathetic and the sympathetic branches of the autonomic nervous system. The parasympathetic system is mainly excitatory, and the sympathetic system is mainly inhibitory. For example, peristalsis is increased by parasympathetic stimulation and decreased by sympathetic stimulation. Sensory information is relayed via both sympathetic and parasympathetic afferent fibres.

The GI tract and accessory organs receive approximately 25% to 30% of the cardiac output. Circulation in the GI system is unique in that venous blood that drains from the GI tract organs empties into the portal vein, which then perfuses the liver. The upper portion of the GI tract receives its blood supply from the splanchnic artery. The small intestine receives its blood supply from branches of the hepatic and superior mesenteric arteries. The large intestine receives its blood supply mainly from the superior and inferior mesenteric arteries. Because such a large percentage of the cardiac output is used to perfuse these organs, the GI tract is a major source from which blood flow can be diverted during exercise or stress.

The two types of movement of the GI tract are *mixing* (segmentation) and *propulsion* (peristalsis). The secretions of the GI system consist of enzymes and hormones for digestion, mucus to provide protection and lubrication, and water and electrolytes.

The abdominal organs are almost completely covered by the peritoneum. The two layers of the peritoneum are the parietal, which lines the abdominal cavity wall, and the visceral, which covers the abdominal organs. The peritoneal cavity is the potential space between the parietal and visceral layers. The two folds of the peritoneum are the mesentery and the omentum. The mesentery is the attachment of the small intestine and part of the large intestine to the posterior abdominal wall and contains blood and lymph vessels. The lesser omentum extends from the lesser curvature of the stomach and the upper duodenum to the liver, and the

greater omentum hangs from the stomach over the intestines like an apron. The omentum contains fat and lymph nodes.

The primary functions of the GI system are (a) ingestion and propulsion (movement) of food; (b) secretion of mucus, water, and enzymes; (c) digestion; (d) absorption; and (e) elimination. Each part of the GI system performs different activities to accomplish these functions.

Ingestion and Propulsion of Food

Ingestion is the intake of food. A person's appetite or desire to ingest food is a significant factor in how much food is eaten. Multiple factors are involved in the control of appetite. An appetite centre is located in the hypothalamus. It is directly or indirectly stimulated by hypoglycemia, an empty stomach, decrease in body temperature, and input from higher brain centres. The hormone *ghrelin,* released from the stomach mucosa, plays a role in appetite stimulation. Another hormone, *leptin,* is involved in appetite suppression (see Chapter 43, Table 43-3). The sight, smell, and taste of food frequently stimulate appetite. Appetite may be inhibited by stomach distension, illness (especially accompanied by fever), hyperglycemia, nausea and vomiting, certain drugs (e.g., amphetamines), and psychological factors, such as depression.

Swallowing **(deglutition)** is the mechanical component of ingestion. The organs involved in the swallowing of food are the mouth, the pharynx, and the esophagus. Swallowed food is moved to the stomach by means of peristalsis, the coordinated, sequential contraction and relaxation of outer longitudinal and inner circular layers of muscles.

Mouth.

The mouth consists of the lips and the oral (buccal) cavity. The lips surround the orifice of the mouth and function in speech. The roof of the oral cavity is formed by the hard and soft palates. The oral cavity contains the teeth—used in mastication (chewing)—and the tongue. The tongue is a solid muscle mass and assists in chewing by keeping food between the teeth during chewing and moving the food to the back of the throat for swallowing. Taste receptors are found on the sides and the tip of the tongue. The tongue is also important in speech.

Within the oral cavity are three pairs of salivary glands: the parotid, the submaxillary, and the sublingual. These glands produce saliva, which consists of water, protein, mucin, inorganic salts, and salivary amylase. Approximately 1 L of saliva is produced each day. Saliva serves many

roles, including the lubrication of food and prevention of bacterial overgrowth in the oral cavity.

Pharynx.

The pharynx is a musculo-membranous tube that is divided into the nasopharynx, the oropharynx, and the laryngeal pharynx. The mucous membrane of the pharynx is continuous with the nasal cavity, the mouth, the auditory tubes, and the larynx. The oropharynx secretes mucus, which aids in swallowing. The epiglottis is a lid of fibrocartilage that closes over the larynx during swallowing. During ingestion, the oropharynx provides a route for the food from the mouth to the esophagus. When receptors in the oropharynx are stimulated by food or liquid, the swallowing reflex is initiated.

Esophagus.

The esophagus is a hollow, muscular tube that receives food from the pharynx and moves it to the stomach by peristaltic contractions. It is 23 to 25 cm long and 2 cm in diameter. The esophagus is located in the thoracic cavity; it starts behind the trachea at the lower end of the pharynx and extends to the stomach. The upper one-third of the esophagus is composed of striated skeletal muscle, and the distal two-thirds are composed of smooth muscle.

With swallowing, the upper esophageal sphincter (cricopharyngeal muscle) relaxes, and a peristaltic wave moves the bolus into the esophagus. Between swallows, the esophagus is collapsed. It is structurally composed of four layers: the inner mucosa, submucosa, muscularis propria, and outermost adventitia. The muscular layers contract (peristalsis) and propel the food to the stomach. The lower esophageal sphincter (LES) at the distal end of the esophagus remains contracted except during swallowing, belching, or vomiting. The LES is an important barrier that prevents reflux of acidic gastric contents into the esophagus.

Digestion and Absorption

Mouth.

Digestion begins in the mouth. *Digestion* involves both a mechanical process (mastication) and a chemical process. Saliva is the first secretion involved, and its main function is to lubricate and soften the food mass,

thus facilitating swallowing. Saliva contains amylase (ptyalin), which hydrolyzes starches to maltose. However, salivary amylase is not necessary for the digestion of carbohydrates.

Stomach.

The functions of the stomach are to store food, secrete digestive juices, mix the food with gastric secretions, and empty the resulting content (called *chyme*) into the small intestine at a rate at which digestion can occur. The stomach absorbs only small amounts of water, alcohol, electrolytes, and certain drugs.

The stomach is usually J-shaped and lies obliquely in the epigastric, umbilical, and left hypochondriac regions of the abdomen (see Figure 41-5 later in this chapter). The shape and position of the stomach change according to the degree of gastric distension. The stomach always contains gastric fluid and mucus. The three main parts of the stomach are the fundus, the body, and the antrum (see Figure 41-1). The pylorus is a small portion of the antrum that lies proximal to the pyloric sphincter. Food passes from the lower esophageal sphincter through the cardiac orifice into the stomach. The chyme is propelled through the pyloric sphincter into the duodenum.

The serous (outer) layer of the stomach is formed by the peritoneum. The muscular layer consists of the longitudinal (outer) layer, the circular (middle) layer, and the oblique (inner) layer. The mucosal layer forms folds called *rugae* that contain many small glands. In response to nutrient intake, these glands secrete most of the gastric juice. In the fundus, the glands contain chief cells, which secrete pepsinogen, and parietal cells, which secrete hydrochloric acid (HCl), water, and intrinsic factor. The secretion of HCl makes gastric juice acidic in comparison with other body fluids. This acidic pH aids in the protection against ingested organisms. Intrinsic factor promotes cobalamin (vitamin B_{12}) absorption in the small intestine. Mucus is secreted by glands in the cardiac and pyloric areas.

Small Intestine.

The two primary functions of the small intestine are digestion and *absorption* (uptake of nutrients from the gut lumen to the bloodstream). The small intestine is a coiled tube approximately 5 to 6 m in length and from 2.5 to 2.8 cm in diameter, diminishing in diameter at the lower end. It extends from the pylorus to the ileocecal valve. The small intestine is composed of the duodenum, the jejunum, and the ileum. The ileocecal

valve, which separates the small intestine from the large intestine, prevents reflux of large intestine contents into the small intestine.

The serous coat of the small intestine is formed by the peritoneum. The mucosa is thick, vascular, and glandular. Folds in the mucosa slow the passage of food and provide a greater surface area for digestion and absorption.

Absorption occurs through the villi, which are functional units present throughout the entire small intestine. **Villi** are minute, finger-like projections in the mucous membrane. They contain goblet cells that secrete mucus and epithelial cells that produce the intestinal digestive enzymes. The epithelial cells on the villi also have *microvilli,* which compose the brush border. Thus the presence of villi and microvilli also greatly increases the surface area for absorption.

The digestive enzymes on the brush border of the microvilli chemically break down nutrients so that they can be absorbed. The villi are surrounded by the crypts of Lieberkühn, which contain the multipotent stem cells for the other epithelial cell types. (Stem cells are discussed in Chapter 16.) Brunner's glands in the submucosa of the duodenum secrete mucus.

Physiology of Digestion.

Digestion is the physical and chemical breakdown of food into absorbable substances. Digestion in the GI tract is facilitated by the timely movement of food through the various organs and the secretion of specific enzymes. These enzymes break down foodstuffs to particles of appropriate size for absorption (Table 41-1).

TABLE 41-1
GASTRO-INTESTINAL SECRETIONS RELATED TO DIGESTION

Daily Amount (mL)	Secretions or Enzymes	Action
Salivary Glands		
1 000–1 500	Salivary amylase (ptyalin)	Initiation of starch digestion
Stomach		
2 500	Pepsinogen	Protein digestion
	HCl acid	Activation of pepsinogen to pepsin
	Lipase	Fat digestion
	Intrinsic factor	Essential for absorption of cobalamin in the ileum
Small Intestine		
3 000	Enterokinase	Activation of trypsinogen to trypsin
	Amylase	Carbohydrate digestion
	Peptidases	Protein digestion
	Aminopeptidase	Protein digestion
	Maltase	Maltose to two glucose molecules
	Sucrase	Sucrose to glucose and fructose
	Lactase	Lactose to glucose and galactose
	Lipase	Fat digestion
Pancreas		
700	Trypsinogen	Protein digestion
	Chymotrypsin	Protein digestion
	Amylase	Starch to disaccharides and trisaccharides
	Lipase	Fat digestion
Liver and Gallbladder		
700–1 200	Bile	Emulsification of fats and aid in absorption of fatty acids and fat-soluble vitamins (A, D, E, and K)

The process of digestion begins in the mouth, where the food is chewed, mechanically broken down, and mixed with saliva. The saliva lubricates the food. In addition, salivary amylase begins the breakdown of starch. Salivary gland secretion is stimulated by chewing movements and the sight, the smell, the thought, and the taste of food. The food is swallowed and passes into the esophagus, where peristaltic waves propel it to the stomach. No digestion or absorption occurs in the esophagus.

In the stomach, the digestion of proteins begins with the release of pepsinogen from chief cells. The acidic environment of the stomach results in the conversion of pepsinogen to its active form, pepsin. Pepsin begins the initial breakdown of proteins. In the stomach, digestion of starches and fats is minimal. The food is mixed with gastric secretions, which are under neural and hormonal control (Tables 41-2 and 41-3). The stomach also serves as a reservoir for food, which is slowly expelled into the small intestine. The length of time that food remains in the stomach depends on the composition of the food, but average meals remain from 3 to 4 hours.

TABLE 41-2

PHASES OF GASTRIC SECRETION

Phase	Stimulus to Secretion	Secretion
Cephalic (nervous)	Sight, smell, taste of food (before food enters stomach); initiated in the CNS and mediated by the vagus nerve	HCl, pepsinogen, mucus
Gastric (hormonal and nervous)	Food in antrum of stomach, vagal stimulation	Release of gastrin from antrum into circulation to stimulate gastric secretions and motility
Intestinal (hormonal)	Presence of acidic chyme (pH <2) in small intestine stimulates release of secretin, gastric inhibitory polypeptide, and cholecystokinin into circulation to decrease acid secretion	Chyme (pH >3) stimulates release of duodenal gastrin to increase acid secretion

CNS, central nervous system; *HCl*, hydrochloric acid.

TABLE 41-3

MAJOR HORMONES CONTROLLING GASTRO-INTESTINAL SECRETION AND MOTILITY

Hormone	Source	Activating Stimuli	Function
Gastrin	Gastric and duodenal mucosa	Stomach distension, partially digested proteins in pylorus	Stimulates gastric acid secretion and motility; maintains lower esophageal sphincter tone
Secretin	Duodenal mucosa	Acid entering small intestine	Inhibits gastric motility and acid secretion; stimulates pancreatic bicarbonate secretion
Cholecystokinin	Duodenal mucosa	Fatty acids and amino acids in small intestine	Causes contraction of gallbladder and relaxation of sphincter of Oddi, allowing increased flow of bile into duodenum; stimulates release of pancreatic digestive enzymes
Gastric inhibitory peptide	Duodenal mucosa	Fatty acids and lipids in small intestine	Inhibits gastric acid secretion and gastric motility

Digestion is completed in the small intestine, where carbohydrates are hydrolyzed to monosaccharides, fats to glycerol and fatty acids, and proteins to amino acids. The physical presence of *chyme* (food mixed with gastric secretions), along with its chemical nature in the small intestine, stimulates motility and secretion. Secretions involved in digestion include enzymes from the pancreas, bile from the liver (see Table 41-1), and intestinal secretions from glands in the small intestine. Both secretion and motility are under neural and hormonal control.

When food enters the stomach and small intestine, hormones are released into the bloodstream (see Table 41-3). The hormone *secretin* stimulates the pancreas to secrete fluid with a high concentration of bicarbonate. This alkaline secretion enters the duodenum and neutralizes

acid in the chyme. The duodenal mucosa also secretes mucus to protect against the HCl acid. In response to the presence of chyme, the hormone *cholecystokinin* (CCK), produced by the duodenal mucosa, enters the bloodstream and stimulates contraction of the gallbladder and relaxation of the sphincter of Oddi. These actions enable bile to flow from the common bile duct into the duodenum. Bile is necessary for the digestion of fats. CCK also stimulates the pancreas to synthesize and secrete enzymes for enzymatic digestion of carbohydrates, fats, and proteins.

Enzymes on the brush border of the microvilli complete the digestion process. These enzymes hydrolyze disaccharides to monosaccharides and peptides to amino acids for absorption.

Absorption is the transfer of the end products of digestion across the intestinal wall to the circulation. Most absorption occurs in the small intestine. The surface area of the small intestine is greatly increased by its circular folds, villi, and microvilli. The movement of the villi enables the end products of digestion to come in contact with the absorbing membrane. Monosaccharides (from carbohydrates), fatty acids (from fats), amino acids (from proteins), water, electrolytes, and vitamins are absorbed.

Elimination

Large Intestine.

The large intestine is a hollow, muscular tube approximately 1.5 to 2 m long and 5 cm in diameter. The four parts of the large intestine are (a) the cecum and the appendix, a narrow tube at the end of the cecum; (b) the colon (ascending colon on the right side, transverse colon across the abdomen, descending colon on the left side, and the sigmoid colon); (c) the rectum; and (d) the anus, the terminal portion of the large intestine (Figure 41-2).

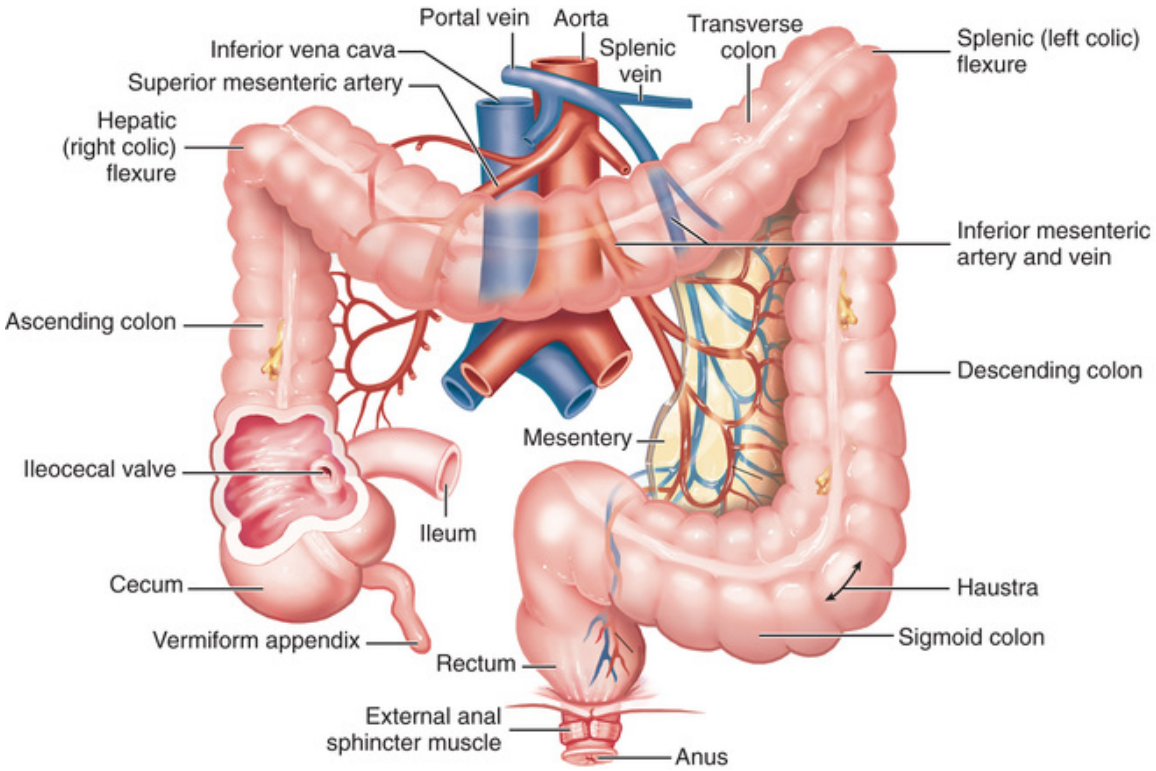

FIGURE 41-2 Anatomical locations of the large intestine. Source: Patton, K. T., & Thibodeau, G. A. (2013). *Anatomy and physiology* (8th ed., p. 885). St. Louis: Mosby.

The most important function of the large intestine is the absorption of water and electrolytes. It also forms feces and serves as a reservoir for the fecal mass until defecation occurs. Feces are composed of water, bacteria, food residue, unabsorbed GI secretions, and desquamated epithelial cells. The large intestine secretes mucus, which acts as a lubricant and protects the mucosa.

Microorganisms in the colon play an important role in metabolism of bile salts, estrogens, androgens, lipids, carbohydrates, various nitrogenous substances, and drugs, as well as in protecting against infection. Intestinal bacteria are responsible for the breakdown of proteins not digested or absorbed in the small intestine. These amino acids are deaminated by the bacteria, leaving ammonia, which is carried to the liver and converted to urea. Bacteria in the colon also synthesize vitamin K and some of the B vitamins. In addition, bacteria play a part in the production of flatus.

The movements of the large intestine are usually slow. When the circular muscles contract, they produce a kneading action termed *haustral churning*. Propulsive mass movement (peristalsis) also occurs. When food enters the stomach and the duodenum, the gastro-colic and duodeno-colic

reflexes are initiated, resulting in peristalsis in the colon. These reflexes are more active after the first daily meal and frequently result in bowel evacuation.

Defecation, the discharge of feces from the rectum, is a reflex action involving voluntary and involuntary control. Feces in the rectum stimulate sensory nerve endings that produce the urge to defecate. The reflex centre for defecation is in the sacral portion of the spinal cord (parasympathetic nerve fibres). These fibres produce contraction of the rectum and relaxation of the internal anal sphincter. Defecation is controlled voluntarily by relaxing the external anal sphincter when the urge to defecate is felt. An acceptable environment for defecation is usually necessary; otherwise the urge to defecate is suppressed. If defecation is suppressed over long periods, problems can occur, such as constipation or stool impaction.

Defecation can be facilitated by appropriate positioning (sitting or squatting) or by the **Valsalva manoeuvre.** This manoeuvre involves contraction of the chest muscles on a closed glottis with simultaneous contraction of the abdominal muscles. These actions result in increased intra-abdominal pressure. The Valsalva manoeuvre may be contraindicated in patients with head injury, cardiac problems, hemorrhoids, or liver cirrhosis with portal hypertension and in those who have undergone recent eye or abdominal surgery.

Liver, Biliary Tract, and Pancreas

Liver.

The liver is the largest internal organ in the body, weighing approximately 1 200 to 1 600 g in adults. It lies in the right hypochondriac and epigastric regions (see Figure 41-5 later in chapter) and is divided into right and left lobes (Figure 41-3). Glisson's capsule, which contains blood vessels, lymphatic vessels, and nerves, covers the liver. Liver disease or swelling may cause this capsule to become distended, leading to pain and oozing of lymphatic fluid into the peritoneal space.

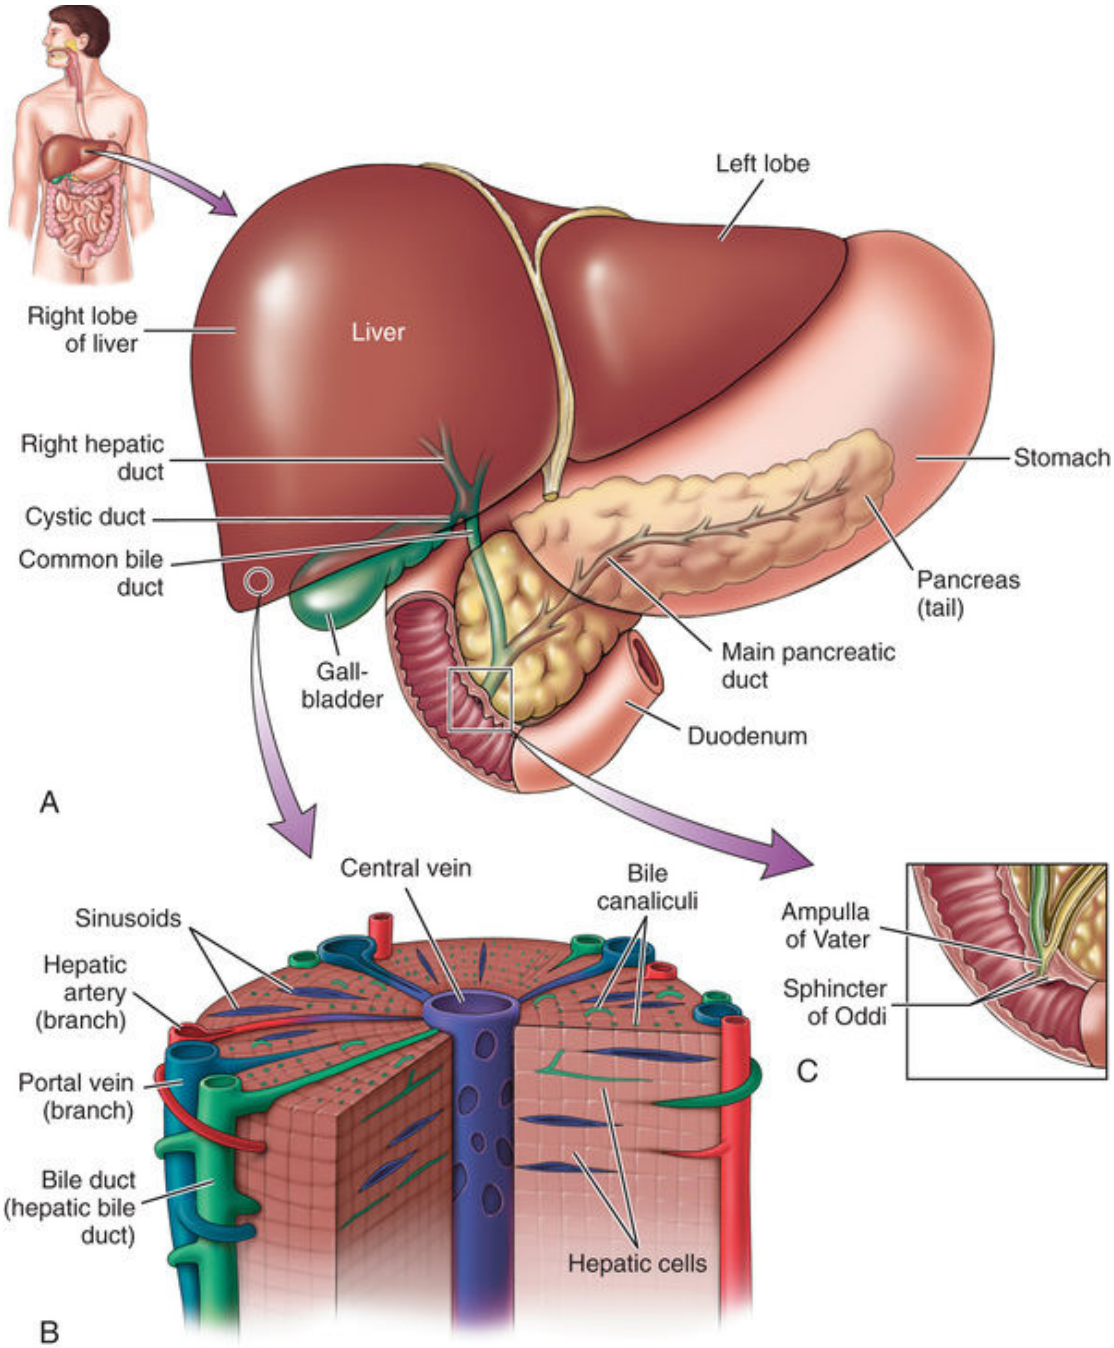

FIGURE 41-3 **A,** Gross structure of the liver, gallbladder, pancreas, and duct system. **B,** Liver lobule. **C,** Entrance of the common bile duct into the duodenum.

The functional units of the liver are lobules. The lobule consists of plates of specialized hepatic cells **(hepatocytes)** arranged around a central vein. The capillaries (sinusoids) are located between the plates of hepatocytes and are lined with **Kupffer cells,** which carry out phagocytic activity (removal of bacteria and toxins from the blood). Kupffer cells also ingest

aged red blood cells, breaking down hemoglobin into heme and globin. The heme is further broken down into iron and bilirubin, which is secreted into the bile. Interlobular bile ducts form from bile capillaries *(canaliculi).* The hepatic cells secrete bile into the canaliculi.

The nerve supply to the liver is from the left vagus and the sympathetic celiac plexus. The liver receives both arterial and venous blood. About one-third of the blood supply comes from the hepatic artery (branch of the celiac artery), and two-thirds comes from the portal vein.

A large amount of blood is required for the liver to fulfill its metabolic functions. The portal (enterohepatic) circulatory system brings blood to the liver from the stomach, intestines, spleen, and pancreas. This blood enters the liver through the portal vein. The portal vein carries absorbed products of digestion directly to the liver. In the liver, the portal vein branches and comes into contact with each lobule. The blood in the sinusoids is a mixture of arterial and venous blood.

The liver is essential for life. It functions in the manufacture, the storage, the transformation, and the excretion of a number of substances involved in metabolism. The functions of the liver are numerous but can be classified into three main areas, as identified in Table 41-4.

TABLE 41-4
MAJOR FUNCTIONS OF THE LIVER

Function	Description
Metabolic Functions	
Carbohydrate metabolism	Glycogenesis (conversion of glucose to glycogen), glycogenolysis (process of breaking down glycogen to glucose), gluconeogenesis (formation of glucose from amino acids and fatty acids)
Protein metabolism	Synthesis of nonessential amino acids, synthesis of plasma proteins (except γ-globulin), urea formation from NH_3 (NH_3 formed from deamination of amino acids by action of bacteria on proteins in colon)
Fat metabolism	Synthesis of lipoproteins, breakdown of triglycerides into fatty acids and glycerol, formation of ketone bodies, synthesis of fatty acids from amino acids and glucose, synthesis and breakdown of cholesterol
Detoxification	Inactivation of drugs and harmful substances and excretion of their breakdown products
Steroid metabolism	Conjugation and excretion of gonadal and adrenal steroid hormones
Bile Synthesis	
Bile production	Formation of bile, containing bile salts, bile pigments (mainly bilirubin), and cholesterol
Bile excretion	Bile excretion by liver (≅1 L/day)
Storage	Glucose in form of glycogen; fat-soluble vitamins (A, D, E, and K) and water-soluble vitamins (B_1, B_2, cobalamin, folic acid); fatty acids; minerals (iron and copper); amino acids in form of albumin and β-globulins
Mononuclear Phagocyte System	
Kupffer cells	Breakdown of old RBCs, WBCs, bacteria, and other particles; breakdown of hemoglobin from old RBCs to bilirubin and biliverdin

NH_3, ammonia; *RBC*, red blood cell; *WBC*, white blood cell.

Biliary Tract.

The biliary tract consists of the gallbladder and the duct system. The gallbladder is a pear-shaped sac located below the liver. The function of the gallbladder is to concentrate and store bile. It can hold approximately 45 mL of bile.

Bile is produced by the hepatic cells and secreted into the biliary canaliculi of the lobules. Bile then drains into the interlobular bile ducts, which unite into the two main left and right hepatic ducts. The hepatic ducts merge with the cystic duct from the gallbladder to form the common bile duct (see Figure 41-3). Most bile is stored and concentrated in the gallbladder. It is then released into the cystic duct and moves down the common bile duct to enter the duodenum at the ampulla of Vater. In the intestines, most of the bilirubin is reduced to stercobilinogen and urobilinogen by bacterial action. Stercobilinogen accounts for the brown colour of stool. A small amount of conjugated bilirubin is reabsorbed by the blood. Some urobilinogen is reabsorbed by the blood and returned to

the liver through the portal circulation and excreted in the bile. An insignificant amount of urobilinogen is excreted in the urine.

Bilirubin Metabolism.

Bilirubin, a pigment derived from the breakdown of aged red blood cells, is produced constantly (Figure 41-4). Because it is insoluble in water, it is bound to albumin for its transport to the liver. This form of bilirubin is referred to as *unconjugated.* In the liver, bilirubin is conjugated with glucuronic acid. Conjugated bilirubin is water soluble and is excreted in bile. Bile also consists of water, cholesterol, bile salts, electrolytes, and phospholipids. Bile salts are needed for fat emulsification and digestion.

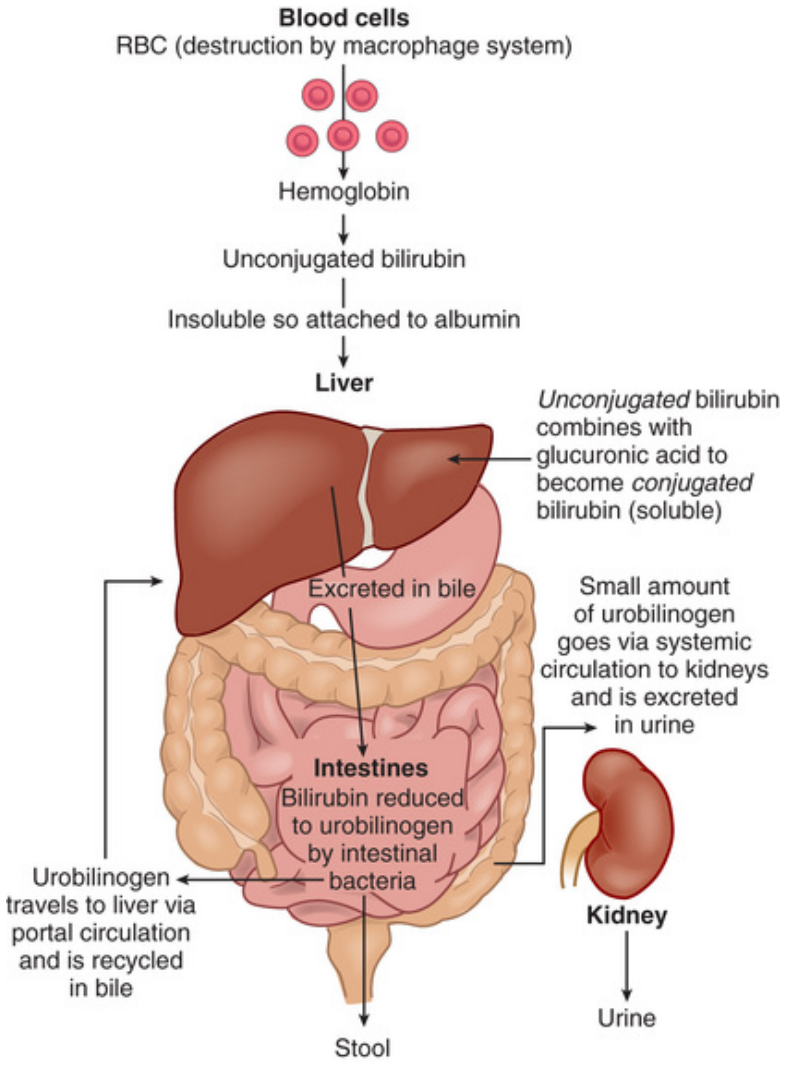

FIGURE 41-4 Bilirubin metabolism and conjugation. *RBC,* red blood cell.

Pancreas.

The pancreas is a 20-cm long, slender gland lying behind the stomach and in front of the first and second lumbar vertebrae. It consists of a head, a body, and a tail. The anterior surface is covered by peritoneum. The pancreas contains lobes and lobules. The pancreatic duct extends along the gland and enters the duodenum through the common bile duct (see Figure 41-3). The pancreas has both exocrine and endocrine functions. The exocrine function of the pancreas contributes to the process of digestion. Exocrine cells in the pancreas secrete pancreatic enzymes (see Table 41-1). The endocrine function occurs in the islets of Langerhans, whose beta cells

secrete insulin; alpha cells secrete glucagon; delta cells secrete somatostatin; and F cells secrete pancreatic polypeptide.

Age-Related Considerations

Effects of Aging on the Gastro-Intestinal System

The process of aging causes changes in the functional ability of the GI system, although to a lesser extent than in other organ systems (Table 41-5). Diet, alcohol intake, and obesity affect organs of the GI system, making it challenging to distinguish the effects of aging from lifestyle. Tooth enamel and dentin wear down, making the teeth susceptible to caries. Periodontal disease can lead to the loss of teeth. Xerostomia (decreased saliva production), or "dry mouth," affects many older adults and may be associated with difficulty swallowing (dysphagia). Dysphagia is characterized by abnormal passage of food from the mouth to the stomach. It may involve oral, pharyngeal, or esophageal processes of swallowing. Dysphagia is more common in older adults because of inadequate chewing or insufficient lubrication. The number of taste buds decreases, the sense of smell diminishes, and salivary secretions lessen, all of which can lead to a decrease in appetite and make eating less pleasurable.

TABLE 41-5

AGE-RELATED DIFFERENCES IN ASSESSMENT
Gastro-Intestinal System

Potential Changes	Differences in Assessment Findings
Mouth	
Periodontal disease	Red, swollen, bleeding gums; painful chewing; loose or sensitive teeth
Loss of teeth	Presence of dentures, difficulty chewing
Decreased sensitivity of taste buds, decreased sense of smell	Diminished sense of taste (especially saltiness and sweetness)
Decreased volume of saliva	Dry oral mucosa
Atrophy of gingival tissue	Poorly fitting dentures
Esophagus	
Decreased tone and motility	Complaints of pyrosis (heartburn), dysphagia, eructation (belching); potential for hiatal hernia and aspiration
Stomach	
Atrophy of gastric mucosa, decreased blood flow	Food intolerances; signs of anemia as result of cobalamin malabsorption; slower gastric emptying
Small Intestine	
Slightly decreased secretion of most digestive enzymes, decreased motility	Complaints of indigestion; slowed intestinal transit; delayed absorption of fat-soluble vitamins
Liver, Gallbladder, Pancreas	
Decreased size and lowered position	Easier palpation because lower border extends past costal margin
Decreased protein synthesis, decreased ability to regenerate cells	Decreased drug and hormone metabolism
Distension of pancreatic ducts, decreased lipase production, impairment of pancreatic reserve	Impaired fat absorption, decreased glucose tolerance
Large Intestine, Anus, Rectum	
Decreased anal sphincter tone and nerve supply to rectal area	Increased possibility of fecal incontinence
Decreased muscular tone, decreased motility	Flatulence, abdominal distension, relaxed perineal musculature
Increased transit time, decreased sensation to defecation	Constipation, fecal impaction

Age-related changes in the esophagus include delayed emptying caused by smooth muscle weakness and an incompetent lower esophageal sphincter (Miller, 2012). Motility of the GI system decreases with age, but secretion and absorption are affected to a lesser extent. Many older adults experience a decrease in HCl secretion (hypochlorhydria), delayed gastric emptying, and constipation. With chronic atrophic gastritis, the number of parietal cells decreases, and the amount of acid and intrinsic factor secreted is subsequently reduced. Intestinal villi are shortened and become more convoluted. Intestinal absorption, motility, and blood flow decrease, thus hampering nutrient absorption.

Liver mass decreases after the age of 40 years, but results of liver function tests remain within normal ranges. Age-related enzyme changes in the liver decrease the liver's ability to metabolize drugs and hormones.

Blood flow to the liver decreases, which affects the efficiency of drug metabolism. The size of the pancreas is unaffected by aging, but it does undergo structural changes such as fibrosis, fatty acid deposits, and atrophy. Secretion of digestive enzymes decreases. Aging does not cause changes in the structure and function of the gallbladder and bile ducts, although the incidence of gallstones increases (Heuman, 2017).

Rectal muscle mass is reduced, and the anal sphincter weakens. Changes in the enteric nervous system and a reduction in dietary fibre, along with reduced fluid intake and decreased physical activity, all contribute to constipation in older adults.

Older adults, especially those older than 85, are at risk for decreased food intake, as a result of financial, environmental, and social circumstances (Miller, 2012). Financial constraints can affect both the quality and quantity of food available. Age-related changes in the GI system and differences in assessment findings are presented in Table 41-5.

Assessment of the Gastro-Intestinal System

Subjective Data

Important Health Information

Past Health History.

Patients should be asked about changes in weight. Any unexplained or unplanned weight loss or weight gain within the past 12 months should be explored in detail. A history of chronic dieting and repeated weight loss and gain should also be documented. Usual patterns of elimination should be noted.

Information should be gathered about the history or existence of the following problems related to GI functioning: abdominal pain, nausea and vomiting, diarrhea, constipation, abdominal distension, jaundice, anemia, heartburn, dyspepsia, changes in appetite, hematemesis, food intolerance (including lactose) or allergies, dysphagia, indigestion, excessive gas, bloating, melena, hemorrhoids, and rectal bleeding. In addition, patients should be asked about the frequency of bowel movements, use of laxatives and antacids, and history or existence of diseases such as gastritis, hepatitis, colitis, gallbladder disease, peptic ulcer, cancer, hernias (especially hiatal hernias), or infection with *Clostridium difficile.* (*C. difficile* is discussed in Chapter 45.)

Case Study

Patient Introduction

Source: Anton_Ivanov/Shutterstock.com.

Lyle Collins is a 58-year-old man from Drury, Ontario. Mr. Collins's wife and family drove 50 kilometres to take him to the hospital because of his deteriorating health. He comes into the emergency department (ED) doubled over in pain. He is grimacing and holding his abdomen with both arms and presents to the triage nurse.

Critical Thinking

Throughout this assessment chapter, think about Mr. Collins with the following questions in mind:

1. What are the possible causes for Mr. Collins's acute abdominal pain?
2. What would be the nurse's priority assessment?
3. What questions should the nurse ask Mr. Collins?
4. What should be included in the physical assessment? What would the nurse be looking for?
5. What diagnostic studies might be ordered?

Medications.

The health history should include an assessment of the patient's past and current use of medications. The names of all drugs, their frequency of use, and their duration of use are important. This is a critical aspect of history taking because many medications not only may have an effect on the GI system but also may be affected by abnormalities of the GI system and surrounding organs. The medication assessment should include information about the use of over-the-counter (OTC) drugs, prescription drugs, and herbal products and nutritional supplements (see Chapter 12). Many chemicals and drugs are potentially hepatotoxic (Table 41-6) and can result in significant harm to the patient unless their use is monitored closely. For example, chronic high doses of acetaminophen may be hepatotoxic. Nonsteroidal anti-inflammatory drugs (NSAIDs) (including acetylsalicylic acid [Aspirin]) may predispose patients to upper GI bleeding if not taken cautiously with food or if a patient has severe liver disease. Antibiotics can cause changes in the normal bacterial composition

in the GI tract that result in diarrhea. The nurse should ask patients about laxative or antacid use, including the type and the frequency.

TABLE 41-6
POTENTIALLY HEPATOTOXIC DRUGS

Dosage-Related	Idiosyncratic/Rare
• Acetaminophen (Tylenol) • ddl/d4T for HIV • Isoniazid (INH) • Methotrexate	• Amiodarone (Cordarone) • Alcohol • Amoxicillin-clavulanic acid (Clavulin) • Carbamazepine • Ketoconazole • NSAIDs • Ramipril (Altace) • Statins • Sulphonamides • Thiazolidinediones

d4T, stavudine; ddl, didanosine; *HIV,* human immunodeficiency virus; *NSAIDs,* nonsteroidal anti-inflammatory drugs.

Surgery or Other Treatments.

Information should be obtained about hospitalizations for any problems related to the GI system, particularly any abdominal or rectal surgery, including the year, the reason for surgery, the postoperative course, and any blood transfusions. Terms related to surgery of the GI system are listed in Table 41-7.

TABLE 41-7

SURGICAL PROCEDURES INVOLVING THE GASTRO-INTESTINAL SYSTEM

Surgical Procedure	Description
Antrectomy	Removal of antrum portion of stomach
Appendectomy	Removal of appendix
Cecostomy	Opening into cecum
Cholecystectomy	Removal of gallbladder
Cholecystostomy	Opening into gallbladder
Choledochojejunostomy	Opening between common bile duct and jejunum
Choledocholithotomy	Opening into common bile duct for removal of stones
Colectomy	Removal of colon
Colostomy	Opening into colon
Gastrectomy	Removal of stomach
Gastrostomy	Opening into stomach
Glossectomy	Removal of tongue
Hemiglossectomy	Removal of half of tongue
Ileostomy	Opening into ileum
Pyloroplasty	Enlargement and repair of pyloric sphincter area
Vagotomy	Resection of branch of vagus nerve

Case Study—cont'd

Subjective Data

Source: Anton_Ivanov/Shutterstock.com.

A focused subjective assessment of Mr. Collins reveals the following information:

History of current illness: Mr. Collins states he has not been feeling well for the past several weeks. He feels weak and is easily fatigued. Denies exposure to chemicals. No recent travel outside of Canada. Rates pain as a 9 on a scale of 0–10. States pain comes and goes in waves. Prefers to lie still with knees flexed and drawn into his abdomen. States has had alternating episodes of constipation and diarrhea. He noticed some bright red blood in stools. Has not had a bowel movement for 4 days.

Past medical history: Negative history for medical or surgical problems.

Medications: None.

Functional assessment: Mr. Collins is 175 cm tall and weighs 64 kg (BMI: 20.9 kg/m^2). States has been losing weight over the past several months and does not have an appetite. No food allergies. Smokes approximately 1 pack of cigarettes/day for 20 yr. Drinks beer on a daily basis, typically three or four bottles per day.

See pp. 960 and 967 for more information on Mr. Collins.

Objective Data

In addition to collecting subjective data related to the patient's diet history and overall health (Table 41-8), objective data related to a nutritional assessment should be obtained. Examples of objective data include anthropometric measurements (height, weight, skinfold thickness), results

of blood studies such as serum protein, albumin, and hemoglobin levels, as well as a physical examination.

TABLE 41-8

HEALTH HISTORY
Gastro-Intestinal System: Questions for Obtaining Subjective Data

Appetite
• Any change in appetite?* Are you more or less hungry? • Any change in weight?* Do your clothes still fit the same as they used to? How much weight have you gained or lost? Over what time frame? Is the change in weight intentional?
Dysphagia
• Any problems swallowing?* How long have you had this problem?
Food Intolerance or Allergies
• Are there any foods you cannot eat?* What happens when you do eat them (e.g., heartburn, gas, bloating, indigestion, allergic reaction)?
Abdominal Pain
• Do you have any abdominal pain?* • Is the pain in one spot, or does it move around? • How long have you had this pain? • Does it come and go, or is it constant? Does it get worse before or after meals? When is the pain worst (e.g., position, stress, activity)? • Can you describe how it feels (e.g., cramping, burning, stabbing, aching)? • What brings on the pain (e.g., menstruation, stress, overeating, fatigue)? • Do any other symptoms occur when you have the pain (e.g., nausea and vomiting, gas, rectal bleeding, frequent urination, vaginal or penile discharge)?* • What works to relieve the pain (e.g., rest, heat, walking, change of position, medication)?*
Nausea and Vomiting
• Any nausea or vomiting?* How much comes up? • What colour is it? Is it bloody? Is there a particular odour? • Do you have pain, diarrhea, fever, or chills at the same time as the nausea and vomiting? • Does anyone else you have been in contact with over the past 24 hours have the same symptoms? Have you eaten any foods in the past 24 hours that you suspect may be the cause?
Bowel Habits
• How often do you have a bowel movement? • Any recent changes in colour, consistency, or frequency? • Any problems with diarrhea or constipation? • Do you use laxatives or stool softeners? Which ones? How often?
Past History
• Any past problems with your digestive system (e.g., ulcer, gallbladder problems, hepatitis, appendicitis, colitis, hernia)?* • Any surgical procedures on your abdomen?* • Do you know the results of any tests that were done relating to your abdomen?*
Medications
• What medications are you currently taking? • How much alcohol do you drink each day? When was your last alcoholic drink? • Do you smoke? How many packs a day?
Nutrition Assessment
• Describe your usual daily food and fluid intake.

*If yes, describe.

Source: Based on Jarvis, C., Browne, A. J., MacDonald-Jenkins, J., et al. (Eds.). (2014). *Physical examination and health assessment* (2nd Canadian ed., 553–554). Toronto: W. B. Saunders.

Physical Examination

Mouth

Inspection.

The lips should be inspected for symmetry, colour, and size and for abnormalities such as pallor or cyanosis, cracking, ulcers, or fissures. The dorsum (top) of the tongue should have a thin white coating; the undersurface should be smooth. The nurse should observe for any lesions. Using a tongue blade, the nurse should inspect the buccal mucosa and note the colour, any areas of pigmentation, and any lesions. Dark-skinned individuals normally have patchy areas of pigmentation. When assessing the teeth and gums, the nurse should look for caries; loose teeth; abnormal shape and position of teeth; and swelling, bleeding, discoloration, or inflammation of the gingivae. Any distinctive breath odour should be noted.

The pharynx is inspected by tilting the patient's head back and depressing the tongue with a tongue blade. The tonsils, the uvula, the soft palate, and the anterior and posterior pillars should be observed. The nurse should have the patient say, "Ah." The uvula and the soft palate should rise and remain in the midline.

Palpation.

The nurse should palpate any suspect areas in the mouth such as ulcers, nodules, indurations, and areas of tenderness.

In older adults, the mouth must be assessed carefully. Particular attention should be given to the condition of the gums and the tongue, the fit and the condition of dentures (if present), the ability to swallow, and the presence of lesions. A patient who has dentures must remove the dentures during an oral examination to allow for adequate visualization and palpation of the area.

Abdomen.

Two anatomical systems are used to describe the surface of the abdomen. In one system, the abdomen is divided into four quadrants by a vertical line from the sternum to the pubic bone and by a perpendicular line across the abdomen at the umbilicus (Figure 41-5, *A*; Table 41-9). In the other system, the abdomen is divided into nine regions (see Figure 41-5, *B*), but only the epigastric, umbilical, and suprapubic or hypogastric regions are commonly addressed.

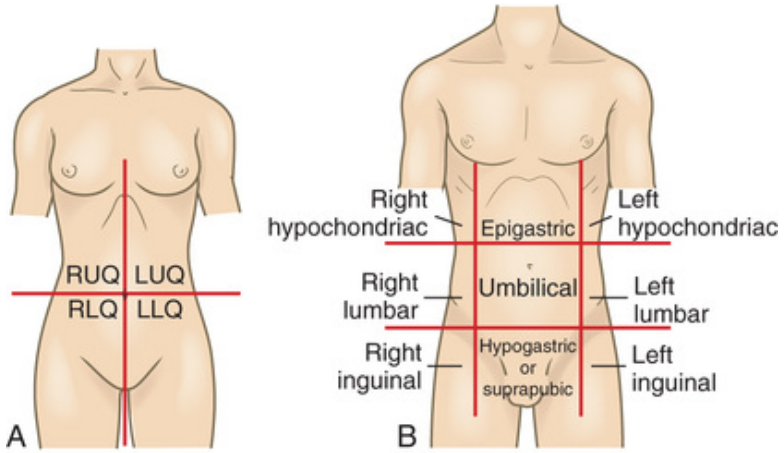

FIGURE 41-5 **A,** Abdominal quadrants. **B,** Abdominal regions. *LLQ,* left lower quadrant; *LUQ,* left upper quadrant; *RLQ,* right lower quadrant; *RUQ,* right upper quadrant.

TABLE 41-9
ABDOMINAL STRUCTURES IN REGIONS OF ABDOMEN

Right Upper Quadrant	Left Upper Quadrant	Right Lower Quadrant	Left Lower Quadrant
• Liver and gallbladder • Pylorus • Duodenum • Head of pancreas • Right adrenal gland • Portion of right kidney • Hepatic flexure of colon • Portion of ascending and transverse colon	• Left lobe of liver • Spleen • Stomach • Body of pancreas • Left adrenal gland • Portion of left kidney • Splenic flexure of colon • Portion of transverse and descending colon	• Lower pole of right kidney • Cecum and appendix • Portion of ascending colon • Bladder (can be palpated only if distended) • Right ovary and salpinx • Uterus (can be palpated only if enlarged) • Right spermatic cord • Right ureter	• Lower pole of left kidney • Sigmoid flexure • Portion of descending colon • Bladder (can be palpated only if distended) • Left ovary and salpinx • Uterus (can be palpated only if enlarged) • Left spermatic cord • Left ureter

Good lighting is required for the abdominal examination. The patient should be in the supine position and as relaxed as possible. To help relax the abdominal muscles, the patient should slightly flex the knees, and the head of the bed should be raised slightly. The patient should have an empty bladder. The nurse's hands should be warm when the abdominal examination is performed, to avoid eliciting muscle guarding. The patient should be instructed to breathe slowly through the mouth.

Inspection.

The nurse should assess the abdomen for skin changes (colour, texture, scars, striae, dilated veins, rashes, and lesions), umbilicus (location and

contour), symmetry, contour (flat, rounded [convex], concave, protuberant, distended), observable masses (hernias or other masses), and movement (pulsations and peristalsis). A normal aortic pulsation may be visible in the epigastric area. The nurse should look across the abdomen tangentially (across the abdomen in a line) for peristalsis. Peristalsis is not normally visible in an adult but may be visible in a thin person.

Auscultation.

During examination of the abdomen, the nurse should auscultate before percussion and palpation because these latter procedures may alter the bowel sounds. Auscultation of the abdomen includes listening for increased or decreased bowel sounds and vascular sounds. The diaphragm of the stethoscope is used to auscultate bowel sounds because they are relatively high pitched. The bell of the stethoscope is used to detect lower-pitched sounds. Normal bowel sounds occur 5 to 35 times per minute and sound like high-pitched clicks or gurgles. Warming the stethoscope in the hands before auscultation helps prevent abdominal muscle contraction. The nurse should listen in the epigastrium and in all four quadrants (starting in the lower right quadrant) for bowel sounds for 2 to 5 minutes. A perfectly "silent abdomen" is uncommon (Jarvis, Browne, MacDonald-Jenkins, et al., 2014). After listening for several minutes, the nurse frequently finds that the sounds are not absent but hypoactive. If the nurse does not hear bowel sounds, the amount of time listened in each quadrant without hearing bowel sounds should be noted.

The frequency and intensity of bowel sounds vary, depending on the phase of digestion. Normally, they sound relatively high pitched and gurgling. Loud gurgles indicate hyperperistalsis and are termed *borborygmi* (stomach growling). The bowel sounds are more high pitched (rushes and tinkling) when the intestines are under tension, such as in intestinal obstruction. The nurse should listen for decreased or absent bowel sounds. Terms used to describe bowel sounds include *present, absent, increased, decreased, high pitched, tinkling, gurgling,* and *rushing*. Normally, no aortic bruits should be heard. A bruit, best heard with the bell of the stethoscope, is a swishing or buzzing sound and indicates turbulent blood flow.

Percussion.

The purpose of percussion of the abdomen is to determine the presence of fluid, distension, and masses. Sound waves vary according to the density of underlying tissues. The presence of air produces a higher-pitched,

hollow sound, termed *tympany,* and the presence of fluid or masses produces a short, high-pitched sound with little resonance, termed *dullness.* The nurse should lightly percuss all four quadrants of the abdomen and assess the distribution of tympany and dullness. Tympany is the predominant percussion sound of the abdomen.

Dullness in the dependent parts of the abdomen may reflect ascites (see Table 41-11). Percussion for s*hifting dullness* is a test used to assess for ascites. With the person in supine position, the nurse percusses from the top of the abdomen down the sides of the abdomen and marks the border between tympany and dullness. Then the person is turned onto the side and the nurse percusses from the upper side of the abdomen downward. The sound changes from tympany to dullness as the fluid level is reached (Jarvis et al., 2014).

To percuss the liver, the nurse should start below the umbilicus in the right midclavicular line and percuss lightly upward until dullness is heard, thus determining the lower border of liver dullness. After determining the lower border of the liver, the nurse should start at the nipple line in the right midclavicular line and percuss downward between ribs to the area of dullness, which indicates the upper border of the liver. The height or vertical space between the two areas should be measured to determine the size of the liver. The height of the person correlates directly with the span of the liver. The normal range of liver span is 6 to 12 cm. A liver span greater than 12 cm may indicate liver enlargement.

Palpation.

Light palpation is used to detect tenderness or cutaneous hypersensitivity, muscular resistance, masses, and swelling. It also helps patients to relax for deeper palpation. The nurse should keep fingers together and press gently with the pads of the fingertips, depressing the abdominal wall about 1 cm. Smooth movements should be used and all quadrants palpated (Figure 41-6, *A*). *Voluntary guarding* occurs when the person is ticklish, cold, or tense, and it occurs bilaterally. The nurse should help the person to relax because guarding interferes with deep palpation.

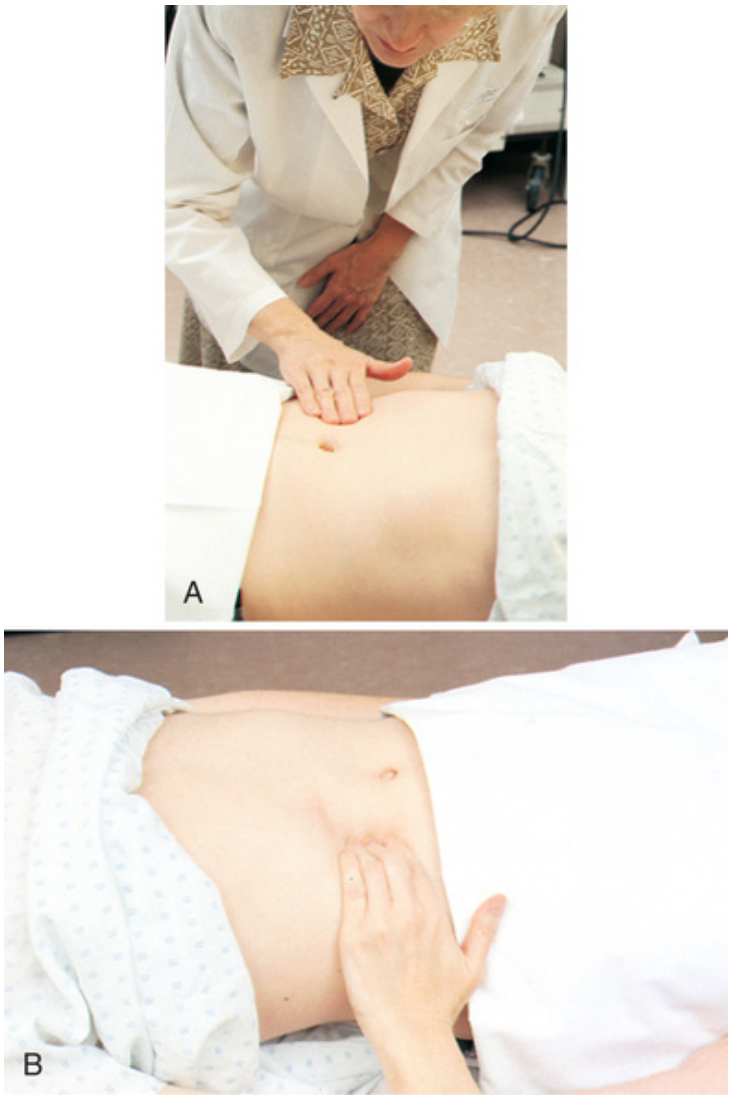

FIGURE 41-6 Palpation of the abdomen. **A,** Technique for light palpation. **B,** Technique for deep palpation. Source: Doughty, D. B., & Jackson, D. B. (1993). *Mosby's clinical nursing series: Gastrointestinal disorders.* St. Louis: Mosby.

Deep palpation is used to delineate abdominal organs and masses (see Figure 41-6, *B*). The palmar surfaces of the fingers should be used to press more deeply. Again, all quadrants should be palpated. When palpating masses, note the location, the size, the shape, and the presence of tenderness. The patient's facial expression should be observed during these manoeuvres because it will provide nonverbal cues of discomfort or pain.

An alternative method for deep abdominal palpation is the two-hand method. One hand is placed on top of the other. The fingers of the top hand apply pressure to the bottom hand. The fingers of the bottom hand

feel for organs and masses. This method may be more effective with an obese abdomen.

Check any areas of concern for rebound tenderness by pressing in slowly and firmly over the painful site. The palpating fingers are withdrawn quickly. Pain on withdrawal of the fingers indicates peritoneal inflammation. Because assessing for rebound tenderness may produce pain and severe muscle spasm, it should be performed at the end of the examination and only by an experienced practitioner. The iliopsoas muscle test is performed when an acute or perforated appendix is suspected. With the patient in the supine position and the hip flexed, the right leg is lifted up. As the patient tries to keep the leg up, push the leg down over the lower part of the right thigh. Pain is felt in the right lower quadrant when the iliopsoas muscle is inflamed, which occurs with appendix inflammation or perforation.

To palpate the liver, the nurse's left hand is placed beneath the supine patient to support the right eleventh and twelfth ribs (Figure 41-7). The patient may relax on the nurse's hand. The nurse should press the left hand forward and place the right hand on the patient's right abdomen, lateral to the rectus muscle. The fingertips should be below the lower border of liver dullness and pointed toward the right costal margin. The nurse should gently press in and up. The patient should take a deep breath with the abdomen so that the liver drops and is in a better position to be palpated. The nurse should try to feel the liver edge as it comes down to the fingertips. During inspiration, the liver edge should feel firm, sharp, and smooth. The nurse should document the description of the surface, contour, and any tenderness.

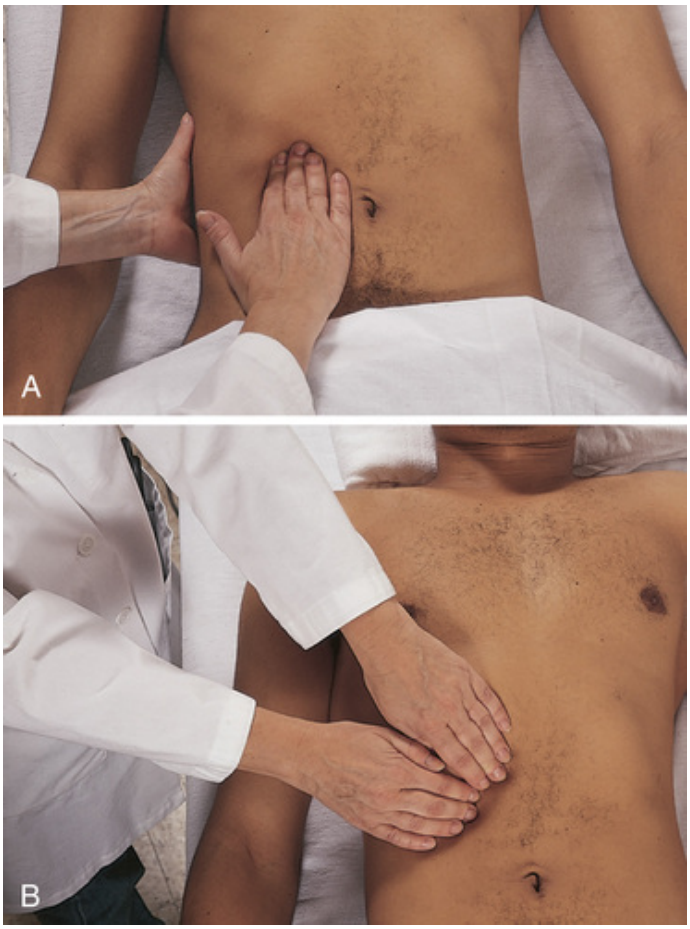

FIGURE 41-7 Liver palpation. **A,** Technique with one hand under the patient. **B,** Alternative technique to palpate liver with fingers hooked over the costal region. Source: Jarvis, C., Browne, A. J., MacDonald-Jenkins, J., et al. (Eds.). (2014). *Physical examination and health assessment* (2nd Canadian ed.). (5th ed., p. 578). Toronto: Elsevier.

To palpate the spleen, the nurse moves to the left side of the patient. The nurse places the right hand under the patient and supports and presses the patient's left lower rib cage forward. The left hand is placed below the left costal margin and presses it in toward the spleen. The nurse should ask the patient to breathe deeply. The nurse's fingertips can feel the tip or edge of an enlarged spleen. The spleen is not normally palpable. If it is palpable, the nurse should not continue because manual compression of an enlarged spleen may cause it to rupture.

Rectum and Anus.

The nurse should inspect the perianal and anal areas for colour, texture, lumps, rashes, scars, erythema, fissures, and external hemorrhoids. Any lumps or unusual areas should be palpated with a gloved hand.

For the digital examination of the rectum, the gloved, lubricated index finger is placed against the anus while the patient strains (Valsalva manoeuvre). Then, as the sphincter relaxes, the nurse inserts the gloved, lubricated finger. The finger is pointed toward the umbilicus. The nurse should try to get the patient to relax. The finger is inserted into the rectum as far as possible, and all surfaces are palpated. Nodules, tenderness, or any irregularities should be assessed. A sample of stool can be removed with the gloved finger and checked for occult blood. However, a single guaiac-based fecal occult blood test has limited sensitivity in detecting colorectal cancer.

Documentation of a normal physical assessment of the GI system is described in Table 41-10. Age-related differences in the GI system and differences in assessment findings are described in Table 41-5. Assessment abnormalities are listed in Table 41-11. A focused assessment is used to evaluate the status of previously identified GI problems and to monitor for signs of new problems (see Table 3-6). A focused assessment of the GI system is presented in the "Focused Assessment" box.

TABLE 41-10

NORMAL FINDINGS IN PHYSICAL ASSESSMENT OF THE GASTROINTESTINAL SYSTEM

Mouth
• Moist, pink lips • Moist, pink buccal mucosa and gingivae without plaques or lesions • Teeth in good repair • Protrusion of tongue in midline without deviation or fasciculations • Pink uvula in midline, soft palate, tonsils, and posterior pharynx • Smooth swallowing without coughing or gagging
Abdomen
• Flat without masses or scars • No abdominal tenderness • No bruises • Bowel sounds in all quadrants • Nonpalpable liver and spleen • Liver 10 cm in right midclavicular line • Generalized tympany
Anus
• Absence of lesions, fissures, and hemorrhoids • Good sphincter tone • Rectal walls smooth and soft • No masses • Stool soft, brown, and heme negative

TABLE 41-11

ASSESSMENT ABNORMALITIES
Gastro-Intestinal System

Finding	Description	Possible Etiology and Significance
Mouth		
Ulcer, plaque on lips or in mouth	Sore or lesion	Carcinoma, viral infections
Cheilosis	Softening, fissuring, and cracking of lips at angles of mouth	Riboflavin deficiency
Cheilitis	Inflammation of lips (usually lower) with fissuring, scaling, crusting	Often unknown
Geographic tongue	Scattered red, smooth (loss of papillae) areas on dorsum of tongue	Unknown
Smooth tongue	Red, slick appearance	Cobalamin deficiency
Leukoplakia	Thickened white patches	Premalignant lesion
Pyorrhea	Recessed gingivae, purulent pockets	Periodontitis
Herpes simplex	Benign vesicular lesion	Herpesvirus
Candidiasis	White, curdlike lesions surrounded by erythematous mucosa	*Candida albicans*
Glossitis	Reddened, ulcerated, swollen tongue	Exposure to streptococci, irritation, injury, vitamin B deficiencies, anemia
Acute marginal gingivitis	Friable, edematous, painful, bleeding gingivae	Irritation from ill-fitting dentures, calculus deposits on teeth, food impaction
Esophagus and Stomach		
Dysphagia	Difficulty swallowing, sensation of food sticking in esophagus	Esophageal problems, cancer of esophagus
Hematemesis	Vomiting of blood	Esophageal varices, bleeding peptic ulcer (bleeding in upper GI tract)
Pyrosis	Heartburn, burning in epigastric or substernal area	Hiatal hernia, esophagitis, incompetent lower esophageal sphincter
Dyspepsia	Burning or indigestion	Peptic ulcer, gallbladder disease
Odynophagia	Painful swallowing	Cancer of esophagus, esophagitis
Eructation	Belching	Gallbladder disease
Nausea and vomiting	Feeling of impending vomiting, expulsion of gastric contents through mouth	GI infections, common manifestation of many GI diseases; stress, fear, and pathological conditions
Abdomen		
Distension	Excessive gas accumulation, enlarged abdomen; generalized tympany	Obstruction, paralytic ileus
Ascites	Accumulated fluid within abdominal cavity; eversion of umbilicus (usually)	Peritoneal inflammation, heart failure, metastatic carcinoma, cirrhosis
Bruit	Humming or swishing sound heard through stethoscope over vessel	Partial arterial obstruction (narrowing of vessel), turbulent flow (aneurysm)
Hyper-resonance	Loud, tinkling rushes	Intestinal obstruction
Borborygmi	Audible waves of loud, gurgling abdominal sounds produced by hyperactive bowel	Hyperactive intestinal peristalsis; result of eating, inflammatory bowel disease, infectious enteritis, mesenteric ischemia
Reduced or absent bowel sounds	No auscultation of bowel sounds	Peritonitis, paralytic ileus, obstruction; hypoactive bowel sounds are normal immediately post-op

Finding	Description	Possible Etiology and Significance
Absence of liver dullness	Tympany on percussion	Air from viscus (e.g., perforated ulcer)
Masses	Lump on palpation	Tumours, cysts
Rebound tenderness	Sudden pain when examiner's fingers are withdrawn quickly (Blumberg sign)	Peritoneal inflammation, appendicitis
Inspiratory arrest	Sharp pain stops inspiration when the liver is palpated during a deep breath (Murphy sign)	Cholecystitis
Nodular liver	Enlarged, hard liver with irregular edge or surface	Cirrhosis, carcinoma
Hepatomegaly	Enlargement of liver, liver edge >1–2 cm below costal margin	Metastatic carcinoma, hepatitis, venous congestion
Splenomegaly	Enlargement of spleen	Chronic leukemia, hemolytic states, portal hypertension, some infections
Hernia	Bulge or nodule in abdomen, usually appearing on straining	Inguinal (in inguinal canal), femoral (in femoral canal), umbilical (herniation of umbilicus), or incisional (defect in muscles after surgery)
Rectum and Anus		
Hemorrhoids	Thrombosed veins in rectum and anus (internal or external)	Portal hypertension, chronic constipation, prolonged sitting or standing, pregnancy
Mass	Firm, nodular edge	Tumour, carcinoma
Pilonidal cyst	Opening of sinus tract, cyst in midline just above coccyx	Probably congenital
Fissure	Ulceration in anal canal	Straining, irritation
Melena	Abnormal, black, tarry stool containing digested blood	Cancer, bleeding in upper GI tract from ulcers, varices
Tenesmus	Spasmodic contraction of the anal sphincter with pain and persistent desire to empty the bowel; painful and ineffective straining at stool	Ulcerative colitis, diarrhea secondary to GI infection such as food poisoning
Steatorrhea	Passage of large amounts of fat as a fatty, frothy, foul-smelling stool	Chronic pancreatitis, biliary obstruction, malabsorption problems (result of failure to digest and absorb fat)

GI, gastro-intestinal.

Focused Assessment

Gastro-Intestinal (GI) System

Use this checklist to make sure the key assessment steps have been done.

Subjective

Ask the patient about any of the following and note the responses:

Loss of appetite	Y	N
Abdominal pain	Y	N
Changes in stools; if so, check colour, consistency, frequency, for presence of blood and any other unexpected findings	Y	N
Nausea, vomiting	Y	N
Painful swallowing	Y	N

Objective: Diagnostic

Check the following laboratory results for critical values:

Endoscopy: colonoscopy, sigmoidoscopy, esophago-gastro-duodenoscopy	✓
Radiology: upper GI series, lower GI series	✓
Stool for occult blood or ova and parasites	✓
Liver function tests	✓

Objective: Physical Examination

Inspect

Skin for colour, lesions, scars, petechiae, and any other unexpected findings	✓
Abdominal contour for symmetry and distension	✓
Anus and rectum for intact skin, presence or absence of hemorrhoids	✓

Auscultate*

Bowel sounds	✓

Palpate

Abdominal quadrants with light touch	✓
Abdominal quadrants with deep technique	✓

*Note: Perform auscultation before palpation.

Case Study

Objective Data: Physical Examination

Source: Anton_Ivanov/Shutterstock.com.

A focused assessment of Mr. Collins reveals the following: BP 120/74, heart rate 110, respiratory rate 24, temp 38°C. Abdomen firm and slightly distended. High-pitched bowel sounds in upper quadrants. No bowel sounds auscultated in left lower quadrant. Mild abdominal palpation elicits pain.

As you continue to read this chapter, consider diagnostic studies that may be ordered for Mr. Collins.

See pp. 956 and 967 for more information on Mr. Collins.

Diagnostic Studies of the Gastro-Intestinal System

Diagnostic studies provide objective data for monitoring the patient's condition and planning appropriate interventions. Table 41-12 lists common diagnostic studies of the GI system. For most diagnostic studies, the nurse should make sure that a signed consent form for the procedure has been completed and is in the patient's health care record. It is the responsibility of the health care provider performing the procedure to explain the procedure and obtain the written consent. However, nurses play an important role in educating patients regarding the procedures. When preparing patients, the nurse must ask about any known allergies to drugs or contrast media.

TABLE 41-12

DIAGNOSTIC STUDIES
Gastro-Intestinal (GI) System

Study	Description and Purpose	Nursing Responsibility
Radiology		
Upper GI series or barium swallow study	Fluoroscopic radiographic study using contrast medium Used to diagnose structural abnormalities of the esophagus, the stomach, and the duodenal bulb	Explain procedure to patient, including the need to drink contrast medium and to assume various positions on radiographic study examination table. Keep patient NPO for 8–12 hr before procedure. Instruct patient to avoid smoking after midnight the night before the study. After radiograph, take measures to prevent contrast medium impaction (fluids, laxatives). Warn patient that stool may be white for up to 72 hr after test.
Small bowel series	Fluoroscopic radiographic study using contrast medium Images are obtained q30 min until medium reaches terminal ileum	Same as for upper GI series.
Lower GI series or barium enema study	Fluoroscopic radiographic examination of colon using contrast medium, which is administered rectally (enema) Double-contrast or air-contrast barium enema is test of choice Air is infused after thick barium flows through transverse colon Endoscopic procedures have made necessity for this test less common than in the past	The evening before the procedure, administer purgatives, laxatives, enemas, or a combination of these until colon is clear of stool. The patient is put on a clear liquid diet the evening before procedure. Keep patient NPO for 8 hr before test. Instruct patient about being given barium by enema. Explain that cramping and urge to defecate may occur during procedure and that patient may be placed in various positions on tilt table. After the procedure, administer fluids, laxatives, or suppositories to assist in expelling barium. Observe stool for passage of contrast medium.
Cholangiography		

Study	Description and Purpose	Nursing Responsibility
• Percutaneous transhepatic cholangiography (PTC)	Fluoroscopic radiographic study used to determine filling of hepatic and biliary ducts After local anaesthesia is induced and with monitored anaesthesia care (formerly called *conscious sedation*), liver is entered with long needle (under fluoroscopy), bile duct is entered, bile withdrawn, and radiopaque contrast medium injected IV antibiotics are administered prophylactically	Observe patient for signs of hemorrhage, bile leakage, and infection. Assess patient's medications for possible contraindications, precautions, or complications with the use of contrast medium.
• Surgical cholangiography	Study performed during surgery on biliary structures, such as gallbladder Contrast medium is injected into common bile duct	Explain to patient that anaesthetic and contrast medium will be used. Assess patient's medications for possible contraindications, precautions, or complications with the use of contrast medium.
• Magnetic resonance cholangiopancreatography (MRCP)	MRI technology used to obtain images of biliary and pancreatic ducts	Explain procedure to patient. Contraindicated in patient with metal implants (e.g., pacemaker) or who is pregnant.
Ultrasonography	Nonradiographic study used to show the size and configuration of organs Noninvasive procedure in which high-frequency sound (ultrasound) waves are passed into body structures and recorded as they are reflected (bounded)	
• Abdominal ultrasonography	Ultrasound study used to detect abdominal masses (tumours and cysts), biliary and liver disease, gallstones A conductive gel (lubricant jelly) is applied to the skin and a transducer is placed on the area	Keep patient NPO for 8–12 hr before procedure. Air or gas can reduce quality of images. Food intake can cause gallbladder contraction, resulting in suboptimal study results.
• Endoscopic ultrasonography (EUS)	Ultrasound study using a small transducer installed on tip of endoscope Because EUS transducer gets close to the organs being examined, images obtained are often more accurate and detailed than images provided by traditional ultrasonography Detects and helps stage esophageal, gastric, rectal, biliary, and pancreatic tumours and abnormalities Also used to guide fine-needle aspiration to diagnose cancer or dysplasia	Same as for esophago-gastro-duodenoscopy.
Nuclear imaging scans (scintigraphy)	Radionuclide studies used to show size, shape, and position of organ Functional disorders and structural defects may be identified Radionuclide (radioactive isotope) is injected IV, and a counter (scanning) device picks up radioactive emission, which is recorded on paper Only tracer doses of radioactive isotopes are used	Tell patient that substance to be ingested contains only traces of radioactivity and poses little to no danger. Schedule no more than one radionuclide test per day. Explain to patient the need to lie flat during the scan.

Study	Description and Purpose	Nursing Responsibility
• Gastric emptying studies	Radionuclide studies used to assess ability of stomach to empty solids or liquids in patients with emptying disorders resulting from peptic ulcer, ulcer surgery, diabetes, gastric malignancies, or functional disorders • Solid-emptying study: cooked egg white containing ^{99m}Tc is eaten • Liquid-emptying study: orange juice with ^{99m}Tc is swallowed Sequential images from gamma camera are recorded q2min for up to 60 min	Same as for nuclear imaging scans.
• Hepatobiliary (HIDA) scintigraphy	Radionuclide study used to identify obstructions of bile ducts (e.g., gallstones, tumours), diseases of gallbladder, and bile leaks Patient is given ^{99m}Tc IV and positioned under camera to record distribution of tracer in the liver, biliary tree, gallbladder, and proximal small bowel	Same as for nuclear imaging scans.
• Scintigraphy of GI bleeding	Radionuclide study used to reveal exact site of active GI blood loss Patient is given ^{99m}Tc-labelled sulphur colloid or patient's own red blood cells (RBCs) labelled with ^{99m}Tc, and images of the abdomen are obtained at intermittent intervals	Same as for nuclear imaging scans.
Computed tomographic (CT) scan	Noninvasive radiological examination allows exposures at different depths Used to detect biliary tract, liver, and pancreatic disorders Use of oral and IV contrast media accentuates density differences	Explain procedures to patient. Determine sensitivity to iodine if contrast material is used.
Magnetic resonance imaging (MRI)	Noninvasive procedure using radiofrequency waves and a magnetic field Used to detect hepatobiliary disease, hepatic lesions, and sources of GI bleeding and to stage colorectal cancer IV contrast medium (gadolinium) may be used	Explain procedure to patient. Contraindicated in patients with metal implants (e.g., pacemaker) or who are pregnant.
Virtual colonoscopy	Combines CT scanning or MRI with computer virtual reality software to detect colon and bowel diseases and conditions, including polyps, colorectal cancer, diverticulosis, and lower GI bleeding Air is introduced via a tube placed in rectum to enlarge colon to enhance visualization Images obtained while patient is on back and stomach Computer combines images to form two- and three-dimensional images, which are viewed on monitor	Bowel preparation similar to that for colonoscopy (see below under "Endoscopy"). Unlike conventional colonoscopy, virtual colonoscopy necessitates no sedatives and no endoscope. Procedure takes about 15–20 min.
Endoscopy		

Study	Description and Purpose	Nursing Responsibility
Esophago-gastro-duodenoscopy (EGD)	Enables direct visualization of mucosal lining of esophagus, stomach, and duodenum with flexible endoscope Video imaging may be used to visualize stomach motility Inflammations, ulcerations, tumours, varices, or Mallory–Weiss tear may be detected Biopsy samples may be obtained, and varices can be treated with band ligation or sclerotherapy	Before the procedure: Keep patient on NPO status for 8 hr. Make sure signed consent is obtained. Give preoperative medication if ordered. Explain to patient that local anaesthetic may be sprayed on throat before insertion of endoscope and that patient will be sedated during the procedure. After the procedure: Keep patient NPO until gag reflex returns (usually 2–4 hr); gently tickle back of patient's throat to determine return of reflex. Instruct patient to use warm saline gargles for relief of sore throat. Check temperature q15–30 min for 1–2 hr (sudden temperature spike is sign of perforation).
Colonoscopy	Enables direct visualization of entire colon up to ileocecal valve with flexible fibre-optic endoscope Patient's position is changed frequently during procedure to assist with advancement of endoscope to cecum Used to detect and diagnose inflammatory bowel disease, polyps, tumours, and diverticulosis and to dilate strictures Procedure allows for removal of colonic polyps without laparotomy	Before the procedure: Bowel preparation is completed. Procedure varies with physician preference. For example, patient may be kept on clear fluids 1–2 days before procedure, and cathartic or enema (or both) administered the night before. An alternative is to give 4.5 L (1 gal) of polyethylene glycol (Colyte) the evening before (8-oz glass q10min). Purgatives such as PICO-SALAX may be administered. Explain to patient that a flexible endoscope will be inserted while patient is in side-lying position and that sedative will be given. After procedure: Be aware that patient may experience abdominal cramps caused by stimulation of peristalsis because bowel is constantly inflated with air during procedure. Observe for rectal bleeding and signs of perforation (e.g., malaise, abdominal distension, tenesmus). Check vital signs.

Study	Description and Purpose	Nursing Responsibility
Capsule endoscopy	Study most commonly used to visualize small intestine and diagnose diseases such as Crohn's disease, small bowel tumours, celiac disease, and malabsorption syndrome and to identify sources of possible GI bleeding in areas not accessible by upper endoscopy or colonoscopy Patient swallows a capsule (approximately the size of a large vitamin) with a camera that provides endoscopic observation of GI tract (see Figure 41-10); camera takes >50 000 images during 8-hr examination Capsule relays images to monitoring device that patient wears on belt After examination, images are downloaded to a workstation Not used in patients with suspected intestinal strictures	Dietary preparation: similar to that for colonoscopy. The video capsule is swallowed, and patient is usually kept NPO until 4–6 hr later. Procedure is comfortable for most patients. Eight hours after swallowing the capsule, the patient returns to have the monitoring device removed. Peristalsis causes passage of the disposable capsule with a bowel movement.
Sigmoidoscopy	Enables direct visualization of rectum and sigmoid colon with lighted flexible endoscope Sometimes special table is used to tilt patient into knee–chest position Used to detect tumours, polyps, inflammatory and infectious diseases, fissures, hemorrhoids	Administer enemas evening before and morning of procedure. Make sure signed consent is obtained. Patient may have clear liquids day before, or no dietary restrictions may be necessary. Explain to patient knee–chest position (unless patient is older adult or very ill), need to take deep breaths during insertion of scope, and possible urge to defecate as scope is passed. Encourage patient to relax and let abdomen go limp. Observe for rectal bleeding after polypectomy or biopsy.

Study	Description and Purpose	Nursing Responsibility
Endoscopic retrograde cholangiopancreatography (ERCP)	Endoscopic technique enables direct visualization of structures Fibre-optic endoscope (using fluoroscopy) is inserted through the oral cavity into descending duodenum, and then common bile and pancreatic ducts are cannulated Contrast medium is then injected into ducts Technique can also be used to retrieve a gallstone from distal common bile duct, dilate strictures, obtain biopsy of tumours, or diagnose pseudocysts	Before the procedure, explain procedure to patient, including patient's role. Keep patient NPO for 8 hr before procedure. Make sure signed consent is obtained. Administer sedative immediately before and during procedure. Administer antibiotics if ordered. After the procedure, check vital signs. Check for signs of perforation or infection. Be aware that ERCP-induced pancreatitis is most common complication; this complication manifests as abdominal pain, nausea, and vomiting. Check for return of gag reflex.
Endoscopic ultrasonography	Combined use of endoscopy and ultrasonography with the use of an ultrasound transducer attached to an endoscope Enables visualization of esophagus, stomach, intestine, liver, pancreas, and gallbladder	Similar to that for esophago-gastro-duodenoscopy.
Laparoscopy (peritoneoscopy)	Enables visualization of peritoneal cavity and contents with laparoscope Biopsy specimen may be obtained Performed with patient under general anaesthesia in operating room Double-puncture peritoneoscopy enables better visualization of abdominal cavity, especially liver Can eliminate need for exploratory laparotomy in many patients	Keep patient on NPO status for 8 hr before study. Make sure signed consent is obtained. Administer preoperative sedative. Ensure that bladder and bowel are emptied. Inform patient that local anaesthetic is used before laparoscope insertion. Observe for possible complications of bleeding and bowel perforation after the procedure.
Blood Studies		
Amylase	Measures secretion of amylase by pancreas Is important in diagnosing acute pancreatitis Level peaks in 24 hr and then drops to normal in 48–72 hr Depending on method, reference range is 100–300 U/L (60–120 SU/dL)	Obtain blood sample in acute attack of pancreatitis. Explain procedure to patient.
Lipase	Measures secretion of lipase by pancreas. Level stays elevated longer than that of serum amylase Reference range is <160 U/L	Explain procedure to patient.

Study	Description and Purpose	Nursing Responsibility
Gastrin	Measures secretion of gastrin by the cells of the antrum of the stomach and by the pancreatic islets of Langerhans Reference interval: 0–180 ng/L (0–180 pg/mL) during fasting	Explain procedure to patient.
Liver Biopsy	Percutaneous procedure uses needle inserted between sixth and seventh or between eighth and ninth intercostal spaces on the right side to obtain specimen of hepatic tissue Often performed under ultrasound or CT guidance	Before procedure, check patient's coagulation status (prothrombin time, clotting or bleeding time). Ensure that patient's blood is typed and crossmatched. Measure vital signs as baseline data. Explain holding of breath after expiration when needle is inserted. Make sure signed consent is obtained. After procedure, check vital signs to detect internal bleeding q15min × 2, q30min × 4, q1hr × 4. Keep patient lying on right side for a minimum of 2 hr to splint puncture site. Keep patient in bed in flat position for 12–14 hr. Assess patient for complications such as bile peritonitis, shock, and pneumothorax.
Fecal Tests		
Fecal immunochemical test	Tests for the presence of blood in stool Possible indicator of colorectal cancer	Explain procedure and indication to patient. No medical or dietary restrictions
Fecal analysis	Form, consistency, and colour of fecal sample are noted Specimen examined for mucus, blood, pus, parasites, and fat content Fecal occult blood test (FOBT): guaiac test, Hemoccult, Hemoccult II, Hemoccult-SENSA, Hematest are performed Single DNA test (PreGen-Plus) is a panel of DNA markers used to detect and monitor colorectal cancer	Observe patient's stools. Collect stool specimens. Check stools for blood. Keep diet free of red meat for 24–48 hr before occult blood test.
Stool culture	Tests for presence of bacteria, including *Clostridium difficile*	Collect stool specimen.

GI, gastro-intestinal; *IV,* intravenously; *ng/L,* nanograms per litre; *NPO,* nothing by mouth; *pg/mL,* pictograms per millilitre; *RBCs,* red blood cells; *SU,* Somogyi units; ^{99m}Tc, technetium-99m; *U/L,* units per litre; *WBCs,* white blood cells.

Many of the diagnostic procedures of the GI system necessitate measures to cleanse the GI tract, as well as the ingestion or injection of a contrast medium or a radiopaque tracer. Often, the patient undergoes a series of GI diagnostic tests. The patient is monitored closely to ensure

adequate hydration and nutrition during the testing period. Some diagnostic studies of the GI system are especially difficult and uncomfortable for older adults. It may be necessary to individualize care and make adjustments. Many radiological studies use either barium sulphate or diatrizoate meglumine and diatrizoate sodium (Gastrografin) as a contrast medium. Barium sulphate is more effective for visualizing mucosal detail. Gastrografin is water soluble and rapidly absorbed, so it is preferred when a perforation is suspected. If barium escapes into the peritoneal cavity, it can cause peritonitis. However, if the patient is at high risk for aspiration, use of water-soluble media is contraindicated and barium is preferred.

Radiological Studies

Upper Gastro-Intestinal Series.

An upper GI series with small bowel follow-through enables visualization of the esophagus, the stomach, and the small intestine by means of fluoroscopy and radiographic examination. A barium swallow study is used to identify esophageal, stomach, and small intestine disorders such as esophageal strictures, varices, polyps, tumours, hiatal hernia, and foreign bodies, as well as peptic ulcers in the stomach or duodenum. The barium swallow study begins with the patient swallowing a thick barium solution (contrast medium). The patient then assumes different positions on the radiographic study examination table. The movement of the contrast medium through the upper GI tract is observed with fluoroscopy, and several radiographic images are obtained (see Table 41-12).

Lower Gastro-Intestinal Series.

The purpose of a lower GI series (barium enema radiograph) is to observe by means of fluoroscopy the filling of the colon with contrast medium and to observe by radiograph the filled colon. This procedure helps identify polyps, tumours, and other lesions in the colon. The patient is administered an enema of contrast medium. The air-contrast barium enema provides better visualization of inflammatory bowel disease, polyps, tumours, and gallstones (Figure 41-8). Because the patient must retain the barium, this study is not tolerated well by patients who are older or immobile.

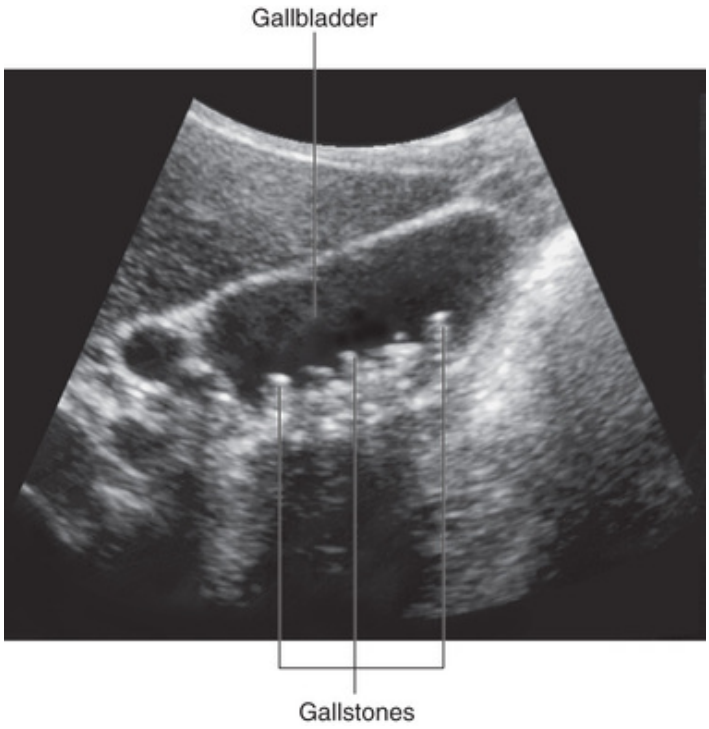

FIGURE 41-8 Ultrasound image of gallbladder, showing multiple gallstones. Source: Drake, R. L., Vogl, W., & Mitchell, A. W. M. (2010). *Gray's anatomy for students* (2nd ed., p. 326). Edinburgh: Churchill Livingstone.

Abdominal Ultrasonography.

Ultrasonography is a noninvasive, nonradiographic approach used to show the size and the configuration of organs. It is the diagnostic procedure of choice for detecting cholelithiasis (gallstones). Ultrasonography is also used for detecting appendicitis, acute cholecystitis, and other changes in abdominal organs (see Table 41-12).

Endoscopy

Endoscopy is the direct visualization of a body structure through a lighted fibre-optic instrument (endoscope). The GI structures that can be examined through endoscopy include the esophagus, the stomach, the duodenum, the colon, and, with the aid of fluoroscopy and radiographs, the pancreas and the biliary tree. The pancreatic, hepatic, and common bile ducts can be visualized with side-viewing flexible endoscopes. This procedure is called *endoscopic retrograde cholangiopancreatography* (ERCP) and is illustrated in Figure 41-9.

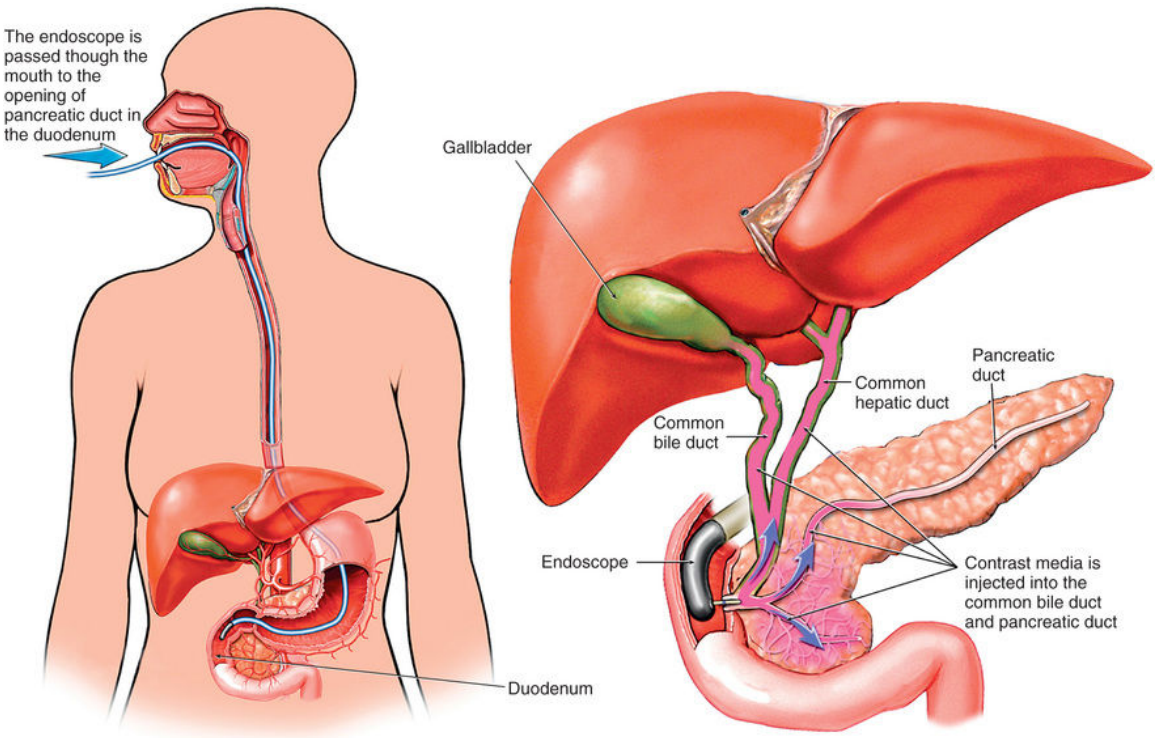

FIGURE 41-9 Endoscopic retrograde cholangiopancreatography.
Source: Nucleus Medical Media Inc./Alamy Stock Photo.

The endoscope is an instrument channel through which biopsy forceps and cytology brushes may be passed. Cameras may be attached to take video recordings and still pictures. Endoscopy of the GI tract is often performed in combination with biopsy and cytological studies. The major complication of GI endoscopy is perforation through the structure being viewed. The incidence of this complication is decreased with the use of the flexible fibre-optic endoscopes.

For all endoscopic procedures, informed written consent is required. Specific endoscopy procedures are discussed in Table 41-12. In addition to diagnostic procedures, many invasive and therapeutic procedures may be performed with endoscopes. These include procedures such as polypectomy, sclerosis of varices, laser treatment, cauterization of bleeding sites, papillotomy, removal of stones in the common bile duct, and balloon dilations. For many endoscopic procedures, patients require intravenous short-acting sedatives.

Case Study

Objective Data: Diagnostic Studies

Source: Anton_Ivanov/Shutterstock.com.

The ED physician performs a rectal examination and finds a palpable mass. The following diagnostic tests are ordered:

- CBC
- Electrolytes
- Liver function tests
- Urinalysis
- CT scan of the abdomen
- Colonoscopy

The CBC reveals an Hb of 68 mmol/L and an Hct of 20%. The white blood cell count is normal. The electrolytes, liver function tests, and urinalysis are within normal limits. The CT scan reveals pockets of gas and fluid in the ascending colon and two medium-sized tumours in the transverse colon.

See pp. 956 and 960 for more information on Mr. Collins.

Endoscopic Ultrasonography.

Endoscopic ultrasound (EUS) is a relatively new endoscopic technique that provides highly accurate images of the esophagus, GI tract, pancreas, and liver. EUS provides high-resolution imaging of the GI tract because of its unique ability to differentiate the histological layers of the GI tract wall. It is most often used for preoperative staging of esophageal, gastric, pancreatic, and colorectal cancers. It can also be used to detect gallstones.

Capsule Endoscopy.

In capsule endoscopy, the patient swallows a capsule containing a disposable video camera (Figure 41-10). As the video camera passes through the intestine, images are transmitted by radiofrequency. This procedure is particularly useful in visualization of the portion of the small bowel that is not within reach of standard upper and lower endoscopy. It allows more access to the small bowel for patients with an obscure source of GI bleeding. This technology may be particularly helpful in discovering the cause of GI bleeding when results of standard upper endoscopy and colonoscopy are normal.

FIGURE 41-10 Capsule endoscopy. **A,** The pill-sized video capsule has its own camera and light source. **B,** As it travels through the GI tract, it sends messages through sensing electrodes placed on the chest and abdomen to a data recorder worn on a waist belt. **C,** After the test, the images are viewed on a computer. Source: Dye, C. E., Gaffney, R. R., Dykes, T. M., et al. (2012). Endoscopic and radiographic evaluation of the small bowel in 2012. *The American Journal of Medicine*, *125*(12), 1228.e1–1288.e12.

Liver Biopsy

A liver biopsy is performed when hepatic tissue is needed to establish a diagnosis such as fibrosis, cirrhosis, hepatitis, and neoplasms. It may also be used for monitoring the progress of liver disease.

Liver biopsy may be performed as an open or closed procedure. The *open method* involves making an incision and removing a wedge of tissue. It is performed in the operating room, often concurrently with another surgical procedure, with the patient under general anaesthesia. The *closed*,

or *needle, biopsy* is a percutaneous procedure in which the site is infiltrated with a local anaesthetic and a needle is inserted between the sixth and seventh or between the eighth and ninth intercostal spaces on the right side. The patient lies supine with the right arm over the head. The patient should be instructed to exhale fully and not breathe while the needle is inserted (see Table 41-12). It is important to perform a nursing assessment before and after a liver biopsy.

Liver Function Studies

Liver function tests are usually described separately from other GI diagnostic studies. Liver function tests are laboratory (blood) studies that reflect hepatic disease. Table 41-13 lists some common liver function tests.

TABLE 41-13

DIAGNOSTIC STUDIES
Liver Function Tests

Test	Description and Purpose
Bile Formation and Excretion	
Serum bilirubin	Measurement of ability of liver to conjugate and excrete bilirubin; enables differentiation between unconjugated (indirect) and conjugated (direct) bilirubin in plasma
• Total	Measurement of direct and indirect total bilirubin Reference range: 5.1–17 mcmol/L
• Direct	Measurement of conjugated bilirubin; level is elevated in obstructive jaundice Reference range: 1.7–5.1 mcmol/L
• Indirect	Measurement of unconjugated bilirubin; level is elevated in hepatocellular (hepatitis, cirrhosis, neoplasm or hepatic congestion) and hemolytic conditions Reference range: 3.4–12 mcmol/L
Urinary bilirubin	Measurement of urinary excretion of conjugated bilirubin Normal finding: 0–0.034 mcmol/L (negative)
Protein Metabolism	
Serum protein levels	Measurement of serum proteins manufactured by the liver Albumin reference range: 35–50 g/L; globulin reference range: 23–34 g/L; total protein reference range: 64–83 g/L Normal A/G ratio: 1.5 : 1–2.5 : 1
α-Fetoprotein	Tumour marker, especially for hepatic cancer Reference range: <40 mcg/L
Ammonia	Conversion of ammonia to urea normally occurs in the liver; elevated ammonia level can result in hepatic encephalopathy secondary to liver cirrhosis Reference range: 6–47 mcmol/L
Hemostatic Functions	
Prothrombin	Determination of prothrombin activity Reference range: 11–12.5 sec
Vitamin K	Essential cofactor for many clotting factors Reference range: 0.22–4.88 nmol/L
Serum Enzyme Tests	
Alkaline phosphatase (ALP)	Origination in bone and liver; serum level elevated when excretion is impaired as a result of obstruction in the biliary tract Reference range: 35–120 U/L
Aspartate aminotransferase (AST)	Serum level elevated in liver damage and inflammation Reference range: 0–35 U/L Women's values are slightly lower than men's
Alanine aminotransferase (ALT)	Serum level elevated in liver damage and inflammation Reference range: 4–36 U/L
γ-Glutamyl transpeptidase (GGT)	Present in biliary tract (not in skeletal muscle or cardiac tissue); serum level elevated in hepatitis and alcoholic liver disease; more sensitive for detecting biliary obstruction, cholangitis, or cholecystitis than ALP Reference ranges: 8–38 IU/L
Lipid Metabolism	
Serum cholesterol	Synthesis and excretion by liver; serum level elevated in biliary obstruction, lowered in extensive liver disease and malnutrition Reference range: <5.0 mmol/L, age dependent HDL reference range: >1.55 mmol/L LDL reference range: <2.59 mmol/L

HDL, high-density lipoprotein; *IU/L,* international units per litre; *LDL,* low-density lipoprotein; *U/L,* units per litre.

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. A client is admitted to the hospital with a diagnosis of diarrhea with dehydration. The nurse recognizes that increased peristalsis resulting in diarrhea can be related to which of the following mechanisms?
   a. Sympathetic inhibition
   b. Mixing and propulsion
   c. Sympathetic stimulation
   d. Parasympathetic stimulation
2. A client has an elevated blood level of indirect (unconjugated) bilirubin. Which of the following might cause this finding?
   a. The gallbladder is unable to contract to release stored bile.
   b. Bilirubin is not being conjugated and excreted into the bile by the liver.
   c. The Kupffer cells in the liver are unable to remove bilirubin from the blood.
   d. There is an obstruction in the biliary tract preventing flow of bile into the small intestine.
3. Which of the following normally protects the bowel from the acidity of gastric contents as they move into the small intestine?
   a. Inhibition of secretin release
   b. Release of bicarbonate by the pancreas
   c. Release of pancreatic digestive enzymes
   d. Release of gastrin by the duodenal mucosa
4. An 80-year-old man states that although he adds a lot of salt to his food, it still does not have much flavour. Which of the following factors related to aging would account for this finding?
   a. Some disorder; he should not experience changes in the ability to taste
   b. Loss of taste buds, especially for sweetness and saltiness
   c. Some loss of taste sensation but no difficulty chewing food
   d. Loss of the sense of taste because the ability to smell is decreased
5. Which of the following questions is appropriate to initiate a GI assessment?

a. "What is your usual bowel elimination pattern?"

b. "What percentage of your income is spent on food?"

c. "Have you travelled to a foreign country in the past year?"

d. "Does stress give you diarrhea?"

6. Which of the following is appropriate for the nurse to undertake during an examination of the abdomen?

a. Position the client in the supine position with the bed flat and knees straight.

b. Listen in the epigastrium and all four quadrants for 2 to 5 minutes for bowel sounds.

c. Use the following order of techniques: inspection, palpation, percussion, auscultation.

d. Describe bowel sounds as absent if no sound is heard in the lower right quadrant after 2 minutes.

7. Which of the following findings would be considered a normal physical assessment finding of the GI system? *(Select all that apply)*

a. Nonpalpable liver and spleen

b. Borborygmi in upper right quadrant

c. Tympany on percussion of the abdomen

d. Liver edge 2 to 4 cm below the costal margin

e. Finding of a firm, nodular edge on the rectal examination

8. Which of the following is correct in preparing a client for a colonoscopy?

a. A signed consent form is not necessary.

b. Sedation may be used during the procedure.

c. Only one cleansing enema is necessary for preparation.

d. A light meal should be eaten the day before the procedure.

1. d; 2. b; 3. b; 4. b; 5. a; 6. b; 7. a and c; 8. b.

CHAPTER 42

Nursing Management

Nutritional Problems

Written by, Rose DiMaria-Ghalili

Adapted by, Ellen Vogel, Christina Vaillancourt, Andrea Miller, Maysam Youssef

LEARNING OBJECTIVES

1. Relate the essential components of a well-balanced diet to their impact on health outcomes.
2. Describe the common etiological factors, clinical manifestations, and management of malnutrition.
3. Describe the components of a nutritional assessment.
4. Explain the indications, complications, and nursing management principles related to the use of enteral nutrition.
5. Explain the indications, complications, and nursing management related to the use of parenteral nutrition.
6. Compare the etiological factors, clinical manifestations, and nursing management of eating disorders.

KEY TERMS

anorexia nervosa, p. 976
bulimia nervosa, p. 976
enteral nutrition (EN), p. 983

food security, p. 975

malabsorption syndrome, p. 975

malnutrition, p. 974

nutrition, p. 970

optimal nutritional status, p. 971

overnutrition, p. 971

parenteral nutrition (PN), p. 987

protein–calorie malnutrition (PCM), p. 974

undernutrition, p. 971

This chapter focuses on problems related to nutrition. A review of normal nutrition provides a basis for evaluating nutritional status. Malnutrition, eating disorders, and types of supplemental nutrition, including enteral and parenteral nutrition, are discussed.

Nutritional Problems

As one of the fundamental requirements for sustaining life, eating is a highly symbolic and culturally meaningful act. It is unusual to hear a newscast that does not have several stories relating to the food we eat. Newspapers and bestseller lists frequently highlight nutrition- and food-related books, illustrating the importance of food and eating to Canadians. Nutrition is also inextricably linked to the development of and the recovery from illness.

Nurses, as the first point of contact for patients, frequently initiate patient referrals to dietitians. Thus, knowledge and skills in nutrition and nutritional screening are essential to effective patient care. Dietitians and nurses often collaborate in the development and implementation of nutritional care plans.

Dietitians, as part of the multidisciplinary team, provide expertise in the assessment of the nutritional status of individuals throughout the life cycle and in development of nutritional care plans for wide-ranging health concerns. Dietitians have extensive knowledge in the biochemical and nutritional components of foods and how these influence metabolic and physiological processes. Importantly, dietitians understand the feeding environment and underlying psychosocial, economic, and health determinants that influence food intake at individual, family, and societal levels (Dietitians of Canada, 2016).

Nutrition is the process by which the body uses food for energy, growth, maintenance, and repair of body tissues. Nutritional status can be viewed as a continuum from undernutrition to optimal nutrition to overnutrition. Any alteration in the process of nutrient intake or use can potentially cause nutritional problems. Nutritional problems can occur in all age groups, cultures, ethnic groups, and socioeconomic classes and across all educational levels. Attitudes toward the importance of food and eating habits are established early. Cultural or religious preferences and requirements are frequently reflected in dietary intakes. The financial status of a family or an individual may influence the type and amount of nutritionally sound food that can be purchased (Tarasuk, Mitchell, & Dachner, 2016).

Today there is much interest in understanding the link between nutrition and the onset of chronic diseases. Numerous reports have shown that a significant portion of morbidity and mortality among Canadians is related to chronic diseases. In 2013, the Public Health Agency of Canada

stated in its strategic plan for preventing chronic disease that three of every five Canadians over 20 live with a chronic disease and four of five are at risk of developing a chronic disease (Public Health Agency of Canada [PHAC], 2013). Internationally, Canada's health care spending is among the highest in the world, representing approximately 11% of the gross domestic product in 2016 (Canadian Institute for Health Information, 2017). Poor nutrition is a key preventable risk factor for many of the chronic diseases that influence morbidity, disability, and premature death in Canada.

Normal Nutrition

Undernutrition occurs when nutritional reserves become depleted or when nutrient intake is inadequate to meet daily requirements or metabolic demands. Undernutrition affects vulnerable groups, including infants, children, pregnant women, new immigrants, individuals living in rural or remote communities, individuals with low incomes, hospitalized people, and older adults. Undernutrition increases the risk for impaired growth and development, lowers resistance to infection and disease, delays wound healing, results in longer hospital stays, and increases health-related expenses.

Optimal nutritional status is achieved when nutrients consumed meet daily requirements and metabolic demands, including any increased demands related to growth, pregnancy, or illness. Individuals with optimal nutritional status have a lower risk of developing chronic diseases and generally live longer than those with a chronic illness.

Overnutrition results from the consumption of nutrients—most frequently, calories, sodium, and fat—in excess of requirements. A major nutritional problem today, overnutrition results in the development of chronic diseases including obesity, some cancers, and type 2 diabetes.

The nutrients required to optimize health over a lifetime are the same for all healthy individuals; however, the amount required of each nutrient differs based on stages of the life cycle. Nutritional needs can be viewed as a continuum across the lifespan: they change as individuals grow, age, and respond to variations in their environment, physical activity, and health. Optimal nutrition is essential for its contribution to overall health and well-being and to the prevention of chronic conditions.

Optimal nutrition in the absence of any underlying disease process results from the ingestion of a balanced diet. *Eating Well With Canada's Food Guide,* commonly referred to as "Canada's Food Guide," provides Canadians with recommendations for healthy eating (Health Canada, 2011) (Figure 42-1). The guide is based on current nutritional science and defines four major foods groups. This standardization ensures that a diet based on the food guide will provide an adequate intake to support optimal nutritional status. The information contained in Canada's Food Guide is based on the most up-to-date evidence at the time of publication. The Food Guide is reviewed and updated periodically based on current evidence and public health priorities. At the time of writing, a new Food

Guide is due to be released in 2018 and is expected to contain significant changes.

FIGURE 42-1 *Eating Well With Canada's Food Guide.* The Resources at the end of this chapter provide a link to the guide and interactive tools ("My Food Guide") that allow nurses and their patients to personalize the information in Canada's Food Guide.

Source: © All rights reserved. *Eating Well with Canada's Food Guide.* Health Canada, 2011. Adapted and reproduced with permission from the Minister of Health, 2017.

Canada's Food Guide can be used by anyone to plan a healthy diet; it is flexible and can be adapted to include combination foods and ethnically diverse foods that reflect the country's multicultural profile. (In addition to English and French, the guide is available in 10 other languages: Arabic, Chinese, Farsi [Persian], Korean, Punjabi, Russian, Spanish, Tagalog, Tamil, and Urdu [Health Canada, 2013].) The food guide also provides alternative choices for meat, milk, and other animal-based foods.

Eating Well With Canada's Food Guide—First Nations, Inuit and Métis is a food guide tailored to reflect traditions and food choices of a specific population group (Health Canada, 2010). This guide includes traditional and store-bought foods that are generally available, affordable, and accessible to Indigenous people across Canada.

Canada's Food Guide was developed in accordance with the daily dietary reference intake (DRI) requirements, a comprehensive set of nutrient reference values for healthy populations (Table 42-1). There is a DRI set for each nutrient. These nutrient reference values are intended to help individuals optimize their health, prevent disease, and avoid overconsumption of any single nutrient. The reference values include the

estimated average requirement (EAR), the recommended dietary allowance (RDA), the adequate intake (AI) and the tolerable upper limit (UL) (Institute of Medicine, 2005). The DRI values are designed to maintain health and prevent disease, not to restore health. Nutrient needs may exceed DRIs during times of acute stress or chronic illness.

TABLE 42-1

RECOMMENDED DAILY VITAMIN INTAKE AND MANIFESTATIONS OF DEFICIENCIES

Vitamin	Dietary Reference Intake	Manifestations of Deficiencies
A (retinol)	*Men:* 900 mcg/retinol equivalents* *Women:* 700 mcg/retinol equivalents	Dry, scaly skin; increased susceptibility to infection; night blindness; anorexia; eye irritation; keratinization of respiratory and GI mucosa; bladder stones; anemia; retarded growth
D	*Adults age 19–70:* 600 IU *Adults age >70:* 800 IU	Muscular weakness, excessive sweating, diarrhea and other GI disturbances, bone pain, active or healed rickets, osteomalacia
E	*Adults:* 15 mg	Neurological deficits
K	*Men:* 120 mcg *Women:* 90 mcg	Defective blood coagulation
B_1 (thiamine)	*Men:* 1.2 mg *Women:* 1.1 mg	Anorexia, fatigue, nervous irritability, constipation, paresthesias, insomnia
B_6 (pyridoxine)	*Men age 19–50:* 1.3–1.7 mg *Men age >51:* 1.7 mg *Women age 19–50:* 1.3–1.5 mg *Women age >51:* 1.5 mg	Seizures, dermatitis, anemia, neuropathy with motor weakness, anorexia
B_{12} (cobalamin)	*Adults:* 2–4 mcg	Megaloblastic anemia, anorexia, glossitis, sore mouth and tongue, pallor, neurological problems such as depression and dizziness, weight loss, nausea, constipation
C	*Men:* 90 mg *Women:* 75 mg	Bleeding gums, loose teeth, easy bruising, poor wound healing, scurvy, dry, itchy skin
Folate (folic acid)	*Adults:* 400 mcg	Impaired cell division and protein synthesis, megaloblastic anemia, anorexia, fatigue, sore tongue, diarrhea, forgetfulness

*1 retinol equivalent = 10 international units vitamin A activity from β-carotene or 3.33 international units vitamin A activity from retinol.

GI, gastro-intestinal.

In recent years, there has been considerable interest in vitamin and mineral supplementation as a means of prevention and treatment of acute and chronic diseases. Although evidence suggests that some nutrients are beneficial to health, it is important to exercise caution when recommending supplementation. Exceeding the UL can increase a person's risk for nutrient toxicity. As well, consumption of high levels of one vitamin or mineral may interfere with the absorption of another. For example, ingestion of high levels of zinc can interfere with the absorption of calcium; ingestion of high levels of vitamin C enhances the absorption of iron, which can lead to iron toxicity. To avoid harmful adverse effects, patients should be encouraged to discuss vitamin and mineral supplementation with their primary care provider before using.

Major Nutrients

The major nutritional constituents of foods are carbohydrates (and fibre), fats, proteins, vitamins, minerals, and water. Carbohydrates, fats, and proteins provide energy. Vitamins, minerals, and water do not provide energy; some serve as structure (e.g., calcium in bones), and all assist in body processes such as food digestion, muscle movement, waste disposal, growth of new tissues (e.g., wound healing), and energy production (from carbohydrates, proteins, and fats). An individual's daily calorie requirements are influenced by body composition, age, gender, and physical activity. Adjustments in caloric intake are necessary when there are changes in a person's health status and daily activity level. An average adult requires an estimated 20 to 35 kcal/kg of body weight per day, leaning toward the higher end if the person is critically ill or very active and the lower end if the person is sedentary (American Society of Parenteral and Enteral Nutrition [ASPEN], 2016). (*Kilocalorie* is the correct unit to designate caloric intake and expenditure; however, *calorie* is the term more commonly used.)

Carbohydrates, the body's primary source of energy, yield approximately 4 kcal/g. Carbohydrates are classified as simple or complex. Simple carbohydrates include *monosaccharides* (e.g., glucose and fructose), found in fruits and honey, and *disaccharides* (e.g., sucrose, maltose, and lactose), found in foods such as table sugar and milk. Complex carbohydrates, or *polysaccharides*, include starches such as cereal grains, potatoes, and legumes. Carbohydrates are the chief protein-sparing ingredients in a nutritionally sound diet. Canada's Food Guide recommends that 55% of daily energy needs be supplied by carbohydrates, especially foods rich in

complex carbohydrates and fibre. The rainbow design of the Food Guide places grain products, vegetables, and fruit in the outermost arcs to ensure that Canadians eat the recommended amount of carbohydrates (Health Canada, 2011).

Fibre is the indigestible parts of plant foods. Diets rich in fibre are associated with improved blood cholesterol and blood glucose levels, healthy bowel function, and healthy body weight (Table 42-2).

TABLE 42-2

DIETARY REFERENCE INTAKE (DRI) FOR FIBRE

	Grams of Fibre per Day
Men 19–50 years of age	38
Men ≥51 years of age	30
Women 19–50 years of age	25
Women ≥51 years of age	21

Fats are stored in adipose tissue and in the abdominal cavity. Besides being a major source of energy, fats act as insulation, which reduces loss of body heat in cold environments and provides padding and protection for vital organs. Fats also act as carriers of essential fatty acids (linoleic and alpha-linolenic) and fat-soluble vitamins (A, D, E, and K). Fats provide a feeling of satiety after eating. Canada's Food Guide recommends that approximately 30% of total energy come from fat, including 10% from saturated fat (Health Canada, 2012). One gram of fat yields 9 calories. A total fat intake of 30% or less equates to an intake of 60 g to 105 g of fat per day (Health Canada, 2015a).

Dietary fat is composed of four types of fatty acids: polyunsaturated, monounsaturated, saturated, and trans fats. Monounsaturated and polyunsaturated fats lower the risk for heart disease. Polyunsaturated fats, including omega-3 and omega-6 fats, are essential to good health. These fatty acids are not synthesized by the body and must be obtained from the diet. Omega-6 essential fatty acids are found in vegetable oils such as corn, sunflower, and soybean oils; primary sources of omega-3 fatty acids are fatty fish, flaxseed, and some nuts. Monounsaturated fats are found in vegetable oils, including olive and canola oils.

Saturated fats are found naturally in both vegetable- and animal-based foods, including coconut and palm oil and butter and full-fat dairy products. Trans fats are found naturally in some animal-based foods. Trans fats are formed when liquid oils are made into semisolid fats like shortening and hard margarine. Saturated and trans fats increase the risk for heart disease because they raise serum low-density lipoprotein (LDL)

cholesterol levels (the so-called bad cholesterol) (Health Canada, 2012). Trans fats are particularly dangerous because they also reduce levels of high-density lipoprotein (HDL) cholesterol (the so-called good cholesterol) (Health Canada, 2012).

Proteins, another essential component of a well-balanced diet, can be obtained from both animal and plant sources. Proteins are essential for tissue growth, repair, and maintenance; body regulatory functions; and energy production. Ideally, proteins provide 15% to 20% of daily caloric needs. The recommended daily intake (RDI) for protein is 0.8 to 1 g/kg of body weight. One gram of protein yields 4 calories. Proteins are complex nitrogenous organic compounds, of which amino acids are the fundamental units of structure. The 22 amino acids can be classified as essential and nonessential. The body is capable of synthesizing nonessential amino acids if an adequate supply of protein is available. The nine essential amino acids must be provided through dietary sources. Protein sources containing all the essential amino acids are considered to be high-quality proteins that are easier to digest. Generally, animal-based proteins are easier to digest and are often referred to as *complete proteins* because they contain all essential amino acids (Institute of Medicine, 2005).

Grain products also contribute to protein intake. Plant-based proteins such as legumes and grains lack one or more of the essential amino acids and are more difficult to digest. These types of proteins are called *incomplete proteins*. The digestion difficulty can be overcome by combining high-protein plant-based foods. This concept is called *mutual supplementation*. Mutual supplementation is the strategy of combining two incomplete protein sources so that the amino acids in one food compensate for the missing ones in the other food. See Table 42-3 for a list of good sources of protein.

TABLE 42-3
GOOD SOURCES OF PROTEIN

Complete Proteins	Incomplete Proteins
• Milk and milk products (e.g., cheese) • Eggs • Fish • Meats • Poultry	• Grains (e.g., corn) • Legumes (e.g., navy beans, soybeans, peas) • Nuts (e.g., peanuts) • Seeds (e.g., sesame seeds, sunflower seeds)

Vitamins are organic compounds required in small amounts for normal metabolism. Vitamins function primarily in enzyme reactions that facilitate the metabolism of amino acids, fats, and carbohydrates. Vitamins

are divided into two categories: water-soluble vitamins (vitamin C and the B-complex vitamins) and fat-soluble vitamins (vitamins A, D, E, and K). Vitamin D, in particular, has recently received widespread attention because of a growing body of evidence that suggests it may have a beneficial effect on some types of cancer, in particular colorectal cancer, and other immune-related diseases (Dietitians of Canada, 2013). Since the body stores fat-soluble vitamins, consuming too much can result in toxicity. Upper limits have been established for vitamins A, D, and E.

Mineral salts (e.g., magnesium, iron, calcium) make up approximately 4% of total body weight. Minerals present in minute amounts are referred to as *trace elements.* Minerals required in amounts greater than 100 mg/day are called *major minerals.* Minerals are necessary to build tissues, regulate body fluids, and assist in various body functions. Some minerals are stored and can be toxic if taken in excess amounts. The daily requirement for minerals varies greatly, from a few micrograms of trace minerals to 1 g or more of the major minerals, such as calcium, phosphorus, and sodium. Table 42-4 lists the major minerals and trace elements. A well-balanced diet based on Canada's Food Guide will typically meet the daily requirements for minerals.

TABLE 42-4

MAJOR MINERALS AND TRACE ELEMENTS

Major Minerals	Trace Elements
• Calcium • Chloride • Magnesium • Phosphorus • Potassium • Sodium • Sulphur	• Chromium • Copper • Fluoride • Iodine • Iron • Manganese • Molybdenum • Selenium • Zinc

Vegetarian Diet

The common element among all vegetarians is the exclusion of meat, poultry, game, fish, shellfish or crustaceans, and meat by-products from the diet. Vegetarians base their diet on convictions founded in religious or cultural beliefs, a respect for all living beings, ethical–ecological ideals, economics, or food preferences. *Vegans* eat only plant-based food, whereas *lacto-ovo-vegetarians* eat plant-based foods as well as dairy products and eggs.

Vegetarians can be at risk for vitamin, mineral, or protein deficiencies unless their diets are well planned. Plant protein, although of a lesser quality than that of animal origin, fulfills most of the protein requirements in a vegetarian diet. Combinations of vegetable-protein foods (e.g., rice and kidney beans) can increase digestibility and nutritional quality. Lacto-ovo-vegetarians obtain additional protein from dairy products and eggs. Soy milk fortified with calcium and vitamin D is a good source of protein and can be an alternative to cow's milk. Many palatable meat analogue products are now available for individuals following a vegetarian diet.

The primary risk for nutrient deficiency in a strict vegan is lack of cobalamin (vitamin B_{12}). Vegans not taking cobalamin supplements or consuming foods fortified with cobalamin are susceptible to the development of megaloblastic anemia and the neurological signs of cobalamin deficiency. Strict vegetarians and lacto-ovo-vegetarians are also at risk for iron deficiency. The iron in plant-based foods such as legumes, dark-green leafy vegetables, iron-fortified cereals, and whole grains and cereals is poorly absorbed. Table 42-5 lists examples of foods high in iron. Consuming foods rich in vitamin C (e.g., citrus fruits, tomatoes, potatoes, peppers, and strawberries) will enhance the absorption of iron from plant-based iron-rich foods.

TABLE 42-5

NUTRITIONAL THERAPY
Foods High in Iron

These foods provide 25%–39% of the dietary reference intake (DRI) of iron.	
Food	**Serving Size**
Breads, Cereals, and Grain Products	
Farina, regular or quick-cooked (enriched)	157 mL (⅔ cup)
Oatmeal, instant, fortified, prepared (enriched)	157 mL (⅔ cup)
Ready-to-eat cereals, fortified (enriched)	30 g
Meat, Poultry, Fish, and Alternatives	
Beef liver, braised	90 g
Pork liver, braised	90 g
Chicken or turkey liver, braised	118 mL (½ cup), diced
Clams: steamed, boiled, or canned (drained)	90 g
Oysters: baked, broiled, steamed, or canned (undrained)	90 g
Soybeans, cooked	118 mL (½ cup)

Culturally Competent Care

People's unique cultural heritages may affect their eating customs and nutritional status. Each culture has its own beliefs and behaviours related to food and the role that food plays in the etiology and treatment of disease. In addition, culture and religion can influence what food is considered edible as well as how it is prepared and when it is eaten. It is important to consider cultural, religious, and ethnic influences when assessing a patient's nutritional status and suggesting interventions requiring dietary changes. Additionally, the nurse should avoid *cultural stereotyping* by making assumptions or generalizations about diet based on an individual's cultural background. Dietary habits differ considerably within and among ethnic groups (Colby, 2013). Acculturation, the extent to which immigrants adopt attributes of a new culture, can also affect dietary practices (Deng, Zhang, & Chan, 2013).

Malnutrition

Malnutrition is a deficit, excess, or imbalance of the essential components of a balanced diet. Malnutrition can refer to alterations in macronutrients (carbohydrates, proteins, and fat) or micronutrients (electrolytes, minerals, and vitamins). The terms *undernutrition* and *overnutrition* are also used to describe malnutrition.

Undernutrition affects body tissues, functional ability, and overall health (Allard, Keller, Jeejeebhoy, et al., 2015). Undernutrition does exist in Canada, where income-related food insecurity is increasingly acknowledged as a key social determinant of health. Between 2013 and 2014, about 12% of all Canadian households experienced food insecurity (Tarasuk, Mitchell, & Dachner, 2016). The food insecurity rate was lower among households with children than those with only adults. In many food-insecure households in Canada, adults were protecting children by compromising their own nutrition. Lone-parent families with children under 18 years and households in Nunavut reported the highest rates of food insecurity in Canada (15.7% and 46.8% respectively) (Tarasuk, Mitchell, & Dachner, 2016).

Malnutrition is a problem in both developing and developed countries and across the continuum of care (community, hospital, long-term care). Prevalence of malnutrition in Canadian hospitals has been reported to be 15% to 75% (Allard, Keller, Jeejeebhoy, et al., 2015).

Etiology of Malnutrition

Several terms describe the types and causes of adult malnutrition. **Protein–calorie malnutrition (PCM)** is the most common form of undernutrition. The following etiology-based terms are preferred for use in clinical practice settings, as they indicate the interaction and importance of inflammation on nutritional status (White, Guenter, Jensen, et al., 2012).

- *Starvation-related malnutrition*, or primary PCM, occurs when nutritional needs are not met (Figure 42-2). In primary PCM, there is chronic starvation without inflammation (e.g., anorexia nervosa).

FIGURE 42-2 Patient with malnutrition. Source: Morgan, S. L., & Weiniser, R. (1998). *Fundamentals of clinical nutrition* (2nd ed.). St. Louis: Mosby.

- *Chronic disease–related malnutrition*, or secondary PCM, is associated with conditions that have sustained mild to moderate inflammation. It occurs when dietary intake does not meet tissue needs because of disease, although it would under normal conditions. Examples of conditions associated with this type of malnutrition include organ failure, cancer, rheumatoid arthritis, obesity, and metabolic syndrome.
- *Acute disease– or injury-related malnutrition* is associated with acute disease or injury states with marked inflammatory response (e.g., major infection, burns, trauma, surgery).

Many factors contribute to the development of malnutrition, including socioeconomic factors, physical illnesses, incomplete diets, food–drug interactions, and psychological illness such as eating disorders. Table 42-6 lists conditions that increase the risk for malnutrition.

TABLE 42-6
CONDITIONS THAT INCREASE THE RISK FOR MALNUTRITION

- Dementia
- Depression
- Alcohol use disorder
- Excessive dieting to lose weight
- Swallowing disorders (e.g., neurological conditions, head and neck cancer, stroke)
- Decreased mobility that limits access to food or its preparation
- Nutrient losses from malabsorption, dialysis, fistulas, or wounds
- Drugs with antinutrient or catabolic properties, such as corticosteroids and oral antibiotics
- Extreme need for nutrients because of hypermetabolism or stresses such as infection, burns, trauma, or fever
- No oral intake, receiving standard intravenous solutions (e.g., 5% dextrose), or both for 5 days

Socioeconomic Factors.

At every stage of the life cycle, health is directly or indirectly influenced by key determinants of health such as education and literacy, income and social status, employment and working conditions, and social environments (PHAC, 2014). Although the health of Canadians is considered to be very good by international standards, a number of factors influence overall quality of life, including the aging of the population; increasing survival rates for potentially fatal conditions; and changes in behaviours related to eating, physical activity, and the use of substances such as drugs, tobacco, and alcohol.

The Food and Agriculture Organization (FAO) of the United Nations (1996) defines **food security** as "when all people, at all times, have physical and economic access to sufficient, safe and nutritious food to meet their dietary needs and food preferences for an active and healthy life." Individuals or families with limited financial resources may have *food insecurity* (inadequate access). Food insecurity is problematic, as it affects the overall quality (i.e., nutritional value) and quantity of food that is available. Families with food insecurity often choose less expensive "filling" foods, which are more energy dense (high fat) and less nutritious. This type of diet increases the risk for nutrient deficiencies.

Individuals and families may use "safety net programs," including food-assistance programs, housing and energy subsidies, and in-kind contributions from relatives, friends, food pantries, or charitable organizations to help them obtain food. Many families with limited economic resources struggle through the "heat or eat" phenomenon: trying both to pay household utility bills and to put food on the table but sometimes having to choose one or the other. Older adults on a fixed income may have an added burden of deciding whether to pay for

medications or buy food. The nurse and the dietitian can assist patients in making food choices that meet nutritional requirements while staying within their limited resources.

Individuals and families with lower social economic status are less likely to consume the nutrients needed for proper health and well-being than those earning higher incomes (Health Canada, 2015b). Studies have also linked food insecurity to the prevalence of unhealthy weights. Lower-income families consume more energy-dense, nutrient-poor diets, whereas families with higher income consume more whole grains, lean meats, low-fat dairy products, and fresh vegetables and fruit.

Physical Illnesses.

Regardless of the illness, an individual who is ill has increased nutritional needs. Pathological conditions are frequently aggravated by undernutrition, and an existing nutrient deficiency is likely to become more severe during illness. Malnutrition is a common consequence of illness, surgery, injury, or hospitalization. Hospitalized patients, especially older adults, are at risk of becoming malnourished. Prolonged illness, major surgery, sepsis, draining wounds, burns, hemorrhage, fractures, and immobilization can all contribute to malnutrition.

Anorexia, nausea, vomiting, diarrhea, abdominal distension, and cramping may accompany diseases of the gastro-intestinal (GI) system. Any combination of these symptoms interferes with usual food consumption and metabolism. Whereas *anorexia* is a loss of normal appetite and may occur as a result of physical or mental illness, *cachexia* refers to a wasting syndrome that causes weakness and loss of weight, fat, and muscle. Cachexia is a major cause of morbidity and mortality in patients with cancer, human immunodeficiency virus (HIV), or other serious long-term illnesses such as chronic obstructive pulmonary disease.

Fever accompanies many illnesses, injuries, and infections, with a concomitant increase in the body's basal metabolic rate (BMR) and nitrogen loss. Each degree of temperature increase on the Celsius scale raises the BMR by about 13%. Without an increase in caloric intake, the body uses protein stores to supply calories, and protein depletion develops. After the body temperature returns to normal, the rate of protein breakdown and resynthesis may be increased for several weeks.

Consider the nutritional requirements of a patient who is not overtly ill but is undergoing diagnostic studies. This patient may be nutritionally fit

on entering the hospital but can become malnourished because of the dietary restrictions imposed by multiple diagnostic studies.

Malabsorption syndrome is the impaired absorption of nutrients from the GI tract. Decreases in digestive enzymes or in bowel surface area can quickly lead to a deficiency state. Many medications have undesirable GI adverse effects and alter normal digestive and absorptive processes. Antibiotic use appears to modify the intestinal microbiome in the normal state. New research suggests that the microbiome likely plays a critical role in the healthy human immune system and metabolism (Tuddenham & Sears, 2015).

Use of Probiotics.

The FAO of the United Nations and the World Health Organization define probiotics as "living microorganisms, which when administered in adequate amounts confer health benefits on the host" (Morelli & Capurso, 2012). Recent research suggests that changes in the gut microbiota may increase a person's predisposition to certain diseases (Zhang, Li, Gan, et al., 2015). Dietary nutrients may be converted into metabolites by intestinal microbes that serve as biologically active molecules, which affect regulatory functions in the host. Probiotics may restore the composition of the gut microbiome and introduce beneficial functions to gut microbial communities, resulting in amelioration or prevention of gut inflammation (Hemarajata & Versalovic, 2013).

Incomplete Diets.

Vitamin deficiencies are rare in most developed countries. When present, vitamin deficiencies usually involve several vitamins. When vitamin imbalances occur because of incomplete diets, they are often found among people with a pattern of alcohol or drug use, people who are chronically ill, such as patients on hemodialysis or those receiving cancer treatment, and individuals who maintain poor dietary practices. People who have had GI surgery may be at risk for vitamin deficiencies. For example, resection of the terminal ileum poses a risk for deficiencies of fat-soluble vitamins. After a gastrectomy, patients require cobalamin (vitamin B_{12}) supplementation. Individuals following fad diets or those with poorly planned vegetarian diets are also at risk.

Clinical manifestations of vitamin imbalances are most commonly exhibited as neurological manifestations. In the growing child, the central nervous system (CNS) is primarily involved, whereas the peripheral

nervous system is most often affected in adults. The recommended DRIs and manifestations of deficiencies are presented in Table 42-1.

Drug–Nutrient Interactions.

A *drug–nutrient interaction* occurs when a medication affects the use of nutrients in the body. Many medications may interact with food or beverages. Potential adverse interactions include incompatibilities, altered drug effectiveness, and impaired nutritional status. For example, many medications produce adverse effects such as changes in taste, changes in appetite, and nausea. Grapefruit juice can increase the absorption of some drugs, enhancing their effect. Recently, individuals taking thyroid replacement hormone (e.g., levothyroxine [Synthroid]) have been instructed to avoid taking dairy products, antacids, or iron preparations within one hour of taking their medication.

Drug–nutrient interactions can also occur with over-the-counter medications and herbs and dietary supplements. The role of the interdisciplinary team is to monitor and prevent these potential interactions for patients while in the hospital and before discharge.

Eating Disorders.

Eating disorders are complex psychiatric disorders strongly associated with other mental illnesses, such as mood, personality, and anxiety disorders. Society's promotion of an ideal body image has also been implicated. Eating disorders have the highest mortality rate of any mental illness. Data provided to the Standing Committee on the Status of Women suggest that as many as 600 000 to 900 000 Canadians meet the diagnostic criteria for an eating disorder, with an even larger number of individuals reporting symptoms that are seriously debilitating but insufficient for diagnosis (LeBlanc, 2014). Eating disorders involve a serious disturbance in eating behaviour in addition to disturbances in perception of body size and shape. There is increasing evidence to suggest that up to 20% of all patients with an eating disorder are male (LeBlanc, 2014). Male and female patients have similar psychological comorbidities, including depression and anxiety. The manifestation of eating disorders in boys and men may be different than those in girls and women. Some men may pursue weight loss, while others may seek to increase their weight through weightlifting (LeBlanc, 2014).

The *female athlete triad* is a syndrome in which eating disorders, amenorrhea, and osteoporosis are present (De Souza, Nattiv, Joy, et al.,

2014). The triad is seen in females participating in sports that emphasize leanness and low body weight.

Anorexia Nervosa.

Anorexia nervosa is a serious, often chronic, and life-threatening eating disorder characterized by self-imposed weight loss, endocrine dysfunction, and a distorted psychopathological attitude toward weight and eating (National Eating Disorder Information Centre [NEDIC], 2014). It manifests clinically as abnormal weight loss, deliberate self-starvation, intense fear of gaining weight or becoming fat, lanugo (soft, downy hair covering the body except the palms and soles), refusal to eat, continuous dieting, hair loss, sensitivity to cold, compulsive exercising, absent or irregular menstruation, dry skin, and constipation. Diagnostic studies often show iron-deficiency anemia and an elevated serum urea (nitrogen) level that reflects marked intravascular volume depletion and prerenal azotemia. A lack of potassium in the diet and loss of potassium in the urine lead to potassium deficiency resulting in muscle weakness, cardiac dysrhythmias, and renal failure. If the eating pattern continues for a prolonged time, body wasting with signs of severe malnutrition become evident, and death may be imminent.

Evidence-Informed Practice

Research Highlight

What Is the Effect of Internet-Based Interventions on Eating Disorders?

Clinical Question

In persons with eating disorders (P), are Internet-based interventions (I) effective in the treatment of eating-disorder behaviours (O)?

Synthesis of Best Available Evidence

- Systematic review of randomized controlled trials (RCTs) and nonrandomized controlled studies.
- Eight studies of persons (n = 609) diagnosed with bulimia nervosa, binge eating, or more than one eating disorder. Participants were

mainly females (97%) with average age of 24 to 45 years old. In most studies, cognitive behavioural therapy (CBT) with a guided self-help component was the basis of the intervention. Planned contact between coach and participant averaged once per week. Outcomes were symptoms of eating-disorder behaviours (e.g., binge eating and purging), anxiety, depression, and quality of life.

- Significant reductions were noted in binge eating and purging. Improvements in depressive symptoms, anxiety, and quality of life were also reported.

Conclusions

- Internet-based interventions using CBT have positive effects on reducing bulimia nervosa and binge eating.

Implications for Nursing Practice

- Why is it important for health care providers to facilitate alternative methods of treatment delivery other than face-to-face?
- How can a nurse help a patient with an eating disorder who resides in a rural area and regularly misses clinic appointments because of transportation problems?

P, patient population of interest; *I*, intervention or area of interest; *O*, outcome(s) of interest (see Chapter 1).

Reference for Evidence

Dölemeyer R, Tietjen A, Kersting A, et al. Internet-based interventions for eating disorders in adults: A systematic review. *BMC Psychiatry*. 2013;13:207; 10.1186/1471-244X-13-207.

Multidisciplinary treatment must involve a combination of nutritional support and psychiatric care. Although most of the treatment for an eating disorder is provided in the community, hospitalization may be necessary for patients with severe physical complications that cannot be managed in an outpatient setting. Nutritional replenishment must be closely supervised to ensure consistent and ongoing weight gain. Refeeding syndrome (discussed later in the chapter) is a rare but serious complication of refeeding programs. The use of enteral or parenteral feedings may be necessary. Improved nutrition is not a cure for anorexia nervosa; the underlying psychiatric problem must be identified and addressed.

Bulimia Nervosa.

Bulimia nervosa is an eating disorder characterized by frequent binge eating, self-induced vomiting associated with loss of control over eating, and a persistent concern with body image (NEDIC, 2014). Individuals with bulimia nervosa may have a normal body mass index (BMI) but weight that fluctuates with bingeing and purging. They may abuse diet drugs, laxatives, or diuretics, or they may exercise excessively. Signs of frequent vomiting—such as macerated knuckles, swollen salivary glands, broken blood vessels in the eyes, and dental problems—are common. Abnormal laboratory parameters, including hypokalemia, metabolic alkalosis, and elevated serum amylase, may occur with frequent vomiting (Westmoreland, Krantz, & Mehler, 2016).

The cause of bulimia remains unclear. It is thought to be similar to that of anorexia nervosa. Substance abuse, anxiety, affective disorders, and personality disturbances have been reported among persons with bulimia. Patients with bulimia often go to great lengths to conceal abnormal eating habits. As the behaviour persists, many problems associated with the condition become increasingly hard for patients to deal with effectively.

As with anorexia, a treatment combination of psychological counselling and diet therapy is essential, as are education and emotional support for

the patient and the family. Fluoxetine (Prozac) is the only Health Canada–approved antidepressant for treating bulimia nervosa. However, it may not be appropriate in all patients with bulimia. Support groups such as the National Eating Disorder Information Centre (see the Resources at the end of this chapter) are helpful to those affected by these disorders.

Pathophysiology of Starvation

Knowledge of the pathophysiology of the starvation process is useful in understanding the physiological changes that occur in PCM. Initially, the body selectively uses carbohydrates (glycogen) rather than fat and protein to meet metabolic needs. These carbohydrate stores, found in the liver and muscles, are minimal and may be depleted within 18 hours. During this early phase of starvation, the only use of protein is in its obligatory participation in cellular metabolism. However, once carbohydrate stores are depleted, protein begins to be converted to glucose for energy. The resulting available plasma glucose allows the metabolic processes to continue. As the body uses amino acids for energy, a negative nitrogen balance (greater nitrogen excretion) occurs. However, within 5 to 9 days, body fat is fully mobilized to supply much of the needed energy.

In prolonged starvation, up to 97% of calories are provided by fat, and protein is conserved. Depletion of fat stores depends on the amount available; fat stores are generally exhausted within 4 to 6 weeks. Once fat stores are depleted, protein, including that from internal organs and plasma, can no longer be spared and rapidly decreases, as it is the only remaining source of energy.

If malnourished patients have surgery, experience bodily trauma, or have an infection, the stress response, with concomitant increase in energy expenditure, is superimposed on the starvation response, resulting in an increase in the metabolic rate and a subsequent increase in energy requirements. Protein stores are no longer spared and are used with increasing frequency to meet the demands of the increased metabolic needs.

As protein depletion continues, liver function becomes impaired, and synthesis of protein decreases. As a result of this decrease, the plasma oncotic pressure lowers. A major function of plasma proteins, primarily of albumin, is to maintain the osmotic pressure of the blood. Because of this decreased plasma oncotic pressure, body fluids shift from the vascular space into the interstitial compartment. As protein ingestion decreases and body stores are depleted, albumin eventually leaks into the interstitial

space along with the fluid. Edema becomes clinically observable, and when present in the face and the legs of a patient, it often masks underlying wasting of muscle.

As total blood volume is reduced, the skin appears dry and wrinkled. With the shift of fluids to the interstitial space, ions also move. Sodium (a predominant extracellular ion) is found in increased amounts within the cell, and potassium (a predominant intracellular ion) and magnesium shift to the extracellular space. The sodium–potassium exchange pump has high energy needs, using 20% to 50% of all calories ingested. When the diet is extremely deficient in calories and essential proteins, the pump will fail, leaving sodium inside the cell (along with water), and the cell will expand, resulting in edema.

The liver is the organ that loses the most mass during protein deprivation. It gradually becomes infiltrated with fat, secondary to decreased synthesis of lipoproteins. Immediate intervention is required, or death will rapidly ensue.

Impact of Inflammation.

Inflammation affects nutrient metabolism and is an important component of nutritional status. During the starvation process, there is a decreased BMR, sparing of skeletal muscle, and decreased protein breakdown. However, in inflammatory states, there are alterations in the expression of proinflammatory (e.g., interleukin-6) and anti-inflammatory cytokines (e.g., interleukin-10). These cytokine changes result in increased protein and skeletal muscle breakdown, increased BMR, increased glucose turnover, decreased negative acute-phase protein (albumin, prealbumin) production, and increased positive acute-phase protein (e.g., C-reactive protein [CRP]) production (Jensen, 2015; Jensen, Hsiao, & Wheeler, 2012).

Clinical Manifestations

The clinical manifestations of malnutrition range from mild to emaciation and death. The most obvious signs on physical examination are apparent in the skin (dry and scaly skin, brittle nails, rashes, hair loss), mouth (crusting and ulceration, changes in tongue), muscles (decreased mass and weakness), and CNS (mental changes such as confusion, irritability). The speed at which malnutrition develops depends on the quantity and quality of the protein intake, caloric value, illness, and the person's age.

The manifestations of malnutrition result from numerous interactions at the cellular level. As protein intake declines, the muscles (which are the

largest store of protein in the body) become wasted and flabby. This wasting away leads to weakness and fatigability. Decreased protein is available for tissue repair, causing delayed wound healing. The person becomes more susceptible to infections. Both humoral and cell-mediated immunity are deficient. Leukocytes in the peripheral blood decrease. Impaired phagocytosis occurs because of the lack of energy needed to drive the process. Many malnourished people are anemic, generally because of nutritional deficiencies in iron and folic acid (necessary building blocks for red blood cells [RBCs]).

Nursing Management High-Risk Nutritional Status

Nursing Assessment

Regardless of setting, the nurse must be aware of the nutritional status of the patient. The nurse is often the first-line health care provider dealing with a patient. The patient's height, weight, and diet history are important components of any nursing assessment. Nutritional status may well be a major factor in the outcome of, and perhaps the underlying reason for, many illnesses.

In many institutions, nurses are responsible for initial nutrition screening to identify individuals who are malnourished or at risk for malnutrition. Results of nutrition screening determine whether a more detailed nutrition assessment is necessary (Table 42-7).

TABLE 42-7

NURSING ASSESSMENT
Malnutrition

Subjective Data
Important Health Information
Current health: ↑ or ↓ weight, weight problems; ↑ or ↓ appetite, typical dietary intake; food preferences and aversions; food allergies or intolerances; ill-fitting or absent dentures; dry mouth, difficulty in chewing or swallowing; bloating or gas; ↑ sensitivity to cold; delayed wound healing; constipation, diarrhea, nocturia, decreased urinary output *Past health history:* Severe burns, major trauma, hemorrhage, draining wounds, bone fractures with prolonged immobility, chronic renal or liver disease, cancer, malabsorption syndrome, GI obstruction, infectious diseases (e.g., TB, AIDS), acute (e.g., trauma, sepsis) or chronic (e.g., rheumatoid arthritis) inflammatory condition *Medications:* Corticosteroids, chemotherapeutic agents, diet pills *Surgery or other treatments:* Recent surgery, radiation *Functional assessment:* ↑ or ↓ activity patterns; weakness, fatigue, ↓ endurance; alcohol or drug abuse; change in family (e.g., loss of a spouse); financial resources
Objective Data
General
Listless, cachectic; underweight for height
Integumentary
Dry, brittle, sparse hair with colour changes and lack of lustre, alopecia; dry, scaly lips, fever blisters, angular crusts and lesions at corners of mouth (cheilosis); brittle, ridged nails; ↓ tone and elasticity of skin; cool, rough, dry, scaly skin with brown-grey pigment changes; reddened, scaly dermatitis, scrotal dermatitis; slight cyanosis; peripheral edema
Eyes
Pale or red conjunctivae, grey keratinized epithelium on conjunctiva (Bitot's spots); dryness and dull appearance of conjunctiva and cornea, soft cornea; blood vessel growth in cornea; redness and fissuring of eyelid corners
Respiratory
↓ respiratory rate, ↓ vital capacity, crackles, weak cough
Cardiovascular
↑ or ↓ heart rate, ↓ BP, dysrhythmias
Gastro-Intestinal
Swollen, smooth, raw, beefy red tongue (glossitis), hypertrophic or atrophic papillae; dental caries, absent or loose teeth, discoloured tooth enamel; spongy, pale, receded gums with a tendency to bleed easily, periodontal disease; ulcerations, white patches or plaques, redness, swelling of oral mucosa; distended, tympanic abdomen; ascites, hepatomegaly, ↓ bowel sounds; steatorrhea
Neurological
Decreased or loss of reflexes, tremor; inattention, irritability, confusion, syncope
Musculo-Skeletal
↓ muscle mass with poor tone, "wasted" appearance; bow legs, knock knees, beaded ribs, chest deformity, prominent bony structures
Possible Diagnostic Findings
↓ hemoglobin and hematocrit; ↓ MCV, MCH, or MCHC (iron deficiency); ↑ MCV or MCH (folic acid or cobalamin deficiency); altered serum electrolyte levels, especially hyperkalemia; ↓ BUN (serum urea [nitrogen]) and creatinine; ↓ serum albumin, transferrin, and prealbumin; ↓ lymphocytes; ↑ liver enzymes; ↓ serum vitamin levels

AIDS, acquired immune deficiency syndrome; *BP*, blood pressure; *BUN*, blood urea nitrogen; *GI*, gastro-intestinal; *MCH*, mean corpuscular hemoglobin; *MCHC*, mean corpuscular hemoglobin concentration; *MCV*, mean corpuscular volume; *TB*, tuberculosis.

Nutrition screening, the first step in assessing nutritional status, can be completed in any setting (e.g., clinic, home, hospital, long-term care facilities). Based on readily obtained data, nutrition screening is an efficient way to identify individuals at nutrition risk, including those who

have experienced unintentional weight loss, inadequate food intake, or recent illness. A variety of valid tools, such as the Canadian Nutrition Screening Tool (CNST), is available for screening different populations (Figure 42-3).

	Date:		Date:	
	Admission		Rescreening	
Ask the patient the following questions*	**Yes**	**No**	**Yes**	**No**
Have you lost weight in the past 6 months **WITHOUT TRYING** to lose this weight? If the patient reports a weight loss but gained it back, consider it as NO weight loss.				
Have you been eating less than usual **FOR MORE THAN A WEEK**?				
Two "YES" answers indicate nutrition risk				

* If the patient is unable to answer the questions, a knowledgeable informant can be used to obtain the information. If the patient is uncertain regarding weight loss, ask if clothing is now fitting more loosely.

FIGURE 42-3 Canadian Nutrition Screening Tool (CNST). Source: Canadian Malnutrition Task Force. (March 2014). *Canadian nutrition screening tool.* Retrieved from *http://nutritioncareincanada.ca/sites/default/uploads/files/CNST.pdf*.

Assessment of Nutritional Intake.

Individuals identified as being at nutritional risk during screening should be referred, when possible, to a dietitian to undergo a *comprehensive nutritional assessment*, which includes evaluation of dietary history and clinical information, physical examination, and anthropometric measures.

Various methods for collecting current dietary intake information are available, including the 24-hour recall, food frequency questionnaire, and food diary. Documentation of nutritional intake for hospitalized patients can best be achieved through calorie counts of nutrients consumed or infused.

The 24-Hour Recall.

The most common method of obtaining information about dietary intake is the *24-hour recall*. The individual or family member is asked to recall everything eaten within the past 24 hours. It is important to be aware of potential information gaps when this method is used: (a) the individual or family member may not be able to recall type or amount of food eaten; (b) intake within the past 24 hours may be atypical of usual intake; (c) the individual or family member may alter the truth for a variety of reasons;

and (d) snack items and use of gravies, sauces, and condiments may be under-reported.

The Food Frequency Questionnaire.

To counter some of the challenges inherent in the 24-hour recall method, a *food frequency questionnaire* may also be completed. Information is collected related to how many times per day, week, or month an individual eats particular foods. The food frequency questionnaire does not quantify amount of food eaten, and, similar to the 24-hour recall, it relies on the individual's or family member's memory.

The Food Diary.

Food diaries require the individual or family member to write down everything consumed for a certain period of time. Three days—2 working and 1 nonworking day—are customarily used. A food diary is most accurate if the individual is instructed to record information immediately after eating. Potential challenges with the food diary include (a) nonadherence, (b) inaccurate recording, (c) atypical intake on the recording days, and (d) conscious alteration of diet during the recording period.

Direct Observation.

Direct observation of the feeding and eating process can lead to detection of problems not readily identified through standard nutrition interviews. For example, observing the typical feeding techniques used by a parent or caregiver and the interaction between the individual and the caregiver can be of value when assessing failure to thrive in children or unintentional weight loss in older adults.

Anthropometric Measurements.

Anthropometric measurements are gross measures of fat and muscle contents. These measurements are most beneficial when done serially and by well-trained anthropometrists to evaluate long-term effects of malnutrition or responses to nutritional interventions. They consist of measures of skinfold thickness at various sites, which are indicators of subcutaneous fat stores, and midarm muscle circumference, an indicator of protein stores. These measurements are then compared with standards for healthy people of the same age and gender.

The sites most reflective of body fat are those over the biceps and the triceps, below the scapula, above the iliac crest, and over the upper thigh. Both skinfold thickness and midarm circumference are decreased in malnutrition. These measurements may also be influenced by shifts in hydration status. The exact relationship of the midarm circumference measure to body composition of functional protein, both muscle and nonmuscle, remains to be established.

Laboratory Studies.

The diagnosis of PCM is best determined by laboratory studies of body composition, including a thorough history of weight loss, dietary history, and measures of functional status and inflammation. Serum albumin has a half-life of approximately 20 to 22 days. In the absence of marked fluid loss, such as from hemorrhage or burns, the serum albumin value lags behind actual protein changes by more than 2 weeks and therefore is not a good indicator of acute changes in nutritional status. Prealbumin, a protein synthesized by the liver, has a half-life of 2 days and is a better indicator of recent or current nutritional status.

However, the extent to which visceral proteins, including albumin, prealbumin, and transferrin, are true markers of malnutrition is questionable. Albumin, prealbumin, and transferrin are *negative acute-phase proteins,* which means that during an inflammatory response, the synthesis of these proteins in the liver is decreased. Therefore, low or below-normal levels of these negative acute-phase proteins correspond to an inflammatory state rather than accurately indicating nutritional status.

CRP, which is a *positive acute-phase protein,* is typically elevated during inflammation and predicts morbidity and mortality. Serum electrolyte levels reflect changes between the intracellular and extracellular spaces. Serum potassium level is often elevated. The RBC count and the hemoglobin level indicate the presence and degree of anemia. The total lymphocyte count decreases with malnutrition. Liver enzyme levels, a reflection of liver function, may be elevated during malnutrition. Serum levels of fat- and water-soluble vitamins are usually decreased. The lowered serum levels of the fat-soluble vitamins correlate with the clinical signs of steatorrhea (fatty stools).

Nursing Diagnoses

Nursing diagnoses for the patient with malnutrition include but are not limited to the following:

- *Imbalanced nutrition: less than body requirements* related to *insufficient dietary intake* (decreased access, ingestion, digestion, or absorption of food)
- *Feeding self-care deficit* related to *fatigue, weakness, discomfort*
- *Deficient fluid volume* related to *insufficient fluid intake* (access to or absorption of fluids)
- *Risk for impaired skin integrity* as evidenced by *inadequate nutrition*
- *Ineffective health maintenance* related to *ineffective coping strategies, insufficient resources*

Planning

The overall goals are that the patient with malnutrition will (a) achieve weight gain, (b) consume a specified number of calories per day (with a diet individualized for the patient), and (c) have no adverse consequences related to malnutrition or nutrition therapies.

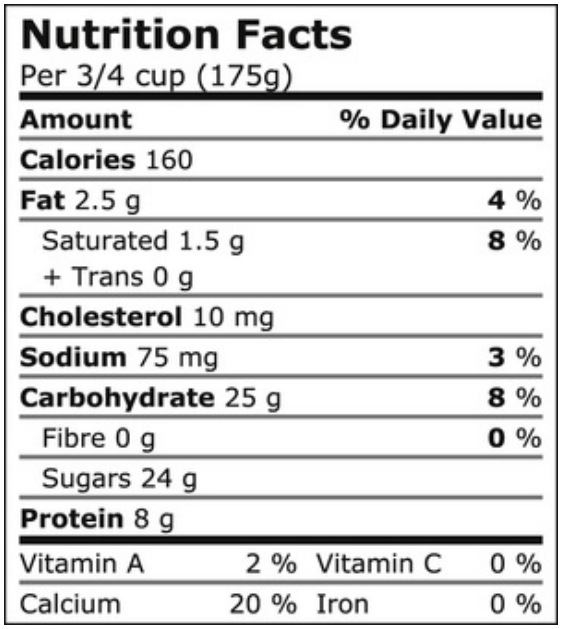
Nursing Implementation

Health Promotion.

Nurses are in an ideal position to teach and reinforce healthy eating habits with individuals and groups of persons throughout the lifespan. Nurses often collaborate with other health care providers (e.g., dietitians, social workers, physicians) in the nutritional assessment and health education of patients. They may use or refer patients to free nutrition resources from Eat Smart Meet Smart (Saskatchewan) or another provincial or territorial source (see the Resources at the end of this chapter).

As part of the health care team, the nurse can support a patient in improving her or his health status by reinforcing healthy eating habits throughout the lifespan. Encouraging healthy eating by teaching Canada's Food Guide and encouraging patients to read food labels will support the patient in making positive changes. Nutrition labelling is mandatory on all prepared foods. The nutrition facts table (Figure 42-4) provides the information needed to make informed food choices; the table includes the amounts of 13 core nutrients and the calories in each serving. This

information allows for the comparison of food products to facilitate healthier food purchases.



Nutrition Facts

Per 3/4 cup (175g)

Amount	% Daily Value
Calories 160	
Fat 2.5 g	**4** %
Saturated 1.5 g + Trans 0 g	**8** %
Cholesterol 10 mg	
Sodium 75 mg	**3** %
Carbohydrate 25 g	**8** %
Fibre 0 g	**0** %
Sugars 24 g	
Protein 8 g	

Vitamin A	2 %	Vitamin C	0 %
Calcium	20 %	Iron	0 %

FIGURE 42-4 Nutrition facts table. An interactive version of this table with explanations of the components and other information are available at the Health Canada Food and Nutrition website (see Resources at the end of this chapter). Acute Care.

Nurses collaborate with the health care provider and dietitian to identify malnutrition and implement appropriate interventions to meet the patient's nutritional needs. The patient's nutritional state, including risk factors for malnutrition, should be assessed during the nurse's physical evaluation.

With increased stress, such as surgery, severe trauma, and sepsis, the patient needs more calories and protein. Wound healing requires increased protein synthesis. The patient who is malnourished or is at risk for malnutrition and is undergoing major surgery needs several weeks of increased protein and calorie intake preoperatively to promote healing and replenish body stores postoperatively. When fever is present, the metabolic rate increases and nitrogen loss accelerates. Despite the return of

body temperature to normal, the rate of protein breakdown and resynthesis may be accelerated for several weeks.

A patient's weight and height should be recorded on admission, and the weight routinely assessed and documented throughout a hospital stay. To ensure accuracy, the nurse should weigh the patient at the same time each day, on the same scale, with the same type or amount of clothing, and with an empty bladder. Before discharge, the patient and caregiver need to be taught the importance of good nutrition and the rationale for recording the daily weight, intake, and output. Daily weights give an ongoing record of body weight gain or loss. Rapid gains and losses are usually the result of shifts in fluid balance. In conjunction with accurate recording of food and fluid intake, the body weight provides a clearer picture of the patient's fluid and nutritional state.

If the patient is able to take food by mouth, obtaining a daily calorie count and diet diary can help ensure an accurate record of food intake. The nurse and the dietitian can assist the patient and family in selecting high-calorie and high-protein foods (unless medically contraindicated). Offering foods preferred by the patient enhances intake, so the family should be encouraged to bring the patient's favourite foods from home.

The environment should be conducive to eating: quiet, with the bedside table cleared of clutter and set at the appropriate height, and urinals, bedpans, and emesis basins placed out of sight. The patient should be offered oral hygiene and hand hygiene and assisted into a comfortable position. If the patient needs help, the nurse should open cartons and packages. Nonurgent care should be performed before or after mealtime to avoid unnecessary interruptions.

Undernourished patients usually need between-meal supplements. These may consist of items prepared in the dietary department or commercially prepared products. These items provide extra calories, proteins, fluids, and nutrients. In addition, offering small, frequent meals may improve a patient's tolerance for food intake by distributing the amount of food more evenly throughout the day. If a patient is unable to consume enough nutrition with a high-calorie, high-protein diet, oral liquid nutritional supplements may be added. The protein and calorie intake required by a malnourished patient depends on the cause of the malnutrition, treatments, and stressors affecting the patient.

Some patients may benefit from appetite stimulants such as megestrol acetate (Megace OS) to improve nutritional intake. If the patient is still unable to take in enough calories, enteral feedings may be considered. Contraindications for enteral nutrition (EN) include GI obstruction,

prolonged ileus, severe diarrhea or vomiting, and enterocutaneous fistula. If enteral feedings are not feasible, parenteral nutrition (PN) may be initiated.

Ambulatory and Home Care.

Patients may be discharged with instructions for a therapeutic diet regimen. Discharge preparation for a patient and family is important. They must be aware of the cause of the undernourished state and strategies to avoid the problem in the future. The patient must be made aware that undernourishment, whatever the cause, can recur and that a diet high in protein and calories for a few weeks cannot fully restore a normal nutritional state; many months are needed to reach this goal. Diet instruction is usually carried out by the dietitian, but it is important for the nurse to assess the patient's understanding and reinforce the information whenever possible. The ability of the patient to follow dietary instructions must be examined in light of past eating habits, religious and ethnic preferences, age, income, community or other resources, and state of health.

The need for continual follow-up care to accomplish and maintain rehabilitation must be emphasized. Discharge planning should include visits by the home health nurse and outpatient dietitian referrals.

Evaluation

The following are expected outcomes for a patient who is malnourished:

- The patient will achieve and maintain optimal body weight.
- The patient will consume a well-balanced diet.
- The patient will experience no adverse outcomes related to malnutrition.
- The patient will maintain optimal physical functioning.

Age-Related Considerations

Malnutrition

Older adults are particularly vulnerable to malnutrition, which increases their rate of hospitalization and care cost. Older hospitalized patients with malnutrition are more likely to have poor wound healing, pressure injuries, infections, decreased muscle strength, postoperative complications, and increased morbidity and mortality risks (DiMaria-Ghalili, 2014). (Pressure injuries are discussed in Chapter 14.) Older adults commonly report a decreased appetite, problems with chewing or swallowing, inadequate nutrient intake, and consumption of only one meal per day. Being on a limited income may play a role in the number of meals eaten per day or the dietary quality of meals. Social isolation is another problem for many older adults. Those who live alone may lose their desire to cook and often report a decrease in appetite. Some older adults may have functional limitations that can affect their ability to purchase food as well as cook and prepare meals. Furthermore, older adults may lack access to transportation to buy food. For a complete list of factors affecting nutritional intake of older adults, see Table 42-8.

TABLE 42-8

AGE-RELATED DIFFERENCES IN ASSESSMENT
Factors Affecting Nutritional Intake in Older Adults

Physical Factors
• Age • Anorexia • Decreased number of taste buds • Dental problems • Food intolerances • Health status • Physical disability • Prescribed diets • Prescribed or over-the-counter drugs
Psychosocial Factors
• Importance of food in the past • Loneliness or loss • Mental awareness • Social isolation
Socioeconomic Factors
• Availability of desired foods • Availability of transportation to food stores • Available time for food preparation and eating • Education level and nutritional knowledge • Financial status • Food restrictions (intentional or unintentional) • Lack of food preparation equipment

Chronic illnesses associated with aging can also affect nutritional status. For example, depression and dysphagia can affect intake. Poor oral health from cavities, gum disease, and missing teeth as well as xerostomia (dry mouth) can impair the older adult's ability to lubricate, masticate, and swallow food. Medications (e.g., antidepressants, antihypertensives, bronchodilators) can cause dry mouth, alter the taste of food, or decrease appetite.

Physiological changes associated with aging include a decrease in lean body mass and redistribution of fat around internal organs, which can decrease caloric requirements. Sarcopenia (loss of lean body mass with aging) affects muscle strength and function (Litchford, 2014). Older adults on bed rest or prolonged inactivity lose more lean body mass than younger adults on bed rest do. Changes in odour and taste perception (due to medications, nutrient deficiencies, or taste-bud atrophy) can also alter nutritional status.

Lifestyle changes such as retirement or relocation to residence living can have a significant impact on the eating habits of older adults. Other factors to assess include ethnic background, previous dietary practices, food preferences, knowledge of proper diet, food availability, accessibility of safe food storage, transportation, and health status. Problems related to

any or all of these areas can alert the nurse to the possibility of a nutritional problem. For older adult patients living in long-term care establishments, eating with others, having the freedom to choose the menu and one's table companions, having appropriate feeding assistance available, and enjoying a calm atmosphere contribute to residents' experiencing more pleasure and gaining more nutrition from their meals.

Some of the physiological changes associated with aging affect the nutritional status of older adults. The following changes are of particular interest:

1. Changes in the oral cavity (e.g., change in bite surfaces of the teeth, periodontal disease, drying of the mucous membranes of the mouth and tongue, poorly fitting dentures, decreased muscle strength for chewing, decreased number of taste buds, decreased saliva production)
2. Changes in digestion and motility (e.g., decreased absorption of cobalamin, vitamin A, and folic acid and decreased GI motility)
3. Changes in the endocrine system (e.g., decreased tolerance to glucose)
4. Changes in the musculo-skeletal system (e.g., decreased bone density, degenerative joint changes)
5. Decrease in vision and hearing (e.g., procurement and preparation of food are more difficult)

Certain illnesses that are more prevalent in the older population are considered to be diet related. These include atherosclerosis, osteoporosis, diabetes mellitus, dementia, cancer, and diverticulosis. Multiple drugs are often required to treat these and other common chronic illnesses of older patients, and many of these drugs have an adverse effect on the appetite, increasing the possibility of inadequate nutrition.

Daily requirements for healthy older adults to maintain their weight include 30 kcal/kg of body weight and 0.8 to 1 g/kg of protein per day, with no more than 30% of calories coming from fat. Requirements may differ among individuals, depending on the degree of malnutrition and physiological stress. To prevent loss of muscle mass and maintain function, older adults should consume a moderate amount of high-quality protein at each meal (Litchford, 2014). Daily vitamin D requirements are also higher for older adults.

Malnutrition can occur in an older person independent of changes in weight and energy requirements. Special strategies, such as adaptive

devices (e.g., large-handled eating utensils), often are helpful in increasing dietary intake. Some older people may require nutritional support therapies until their strength and general health improve. Before starting any nutritional support therapy (e.g., EN or PN), the nurse should review the older adult's advance directives regarding the use of artificial nutrition and hydration.

Some communities offer community nutrition programs for older people as well as home-delivered meal programs such as Meals on Wheels. However, these programs alone may not be able to fully support older adults in accessing adequate nutritious food. It is not uncommon for older adults to access food banks.

Dysphagia

Dysphagia, or difficulty in swallowing, is a symptom of disease or dysfunction and can result from a number of medical conditions. Among adults, the prevalence of dysphagia ranges from 12% to 13% in acute-care facilities and up to 60% in long-term care facilities (Touhy, Jett, Boscart, et al., 2012). Dysphagia increases the risk for malnutrition, dehydration, choking episodes, aspiration, chest infections or pneumonia, and death; in addition, it can cause psychosocial problems, such as social isolation and embarrassment, which may reduce quality of life (Dietitians of Canada, 2015).

Nurses must carefully assess all patients for signs of dysphagia (Table 42-9). A swallowing assessment, performed by a speech–language pathologist can help identify patients at risk for aspiration, including the location of the swallowing problem and which food consistencies are safest. The speech–language pathologist may also determine swallowing exercises, appropriate head positioning, and swallowing techniques.

TABLE 42-9
INDICATORS OF DYSPHAGIA

Obvious Indicators of Dysphagia
• Difficult, painful chewing or swallowing • Regurgitation of undigested food • Difficulty controlling food or liquid in the mouth • Drooling • Hoarse voice • Coughing or choking before, during, or after swallowing • Globus sensation (lump in the throat) • Nasal regurgitation • Feeling of obstruction • Unintentional weight loss—for example, in people with dementia
Less Obvious Indicators of Dysphagia
• Change in respiration pattern • Unexplained temperature spikes • Wet voice quality • Tongue fasciculation (may indicate motor neuron disease) • Xerostomia • Heartburn • Change in eating—for example, eating slowly or avoiding social occasions • Frequent throat clearing • Recurrent chest infections • Atypical chest pain

Source: University of Maryland Medical Centre. (2016). *Dysphagia*. Retrieved from *http://www.umm.edu/health/medical/altmed/condition/dysphagia*.

The goal of nutrition intervention in dysphagia management should be to minimize weight loss (through adequate energy and protein intakes) and maintain hydration. Diet texture and fluid consistency modifications may be required for patient safety. Food texture may be modified with the addition of sauces or gravies and through mechanical alteration such as mincing or puréeing. The consistency of beverages may also be modified through the use of thickening agents. Thickened fluids range in consistency from nectar-like to honey-like to pudding-like consistency.

Evidence-Informed Practice

Research Highlight

Does Nutritional Education Improve Functional Outcomes in Older Adults?

Clinical Question

In older adults (P), what is the effect of nutritional education (I) on diet, physical and emotional functioning, and quality of life (O)?

Best Available Evidence

- Systematic review of RCTs

Critical Appraisal and Synthesis of Evidence

- Twenty-three RCTs (n = 12 610) of community-dwelling older adults (65 yr and older) with various diseases. Five trials with nutritional education only; remaining trials with nutritional and lifestyle advice, exercise advice, or screening. Education varied in format and intensity.
- Outcomes included diet, functional outcomes (e.g., strength, balance), hospital readmissions, depression, anxiety, and quality of life.
- Results showed improved body mass index, weight loss, and physical health with decreased depression.
- Brief interventions were as effective as more lengthy ones.

Conclusion

- Nutritional education alone or in combination with other interventions positively influences physical and emotional health.

Implications for Nursing Practice

- Locate nutritional educational resources for older patients residing at home.
- Help patients identify community programs to make positive changes in lifestyle and exercise.

P, patient population of interest; *I*, intervention or area of interest; *O*, outcomes of interest (see Chapter 1).

Specialized Nutrition Support

Oral Nutrition

If patients are unable to maintain or achieve adequate nutritional status, nutrition support may be necessary. High-calorie oral supplements can help improve the nutritional status of older adults. It is important to note that these supplements should not be used as meal substitutes but between meals as snacks. In some hospitals and long-term care facilities, these beverages are used instead of water with oral medication administration to increase caloric or protein intake (often referred to as *Med Pass*).

For patients who are unable to consume enough nutrition orally with a high-calorie, high-protein diet (food and supplements), nutrition support such as EN (also called *tube feeding*) may be considered. If EN is not feasible, PN may be considered. For a decision-making plan related to nutrition support, see the algorithm in Figure 42-5.

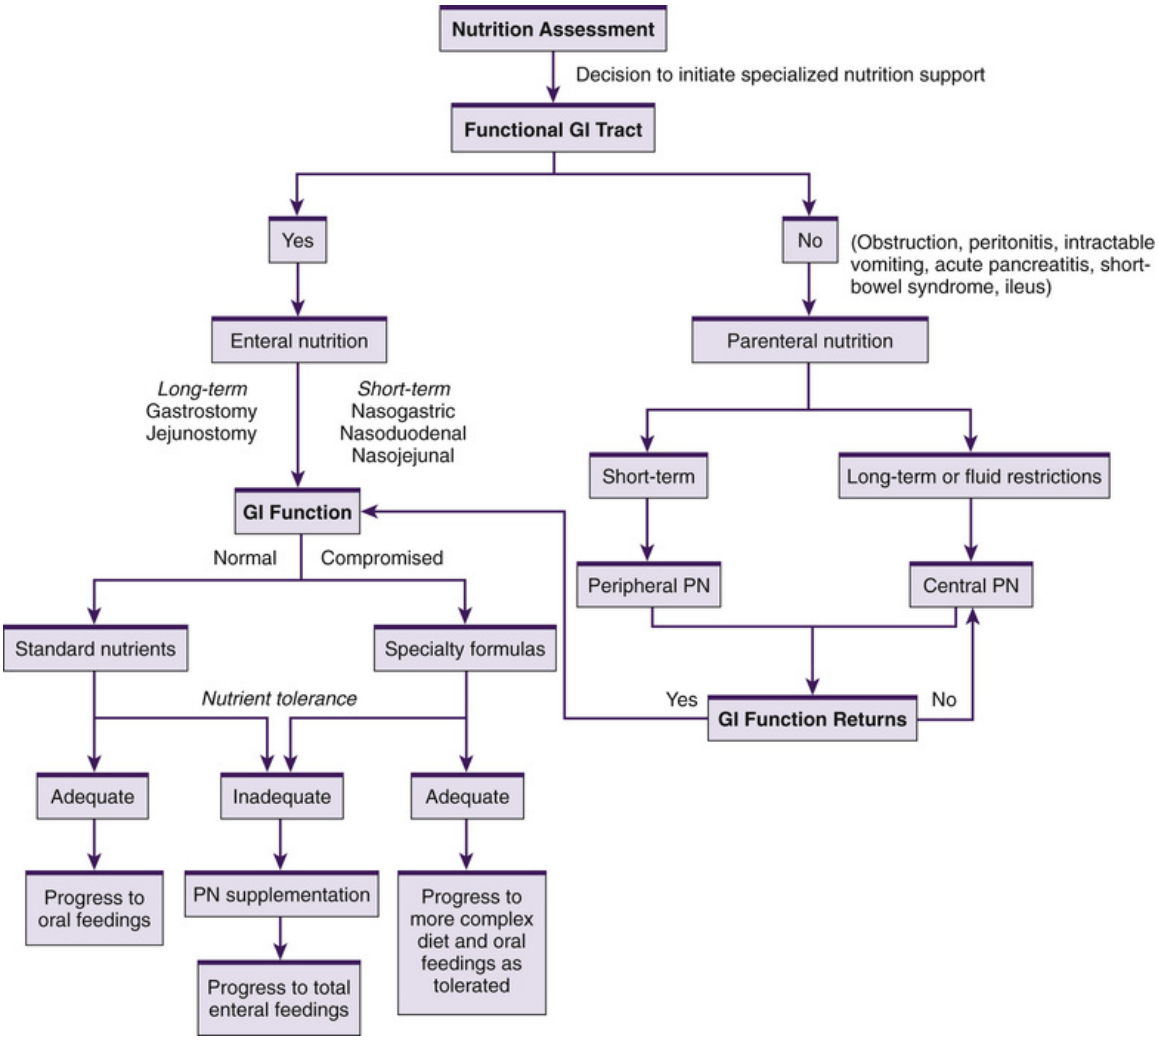

FIGURE 42-5 Nutrition support algorithm. *GI*, gastro-intestinal, *PN*, parenteral nutrition. Source: Adapted with permission of the American Society for Parenteral and Enteral Nutrition (ASPEN). ASPEN Board of Directors. (2002). Guidelines for the use of parenteral and enteral nutrition in adult and pediatric patients. *Journal of Parenteral and Enteral Nutrition*, *26*(Suppl. 1), 8SA.

Enteral Nutrition

Enteral nutrition (EN), also known as *tube feeding,* is nutrition (e.g., a nutritionally balanced liquefied food or formula) delivered through the GI tract distal to the oral cavity via a tube, catheter, or stoma (Boullata, Carney, & Guenter, 2010). EN may be ordered for the patient who has a functioning GI tract but is unable to take any or enough oral nourishment.

Indications for EN may include anorexia, orofacial fractures, head and neck cancer, neurological or psychiatric conditions that prevent oral intake, extensive burns, critical illness, mechanical ventilation, and

chemotherapy or radiation therapy. EN is considered to be more easily administered, safer, more physiologically efficient, and less expensive than PN. EN is used to provide nutrients by way of the GI tract either alone or as a supplement to oral nutrition or PN.

There are a wide variety of enteral formulas. Formula concentration, flavour, osmolality, and amounts of protein, sodium, and fat vary. There are special formulas for patients with diabetes and liver, kidney, or lung disease. Most enteral formulas are lactose free. Most standard formulas provide between 1 and 1.5 kcal/mL; high-energy formulas provide 2 kcal/mL. The more calorically dense the formula, the less water it contains. The number and size of particles in the formula determines its osmolality. The more hydrolyzed or broken down the nutrients, the greater the osmolality.

Common delivery options are continuous or cyclical infusion by pump, intermittent infusion by gravity, or by bolus with a syringe. Continuous infusion is used most often with critically ill patients. Intermittent feeding may be preferred as the patient improves or is discharged home on a tube-feeding regimen (Bankhead, Boulatta, Brantley, et al., 2009).

A nasogastric (NG) tube is commonly used for short-term feeding (<4 weeks). If the feedings are necessary for an extended time, other means of feeding may be used, such as an esophagostomy tube, a gastrostomy tube, or a jejunostomy tube that delivers nutrients directly into the jejunum. Transpyloric (nasointestinal) tube placement or placement into the jejunum is used when physiological conditions warrant feeding the patient below the pyloric sphincter. Figure 42-6 shows the locations of commonly used enteral feeding tubes.

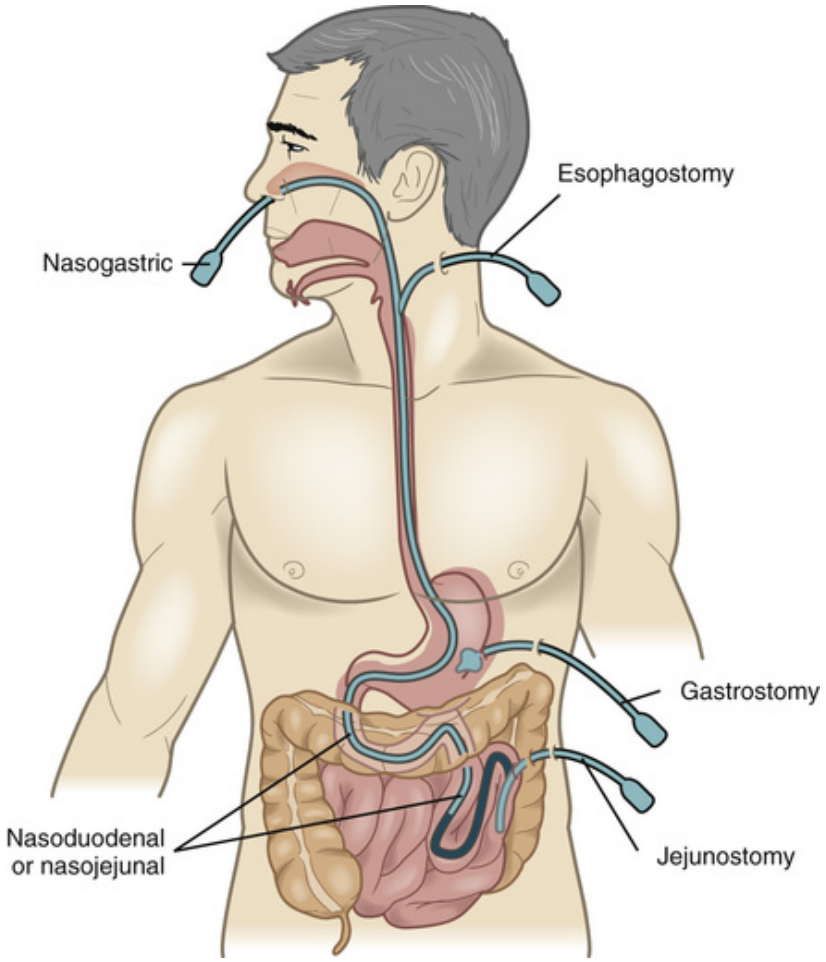

FIGURE 42-6 Common enteral feeding tube placement locations.

Orogastric, Nasogastric, and Nasointestinal Tubes.

Polyurethane or silicone feeding tubes are long, small in diameter, soft, and flexible, thereby decreasing the risk for mucosal damage from prolonged placement. Polyurethane and silicone tubes are radiopaque, making their position readily identified by radiograph. Placement into the small intestine decreases the likelihood of regurgitation of contents into the esophagus and subsequent aspiration. With the use of a stylet, these tubes can be placed in a comatose patient because the ability to swallow is not essential during insertion.

Although the smaller feeding tubes (12-8 French) have advantages over wider-lumen tubes (≥14 French), such as the standard decompression NG tube, there are some disadvantages. Because of the small diameter, these tubes are more easily occluded, and it can be more problematic to check for gastric residual volumes. They are particularly prone to obstruction

when oral drugs have not been thoroughly crushed and dissolved in water before administration. Failure to flush the tubing after both drug administration and residual volume determinations can result in tube clogging. Clogging of the tube may necessitate removal and insertion of a new tube, adding to cost and patient discomfort.

Gastrostomy and Jejunostomy Tubes.

A gastrostomy tube may be used for a patient who requires EN over an extended time (>4–6 weeks) (Figure 42-7).

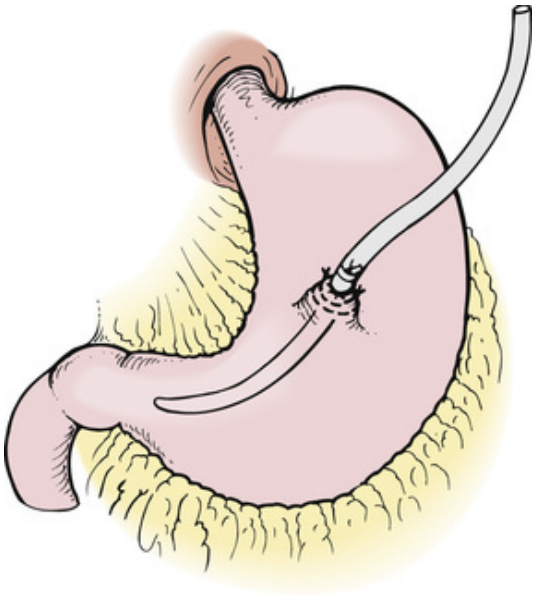

FIGURE 42-7 Placement of a gastrostomy tube. Source: Redrawn from Mahan, L. K., & Arlin, M. (1992). *Krause's food, nutrition, and diet therapy* (8th ed.). Philadelphia: Saunders.

Gastrostomy tubes can be placed surgically, radiologically, or endoscopically. The placement of a percutaneous endoscopic gastrostomy (PEG) tube is shown in Figure 42-8. The patient must have an intact, unobstructed GI tract, and the esophageal lumen must be wide enough to pass the endoscope for PEG tube placement. A PEG tube and a radiologically placed gastrostomy tube have several advantages. These procedures have fewer risks than surgical placement. They require IV sedation and local anaesthesia, a technique that can be done at a lower cost. IV antibiotics are given before the procedure.

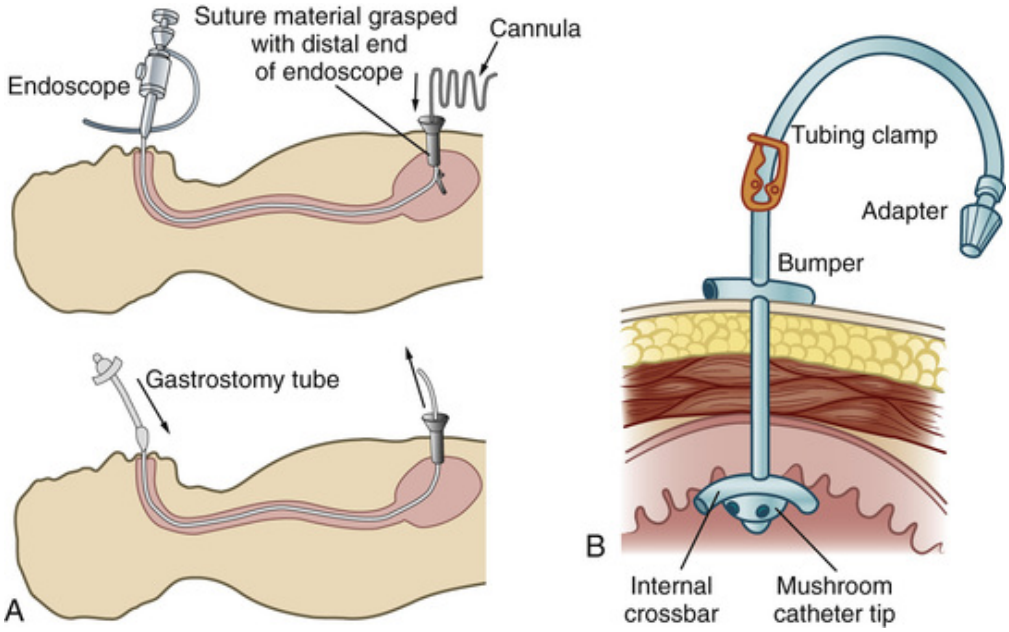

FIGURE 42-8 Percutaneous endoscopic gastrostomy. **A,** Gastrostomy tube placement via percutaneous endoscopy. Using endoscopy, a gastrostomy tube is inserted through the esophagus into the stomach and then pulled through a stab wound made in the abdominal wall. **B,** A retention disc and bumper secure the tube.

For the patient with chronic reflux, a jejunostomy tube with continuous feedings may be appropriate to reduce the risk for aspiration (Bankhead, Boullata, Brantley, et al., 2009). Jejunostomy tubes are placed either endoscopically or with open or laparoscopic surgery. Combination gastro-jejunostomy (GJ) tubes allow for simultaneous gastric decompression and small bowel feeding. When a patient has a GJ tube, it is important to know which port is the gastric and which is the jejunal.

Enteral feedings can be started within 24 to 48 hours after surgical placement of a gastrostomy or jejunostomy tube, without waiting for flatus or a bowel movement. Most PEG tube feeding can start within 2 hours of insertion, although institutional policies may vary (Boullata, Carney, & Guenter, 2010). The feeding tube is either premarked or marked at the skin insertion site. At regular intervals, the tube insertion length should be rechecked. The tube is most often connected to a pump for continuous feeding.

Tube Feedings and Safety.

Nurses play a critical role in ensuring that tube feedings are administered safely. Aspiration and dislodged tubes are two important safety concerns.

Nursing management of tube feedings is addressed in Table 42-10.

TABLE 42-10
NURSING MANAGEMENT: FEEDING TUBES

1. The nurse should check tube placement before feeding and before each drug administration.
2. GI contractility factors should be evaluated when initiating EN; however, overt signs of contractility should not be required prior to initiation of EN.
3. Liquid medications should be used rather than pills, as appropriate.
    - Viscous liquid medications should be diluted.
    - The nurse should confirm whether medications are intended to be taken with meals.
    - Medications should not be added to enteral feeding formula.
4. If it is necessary to use tablets, they should be crushed to a fine powder to prevent clogging feeding tubes.
5. General principles of tube feeding (e.g., bed elevation, checking gastric residual volume, and flushing tube with water) must be followed.
6. The nurse should assess regularly for complications (e.g., aspiration, diarrhea, abdominal distension, hyperglycemia, constipation, and fecal impaction).

EN, enteral nutrition; *GI*, gastro-intestinal.

Accidental tube removal can result in delayed feedings and potential discomfort because of tube replacement. The management of common problems in patients receiving tube feedings is presented in Table 42-11. A nursing care plan (NCP) 42-1 for the patient receiving enteral nutrition is available on the Evolve website.

TABLE 42-11
COMMON PROBLEMS OF PATIENTS RECEIVING TUBE FEEDINGS

Problems and Possible Causes	Corrective Measures
Vomiting and Aspiration	
Improper tube placement	Replace tube in proper position and check tube position before beginning feeding and q8h if feedings are continuous
Delayed gastric emptying, increased residual volume	Hold feeding for 1 hr; then, if residual volume is less than before, resume feeding
Aspiration risk	Keep head of bed elevated to 30- to 45-degree angle Have patient sit up on side of bed or in chair Encourage ambulation unless contraindicated
Contamination of formula	Refrigerate unused formula and recording date opened; discard outdated formula every 24 hr Discard formula left standing for longer than manufacturer's guidelines: 8–12 hr for ready-to-feed formulas (cans) or 4 hr for reconstituted formula or closed system as per manufacturer's guidelines
Diarrhea	
Feeding too fast, hypertonic formula, or medications	Evaluate number and volume of stools (if greater than three to five per day or >500 mL), consider patient's medical history, and assess abdomen for distension or pain Contact physician, consider medications, and rule out infection *(Clostridium difficile)* Decrease rate of feeding Change to continuous drip feedings Check for drugs that may cause diarrhea (e.g., antibiotics)
Contamination of formula or tubing	Change tubing q24h Follow manufacturer's guidelines for maximum length of time formula can be at room temperature
Low-fibre formula	Change to formula with more fibre
Tube moving distally	Properly secure tube before beginning feeding Check tube position before each feeding or at least q24h if feedings are continuous
Constipation	
Low fibre	Consult health care provider for change in formula to one with higher fibre content Obtain bowel routine order
Poor fluid intake	Increase fluid intake if not contraindicated Give free water, as well as formula, to a total fluid intake of 30 mL/kg body weight
Medications	Check for medications that may be constipating
Impaction	Perform rectal examinations to check for and manually remove feces if present
Dehydration	
Excessive diarrhea, vomiting	Decrease rate or changing formula Check drugs that patient is receiving, especially antibiotics Take care to prevent bacterial contamination of formula and equipment
Poor fluid intake	Increase intake, if appropriate, and check amount and number of feedings
High-protein formula	Change formula
Hyperosmotic diuresis	Check blood glucose levels frequently Change formula

Specific care and teaching related to feeding tubes and enteral nutrition are summarized in the following section. Remember that it is important to teach the patient and caregiver how to care for the feeding tube and how to properly administer enteral nutrition.

Patient Position.

Proper patient positioning decreases the risk for aspiration. To prevent aspiration, the nurse should elevate the head of the bed to a minimum of 30 degrees, but preferably 45 degrees. If the patient does not tolerate a backrest elevation, the reverse Trendelenburg position should be used to elevate the head of the bed unless contraindicated. If the head of the bed needs to be lowered for a procedure, the patient should be returned to an elevated position as soon as possible. Institution policy should be followed for suspending feeding while the patient is supine. If intermittent delivery is used, the head should remain elevated for 30 to 60 minutes after feeding.

Aspiration Risk.

All enterally fed patients should be evaluated for risk of aspiration. Before starting tube feedings, the nurse should ensure the tube is in the proper position and maintain head-of-bed elevation as described above. Checking gastric residual volumes is important when giving feedings into the stomach. An increased residual volume increases the risk for aspiration of the formula into the lungs (Boullata, Carney, & Guenter, 2010).

Gastric residual volumes should be checked every 4 hours during the first 48 hours for gastrically fed patients. After attaining the enteral feeding rate goal, gastric residual monitoring can be decreased to every 6 to 8 hours in non–critically ill patients or continued every 4 hours in critically ill patients. Promotility drugs such as erythromycin or metoclopramide improve gastric emptying and may reduce aspiration risk. Feeding tubes may need to be advanced below the ligament of Treitz (jejunostomy) if gastric residual volumes consistently measure more than 500 mL. The nurse should not obtain residual volumes for EN delivered through a jejunostomy tube.

Tube Position.

Radiographic confirmation of proper positioning in the GI tract needs to be obtained for newly inserted nasal or orogastric tubes (small-bore or large-bore) before administering feedings or medications. Smaller feeding tubes can pass directly into the bronchus on insertion without any obvious respiratory manifestations. The nurse should not rely on the auscultation method to differentiate between gastric and respiratory or gastric and small bowel placement.

Proper placement of the tube needs to be maintained after starting feedings. A small bowel tube may dislocate upward into the stomach, or the tube's tip can dislocate upward into the esophagus. To determine if a feeding tube is still in the proper position, the nurse should mark the exit

site of the feeding tube at the time of the initial radiograph and check the tube's external length regularly.

The nurse should observe for negative pressure when attempting to withdraw fluid from the feeding tube (Boullata, Carney, & Guenter, 2010). Negative pressure is more likely to be felt during attempts to aspirate fluid from a small bowel tube than from a gastric tube. The nurse also needs to observe for unexpected changes in residual volume. An increase in gastric residual volume may indicate displacement of a small intestine tube into the stomach (Boullata, Carney, & Guenter, 2010). If a significant increase is observed in the external length, other bedside tests should be used to help determine whether the tube has become dislocated. These measures include assessing aspirate colour and pH. Because each of these measures has limitations, placement should be confirmed with more than one test. The nurse should consider applying a nasal bridle in patients who attempt to pull out a tube or for whom taping the nose is difficult.

Site Care.

Skin care around gastrostomy and jejunostomy tube sites is important because the action of digestive juices irritates the skin. The skin around the feeding tube should be assessed daily for signs of redness and maceration. The nurse needs to monitor bumper tension and routinely check for pressure injury.

To keep the skin clean and dry, the nurse should initially rinse it with sterile water, dry it, and apply a dressing until the site is healed. After that, the site can be washed with mild soap and water. A protective ointment (zinc oxide, petroleum gauze) or a skin barrier may be used on the skin around the tube. If the skin is irritated, the nurse should consider using other types of drain or tube pouches. A wound, ostomy, and continence nurse can provide assistance if issues arise.

Tube Patency.

All enteral feeding tubes require routine flushing. They should be flushed with 30 mL of warm tap water every 4 hours during continuous feedings or before and after each intermittent feeding. Sterile water should be used in immuno-compromised and critically ill patients. Tubes must be flushed between each medication and after all medications are given. The nurse should try to only use liquid medications and not mix medications (Boullata, Carney, & Guenter, 2010). Clogged tubes should be flushed with warm water, using a back-and-forth motion.

Misconnection.

An *enteral feeding misconnection* is an inadvertent connection between an enteral feeding system and a nonenteral system such as an IV line, a peritoneal dialysis catheter, or a tracheostomy tube cuff. With an enteral feeding misconnection, nutritional formula intended for administration into the GI tract is administered via the wrong route, resulting in serious and potentially life-threatening consequences. Nursing interventions aimed at decreasing the risk for enteral feeding misconnections are found in Table 42-12. (See also NCP 42-1, available on the Evolve website, for patients receiving EN.)

TABLE 42-12

NURSING MANAGEMENT: DECREASE RISK FOR ENTERAL FEEDING MISCONNECTIONS

To decrease the risk for enteral feeding misconnections, the nurse should do the following:
1. Teach visitors and nonclinical staff to notify a nurse if an enteral feeding line becomes disconnected.
2. Teach visitors and nonclinical staff not to reconnect enteral feeding lines.
3. Never modify or adapt IV or feeding devices, because doing so may compromise the safety features incorporated into their design.
4. When making a reconnection, routinely trace lines back to their origins and then ensure that they are secure.
5. Never force connections if the device parts do not seem to fit properly. Ill-fitting pieces indicate a problem.
6. When a patient arrives on a new unit or in a new setting, or during shift-to-shift hand-off, recheck connections and trace all tubes.
7. Route tubes and catheters that have different purposes in distinct and standardized directions (e.g., IV lines should be routed toward the patient's head, enteral lines should be routed toward the feet).
8. Package together all parts needed for enteral feeding and reduce the availability of additional adapters and connectors so as to minimize the presence of dissimilar tubes or catheters that could be improperly connected.
9. Label or colour-code feeding tubes and connectors and educate staff about the labelling or colour-coding process in the institution's enteral feeding system.
10. Always identify and confirm the solution's label, because a three-in-one parenteral nutrition solution can appear similar to an enteral nutrition formulation bag. The bags should be labelled with large, bold statements such as "WARNING! For Enteral Use Only—NOT for IV Use."
11. Make all connections under proper lighting conditions.
12. Follow the facility's protocol for reporting adverse events and near misses.

Hicks, Debora Simmons, Jay Crowley, Stephanie Joseph, Richard Croteau, Cathie Gosnell, Nancy G. Pratt, Timothy W. Vanderveen, Enteral feeding misconnections: A consortium position statement, pp. 289–290, Copyright 2008, with permission from Elsevier.

Age-Related Considerations

Enteral Feeds

EN feeding strategies are used in older patients to improve nutritional status. Because of physiological changes associated with aging, older adults are more vulnerable to complications associated with nutritional interventions, especially fluid and electrolyte imbalances. Complications such as diarrhea can leave the patient dehydrated. Decreased thirst perception or impaired cognitive function decreases the patient's ability to seek additional fluids.

With aging comes an increased risk for glucose intolerance. As a result, older patients may be more susceptible to hyperglycemia in response to the high carbohydrate load of some EN formulas. Older adults with compromised cardiovascular function (e.g., heart failure) will have a decreased ability to handle large volumes of formula. If this happens, the patient may need a more concentrated formula (2.0 kcal/mL). Older adults have an increased risk for aspiration caused by gastro-esophageal reflux disease (GERD), delayed gastric emptying, hiatal hernia, or diminished gag reflex. Physical mobility, fine motor movement, and visual system changes associated with aging may contribute to difficulties in managing EN in the home setting.

Parenteral Nutrition

Parenteral nutrition (PN) refers to the administration of nutrients by a route other than the GI tract (e.g., the bloodstream). (Parenteral nutrition was formerly called total parenteral nutrition [TPN].) PN is used when the GI tract cannot be used for the ingestion, digestion, and absorption of essential nutrients. PN is a relatively safe method of providing complete nutritional support.

PN is customized to meet the needs of each patient. The composition is reformulated as the patient's condition changes. The nurse, therefore, must collaborate with the interprofessional team in delivering PN to the patient.

Composition.

Commercially prepared PN base solutions are available. These solutions contain dextrose and protein in the form of amino acids. The pharmacy adds prescribed electrolytes (e.g., sodium, potassium, chloride, calcium,

magnesium, and phosphate), vitamins, and trace elements (e.g., zinc, copper, chromium, and manganese) to meet the patient's needs. A three-in-one or total nutrient admixture containing an IV fat emulsion (lipids), dextrose, and amino acids is widely used. Premixed PN solutions are relatively new and require manipulation of the dextrose and amino acids prior to use. Standard electrolytes are available in premixed solutions, and multivitamins are added prior to use (Ayers, Holcombe, Plogsted, et al., 2014). Table 42-13 lists common indications for the use of PN. NCP 42-2, available on the Evolve website, presents nursing diagnoses and care for patients undergoing parenteral nutrition.

TABLE 42-13
COMMON INDICATIONS FOR PARENTERAL NUTRITION*

- Chronic severe diarrhea and vomiting
- Complicated surgery or trauma
- Gastro-intestinal obstruction
- Gastro-intestinal tract anomalies and fistulas
- Intractable diarrhea
- Severe anorexia nervosa
- Severe malabsorption
- Short bowel syndrome

*This list is not all-inclusive.

Calories.

Calories in PN are supplied primarily by carbohydrates in the form of dextrose and by fat in the form of fat emulsion. The administration of between 100 and 150 g of dextrose (1 g provides ≈3.4 kcal, as opposed to oral carbohydrates, which provide 4 kcal) has a protein-sparing effect. Providing adequate nonprotein calories in the form of glucose and fat allows the use of amino acids for wound healing and not for energy. However, overfeeding can lead to metabolic complications. To minimize these problems, an energy intake of 25 to 35 kcal/kg/day in a nonobese patient is often recommended.

Fat-emulsion solutions of 10%, 20%, and 30% are available. Fat emulsions provide approximately 1 kcal/mL (10% solution) or 2 kcal/mL (20% solution). Fat emulsions primarily contain soybean or safflower triglycerides with egg phospholipids added as an emulsifier. They provide a large number of calories in a relatively small amount of fluid. This is beneficial when the patient is at risk for fluid overload.

IV fat emulsions should provide up to 30% of total calories. Most stable patients receive 1 g/kg/day, and the maximum daily lipid dose is 2.5 g/kg.

Critically ill patients may not tolerate this dose and may receive less than 1 g/kg/day. Serum triglyceride levels are determined at the beginning of PN and then monitored closely after that. IV fat emulsions administered separately should be administered over a course of 8 to 10 hours, and infusion rates should not exceed 0.11 g/kg/hour (Ayers, Holcombe, Plogsted, et al., 2014).

Nausea, vomiting, and elevated temperature may occur, especially when lipids are infused quickly. Fat emulsions are contraindicated in the patient with a disturbance in fat metabolism, such as hyperlipidemia. They are used cautiously in the patient at risk for fat embolism (e.g., fractured femur) and the patient with an allergy to eggs or soybeans. Lipid emulsions are also used cautiously in patients with pancreatitis, bleeding disorders, liver failure, or respiratory disease.

Protein.

The normal healthy person of average body size needs approximately 45 to 65 g (0.8–1 g/kg/day) of protein daily. Protein should be provided at the rate of 1 to 1.5 g/kg/day depending on the patient's needs. In a nutritionally depleted patient who is also under the stress of illness or surgery, protein requirements can exceed 150 g/day (1.5 to 2 g/kg/day) to ensure positive nitrogen balance. Burn patients, who are often on PN, EN, and oral food, may need upward of 2 g/kg/day. Protein needs may be lower than 1 g/kg/day and restricted in individuals with end-stage renal disease who are not on dialysis.

Electrolytes.

The exact amount of electrolytes needed depends on the patient's health problem and on serum electrolyte levels. The assessment of individual requirements should take place daily at the beginning of therapy and then several times a week as the treatment progresses. The following are ranges for average daily electrolyte requirements for adult patients without renal or hepatic impairment (Ayers, Holcombe, Plogsted, et al., 2014).

Sodium: 1 to 2 mmol/kg/day
Potassium: 1 to 2 mmol/kg/day
Chloride: as needed to maintain acid–base balance
Magnesium: 8 to 20 mmol/day
Calcium: 10 to 15 mmol/day
Phosphate: 20 to 40 mmol/day

The exact amount of electrolytes needed depends on the patient's health problem and on electrolyte levels as determined by blood testing.

Trace Elements and Vitamins.

Zinc, copper, chromium, manganese, selenium, molybdenum, and iodine supplements may be added according to the patient's condition and needs. Levels of these elements are monitored in the patient receiving PN. The health care provider may order additional amounts of these elements to be added to the solutions according to the patient's requirements.

The daily addition of a multivitamin preparation to the PN generally meets the vitamin requirements.

Methods of Administration.

PN may be administered as central parenteral nutrition (CPN) or peripheral parenteral nutrition (PPN). Both CPN and PPN are used in a patient who is not a candidate for EN.

Central Parenteral Nutrition.

Central peripheral nutrition is indicated when long-term support is necessary or when the patient has high protein and caloric requirements. CPN is administered through a central venous catheter or a peripherally inserted central catheter (PICC) whose tip lies in the superior vena cava (see Chapter 19). CPN solutions are hypertonic, measuring at least 1 600 mmol/L. The high glucose content ranges from 20% to 50%. CPN must be infused in a large central vein so that rapid dilution can occur. The use of a peripheral vein for hypertonic CPN solutions would cause irritation and thrombo-phlebitis.

CPN may be given through a central venous catheter that originates at the subclavian or jugular vein and whose tip lies in the superior vena cava (see Figure 42-9). It can also be given using a PICC that is placed into the basilic or cephalic vein and then advanced into the distal end of the superior vena cava (see Figure 19-19).

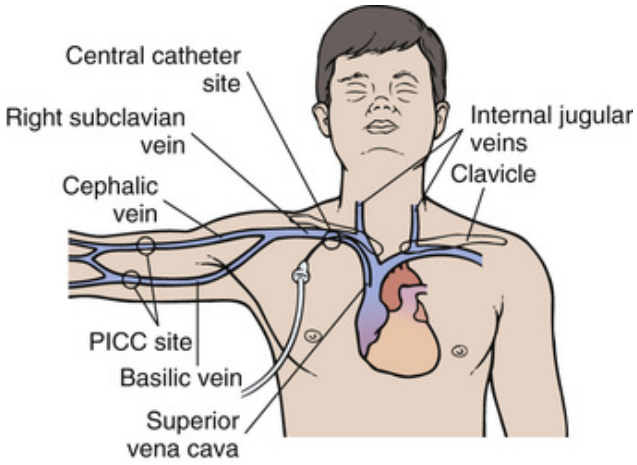

FIGURE 42-9 Placement of a catheter for central parenteral nutrition using the subclavian vein. Peripherally inserted central catheters (PICCs) are inserted using the basilic or the cephalic vein.

Source: Redrawn from Mahan, L. K., & Arlin, M. (1992). *Krause's food, nutrition, and diet therapy* (8th ed.). Philadelphia: Saunders.

Peripheral Parenteral Nutrition.

Peripheral parenteral nutrition is administered through a peripherally inserted catheter or vascular access device, which uses a large vein. PPN is used when (a) nutritional support is needed for only a short time, (b) protein and caloric requirements are not high, (c) the risk of a central catheter is too great, or (d) PN is used to supplement inadequate oral intake.

Comparison of Central and Peripheral Parenteral Nutrition.

Compared with CPN, PPN contains fewer nutrients. Although having fewer nutrients makes PPN less hypertonic, it still has an osmolality of up to 800 mmol/L. This level of osmolality increases the risk for phlebitis. Another potential complication of PPN is fluid overload. PPN requires large volumes of fluid, which many patients cannot tolerate.

Complications.

Complications associated with PN are related either to the catheter or to the PN infusion itself (Table 42-14).

TABLE 42-14
COMPLICATIONS OF PARENTERAL NUTRITION

Infection
• Fungal • Gram-positive bacteria • Gram-negative bacteria
Metabolic
• Hyperglycemia; hypoglycemia; and hyperosmolar, hyperglycemic state • Altered renal function (prerenal azotemia) • Essential fatty acid deficiency • Electrolyte and vitamin excesses and deficiencies • Trace mineral deficiencies • Dyslipidemia
Catheter-Related Problems
• Air embolus • Pneumothorax, hemothorax, and hydrothorax • Hemorrhage • Dislodgement • Thrombosis of great vein • Phlebitis

Refeeding syndrome is characterized by fluid retention and electrolyte imbalances (hypophosphatemia, hypokalemia, hypomagnesemia). Hypophosphatemia is the hallmark of refeeding syndrome and is associated with serious outcomes, including cardiac dysrhythmias, respiratory arrest, and neurological disturbances (e.g., paresthesias). Conditions that predispose patients to refeeding syndrome include longstanding malnutrition states, such as alcohol use disorder, vomiting and diarrhea, chemotherapy, and major surgery. Refeeding syndrome can occur any time a malnourished patient starts aggressive nutritional support.

Nursing Management Parenteral Nutrition

Home Nutrition Support

Home PN or EN is an accepted mode of nutritional therapy for the person who does not require hospitalization but requires continued nutrition support. Some patients have been successfully treated at home for many months and even years. It is important for the nurse to educate the patient or caregiver about catheter or tube care, proper technique in mixing and handling of the solutions and tubing, and adverse effects and complications.

Home nutritional therapies are expensive, and specific criteria must be met for these expenses to be reimbursed by provincial, territorial, or private health insurance programs. The discharge planning team needs to be involved early in the admission to help plan for discharge. Home nutrition support may also be a burden on the patient and caregivers and may affect quality of life.

Case Study

Undernutrition

Source: Tolikoff Photography/Shutterstock.com.

Patient Profile

Mrs. Mary Smith is a 70-year-old woman who is 162.5 cm tall and weighs 45.4 kg. She was recently admitted to the medical unit at a community hospital in Yellowknife, Northwest Territories.

Subjective Data

- Reports 13.5-kg weight loss during past 2 months
- Has recently had a thrombotic stroke with hemiparesis and dysphagia
- Has a history of rheumatoid arthritis
- Has had nothing by mouth for the past 24 hours and just started enteral nutrition via a PEG tube
- Lives with her daughter, who is at her bedside

Objective Data

Physical Examination

- Has left-sided weakness
- Blood pressure is 150/90 mm Hg
- A PEG tube was recently placed

Laboratory Results

- Serum albumin 29 g/L
- Prealbumin 1.1 g/L

Discussion Questions

1. What are Mrs. Smith's risk factors for malnutrition?
2. What is her BMI?
3. What factors increase her risk for developing dysphagia and malnutrition?
4. What should the nurse include in a successful weight-gain program for Mrs. Smith?
5. What possible complications of enteral nutrition could Mrs. Smith be at risk for developing?
6. ***Priority decision:*** What is the priority of the nursing care for Mrs. Smith?
7. ***Priority decision:*** Based on the assessment data presented, what are the priority nutrition-related problems and the issues that the

multidisciplinary team could collaborate on to improve Mrs. Smith's nutritional status?

8. ***Evidence-informed practice:*** Mrs. Smith's daughter tells the nurse that her mother's abdomen appears bloated, and she wonders if she should massage it.

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. The percentage of daily calories (acceptable macronutrient ranges) for healthy adults (≥19 yr) as described in Canada's Food Guide consists of which of the following?
   a. 10%–20% carbohydrate, 30%–45% protein, 10%–25% fat
   b. 30%–45% carbohydrate, 15%–30% protein, 25%–40% fat
   c. 5%–15% carbohydrate, 35%–55% protein, 5%–20% fat
   d. 55% carbohydrate, 15%–20% protein, 30% fat
2. During starvation, in what order does the body obtain substrate for energy?
   a. Glycogen, skeletal protein, fat, visceral protein
   b. Visceral protein, fat stores, glycogen
   c. Fat stores, skeletal protein, visceral protein
   d. Liver protein, muscle protein, visceral protein
3. For which type of client is a complete nutritional assessment including anthropometric measurements important? *(Select all that apply)*
   a. A client with a BMI of 17.5 kg/m^2
   b. A client complaining of frequent nocturia
   c. A client who reports a 5-year history of constipation
   d. A client who reports an unintentional weight loss of 5 kg in 2 months
4. What is one advantage of a percutaneous endoscopic gastrostomy (PEG) tube placement relative to nasogastric (NG) feedings for the client receiving long-term enteral nutrition?
   a. It increases client comfort.
   b. It eliminates the risk for aspiration.
   c. Feedings can be initiated before bowel sounds are present.
   d. More calories can be delivered compared with NG feeding.
5. A client is receiving peripheral parenteral nutrition. The PN solution is completed before the new solution arrives on the unit. What should the nurse administer?
   a. 20% intralipids

b. 5% dextrose solution

c. 5% Ringer's lactate solution

d. 0.45% normal saline solution

6. A client with anorexia nervosa shows signs of malnutrition. During initial refeeding, what does the nurse carefully assess the client for?

a. Hyperkalemia

b. Hypoglycemia

c. Hypercalcemia

d. Hypophosphatemia

1. d; 2. a; 3. a, d; 4. a; 5. b; 6. a.

CHAPTER 43

Nursing Management

Obesity

Written by, Sharon L. Lewis

Adapted by, Kathy G. Danzinger, Jenifer R. Bennett

LEARNING OBJECTIVES

1. Discuss the epidemiology and etiology of obesity.
2. Describe the classification systems for determining a person's body size and associated health risks.
3. Explain the health risks associated with obesity.
4. Discuss nutritional, physical activity, and behaviour-modification therapies for patients who are obese.
5. Describe the different bariatric surgical procedures used to treat obesity.
6. Describe the nursing management related to conservative and surgical therapies for obesity.
7. Describe the etiology, the clinical manifestations, and the nursing and collaborative management of metabolic syndrome.

KEY TERMS

bariatric surgery, p. 1004
body mass index (BMI), p. 994
lipectomy, p. 1007

metabolic syndrome, p. 998
morbidly obese, p. 995
obese, p. 995
obesity, p. 993
overweight, p. 994
waist-to-hip ratio (WHR), p. 995

Obesity

Obesity is a complex, chronic, multifactorial disease that develops from the interaction between genetics and the environment. It manifests as an abnormal increase in the proportion of fat cells in the body. Weight gain in which the body is moving toward an overweight or obese state is characterized predominantly by adipocyte hypertrophy and hyperplasia. Through this process, adipocytes can increase their volume several thousand times to accommodate large increases in lipid storage. In addition, preadipocytes are triggered to become adipocytes. This process occurs primarily in the visceral (intra-abdominal) and subcutaneous tissues of the body (Cornier, Després, Davis, et al., 2011).

Overweight and obesity result from a complex interaction of genetic, nutritional, physiological, psychological, behavioural, environmental, and social factors that create an imbalance between energy intake and energy expenditure. There is increasing evidence that obesity is not a problem resulting from a lack of willpower and self-control but, instead, is a pervasive, progressive, and serious chronic condition that is strongly associated with a variety of comorbid conditions and that has a major effect on the physical, mental, social, cultural, and economic health of those affected (Williams, Mesidor, Winters, et al., 2015). The Canadian Medical Association's having recognized obesity as a chronic disease will lead to enhanced funding for research, prevention, and treatment (Rich, 2015). Interventions to address obesity must account for the complexity and progressive nature of the chronic condition and support appropriate lifelong management, which often necessitates sustained contact and support from trained health care providers (Kirk, Penney, McHugh, et al., 2011).

Classifications of Body Weight and Obesity

The majority of people with obesity have *primary obesity*, which is calorie intake that exceeds the body's metabolic demands. Others have *secondary obesity*, which can result from various congenital anomalies, chromosomal anomalies, metabolic problems, or lesions and disorders of the central nervous system. The first step in the treatment of obesity is to determine whether the patient has any physical conditions that may be causing or contributing to the obesity. A thorough history and physical examination are necessary and will reveal the extent and duration of the obesity.

The degree to which a patient is classified as underweight, healthy (normal) weight, overweight, or obese is assessed with the use of a **body mass index (BMI)** chart (Figure 43-1). BMI is calculated by dividing weight (in kilograms) by height (in metres squared). Research studies in large groups of people have shown that the BMI can be classified into ranges associated with health risk (Table 43-1). Individuals with a BMI of 25 to 29.9 kg/m^2 are classified as being **overweight,** those with a BMI of 30 to 40 kg/m^2 are classified as **obese,** and those with a BMI of more than 40 kg/m^2 are classified as **morbidly obese.**

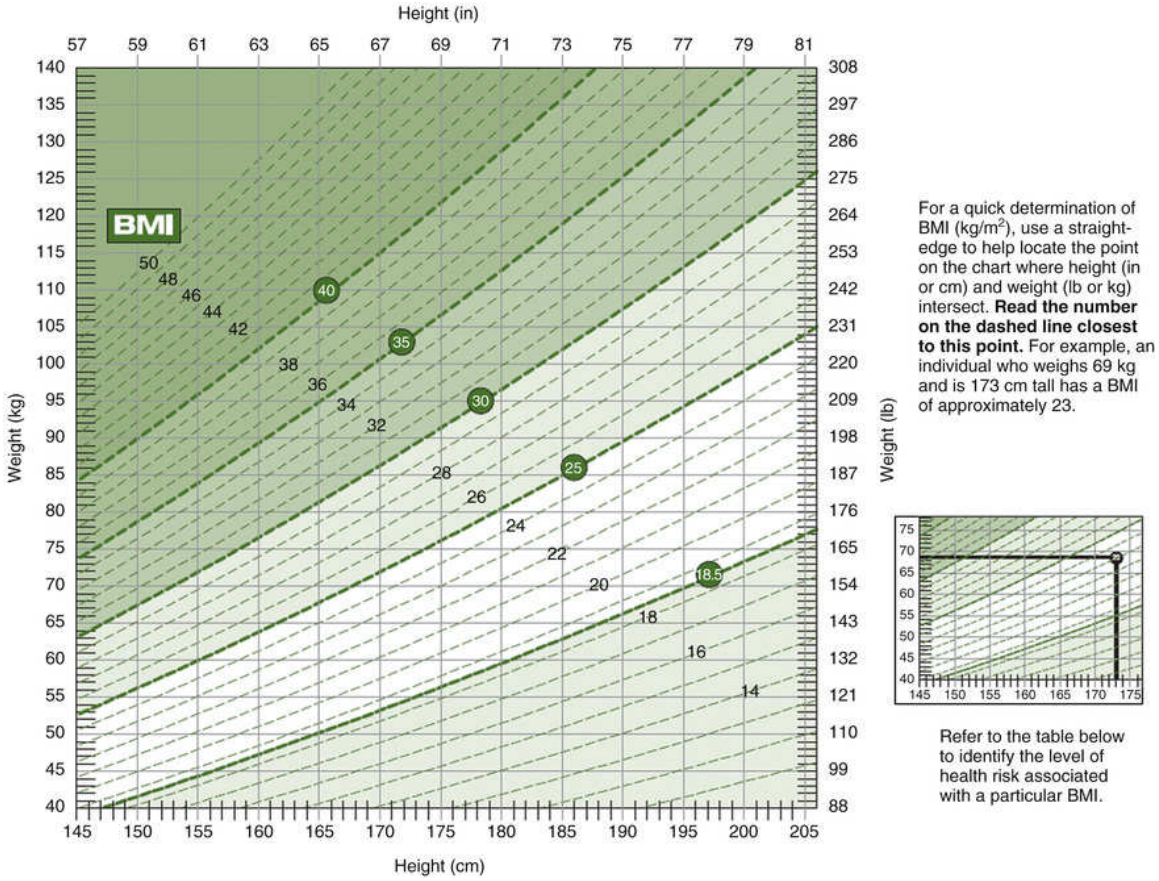

FIGURE 43-1 Body mass index chart. Source: Health Canada. (2003). *Canadian guidelines for body weight classification in adults* (Cat. no. H49-179/2003E). Ottawa: Author. Retrieved from *http://www.hc-sc.gc.ca/fn-an/alt_formats/hpfb-dgpsa/pdf/nutrition/cg_quick_ref-ldc_rapide_ref-eng.pdf*.

TABLE 43-1
CLASSIFICATION OF OVERWEIGHT AND OBESITY

			Disease Risk Based on Waist Circumference*	
	BMI (kg/m^2)	Obesity Class	Men ≤102 cm Women ≤89 cm	Men >102 cm Women >89 cm
Underweight	<18.5	—	—	—
Normal†	18.5–24.9	—	—	—
Overweight	25.0–29.9	—	Increased	High
Obese	30.0–34.9	Class I	High	Very high
	35.0–39.9	Class II	Very high	Very high
Morbidly obese	≥40.0	Class III	Extremely high	Extremely high

*Disease risk for type 2 diabetes, hypertension, and cardiovascular disease.

†Increased waist circumference can also be a marker for increased risk in persons of normal weight.

BMI, body mass index.

Source: Adapted from National Heart, Lung, and Blood Institute: Classification of overweight and obesity by BMI, waist circumference, and associated disease risks. (n.d.) Retrieved from *http://www.nhlbi.nih.gov/health/public/heart/obesity/lose_wt/bmi_dis.htm.*

Waist circumference is another way to assess and classify a person's weight (see Table 43-1). Health risks increase with a waist circumference greater than 101.6 cm in men and greater than 88.9 cm in women (Ford, Maynard, & Li, 2014). People who have visceral fat with truncal obesity are at an increased risk for cardiovascular disease and metabolic syndrome (discussed later in this chapter).

The **waist-to-hip ratio (WHR)** is another method used to assess obesity. This ratio is a method of describing the distribution of both subcutaneous and visceral adipose tissue. The ratio is calculated by dividing the waist measurement by the hip measurement. A WHR less than 0.8 is optimal. A WHR greater than 0.8 indicates more truncal fat, which puts the individual at a greater risk for health complications.

Body shape is another method of identifying those who are at a higher risk for health problems (Table 43-2). Individuals with fat located primarily in the abdominal area, an *apple-shaped body,* have *android obesity*. Those with fat distribution in the upper legs, a *pear-shaped body,* have *gynoid obesity*. Genetics has an important role in determining a person's body shape and weight (Wei, Hemani, Gyenesei, et al., 2012). Gynoid obesity carries a better prognosis but is more difficult to treat. It is believed that abdominal fat is more readily available and can be mobilized to maintain elevated triglyceride and lipid levels. Individuals with an apple shape carry more visceral fat than people with a pear shape and have

increased amounts of fat around the organs. Pear-shaped individuals carry more subcutaneous fat, which causes more cellulite to appear. Abdominal and visceral fat have been linked to metabolic syndrome, a major complication of obesity (Tchernof & Després, 2013). Visceral fat actively harms the body by decreasing insulin sensitivity and levels of high-density lipoprotein (HDL) cholesterol and increasing blood pressure. Visceral fat also releases more free fatty acids into the bloodstream.

TABLE 43-2

RELATIONSHIP BETWEEN BODY SHAPE AND HEALTH RISKS

Body Shape	Health Risks
Gynoid (pear) 	• Osteoporosis • Varicose veins • Cellulite • Subcutaneous fat traps and stores of dietary fat • Trapped fatty acids stored as triglycerides

Android (apple) 	• Heart disease
	• Diabetes mellitus
	• Breast cancer
	• Endometrial cancer
	• Visceral fat more active, causing:
	  • ↓ insulin sensitivity
	  • ↑ triglycerides
	  • ↓ HDL cholesterol
	  • ↑ BP
	  • ↑ free fatty acid release into blood

BP, blood pressure; *HDL*, high-density lipoprotein.

Epidemiology of Obesity

In developed and developing countries, obesity has reached epidemic proportions. The prevalence of overweight and obesity among Canadians has approximately doubled since the early 1980s. In 2014, approximately 40% of Canadians self-reported as overweight or obese (Statistics Canada, 2014). About one in four adult Canadians were obese in 2011–2012. The proportion of Canadians who are obese has increased 17.5% since 2003. In

general, more men than women are obese, and obesity rates have increased more for men than for women since 2003. The highest proportions of people with obesity are found in Atlantic Canada, the Prairie provinces, the Northwest Territories, Nunavut, Yukon, and smaller cities in northern and southwestern Ontario. The lowest proportions of people with obesity are found in Toronto, Montreal, Vancouver, and areas of southern British Columbia (Navaneelan & Janz, 2014).

Obesity in adulthood is often a problem that begins in childhood or adolescence. Between 2009 and 2011, 31.5% (1.6 million) of Canadian children aged 5 to 17 were classified as overweight or obese (Roberts, Shields, de Groh, et al., 2012). Reversing the childhood obesity crisis is key to addressing the overall obesity epidemic.

In Indigenous populations, 26% of off-reserve adults and 36% of on-reserve First Nations people are estimated to be obese (Canadian Institute for Health Information [CIHI] & Public Health Agency of Canada [PHAC], 2011). Although data examining changes in obesity prevalence among Indigenous peoples are limited, obesity remains more prominent among adults and children in this population than among non-Indigenous populations.

Obesity is a societal problem as much as a complex medical concern, because of the adverse health conditions related to weight gain and the associated expenses for health care. Obesity costs the Canadian economy somewhere between $4.6 billion and $7.1 billion a year. Those costs are split evenly between direct health care costs and indirect costs such as lost productivity of people unable to work either because of disability or because they are unable to find employment due to discrimination (CIHI & PHAC, 2011).

Etiology and Pathophysiology

In one sense, the etiology of obesity can be considered simplistically. It occurs because energy intake exceeds energy output. However, the processes leading to obesity are much more complex and still undergoing investigation. The causes of obesity involve significant genetic–biological susceptibility factors that are highly influenced by environmental and psychosocial factors.

Genetic–Biological Basis.

Studies of twins suggest the existence of genetic factors in obesity (Naukkarinen, Rissanen, Kaprio, et al., 2012). Estimates suggest obesity is

inherited in more than 50% of cases (Malis, Rasmussen, Poulsen, et al., 2005). However, genetic factors do not totally account for the etiology of obesity.

A number of genes have been linked to obesity. Genes actually may influence how calories are stored and energy released. “Energy-thrifty” genes, once protective against long periods when food was not available, are now maladaptive in societies in which food availability is no longer a primary issue. Genes may be responsible for why two individuals living in the same environment can vary considerably in body size.

A strong link exists between a gene known as *FTO* (fat mass and obesity-associated gene) and a person's BMI. Variants of this gene may explain why some people become overweight, whereas others do not. People with two copies of a certain allele at the *FTO* gene weigh 3 kg more and have a greater risk for obesity than those who do not have the risk allele (Tung, Yeo, O'Rahilly, et al., 2014). More research is needed to better understand the role of genes in obesity.

Regulation of eating behaviour, energy metabolism, and body fat metabolism are controlled by signals from the periphery that act on the hypothalamus (Figure 43-2). Appetite is influenced by many factors that are integrated by the brain, most importantly within the hypothalamus. Input to the hypothalamus is received from the periphery from many different hormones and peptides (Table 43-3). Interaction of these hormones and peptides at the level of the hypothalamus may be an important determinant in factors contributing to obesity.

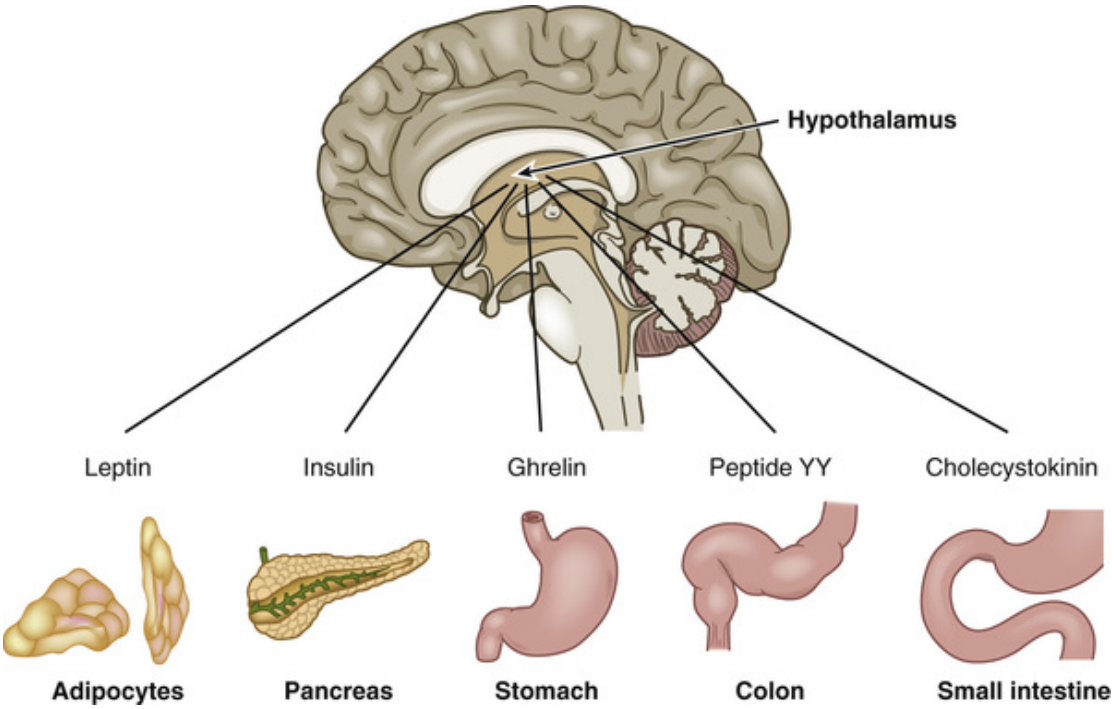

FIGURE 43-2 Some of the common hormones and peptides that interact with the hypothalamus to control and influence eating patterns, metabolic activities, and digestion. Obesity causes a disruption in this balance (see Table 43-3).

TABLE 43-3
HORMONES AND PEPTIDES IN OBESITY

Hormone or Peptide	Where Produced	Normal Function	Alteration in Obesity
Leptin	Adipocytes	Suppresses appetite and hunger Regulates eating behaviour	Obesity is associated with high leptin levels, and when leptin levels are high, leptin resistance develops; thus people who are obese may lose the effect of appetite suppression.
Insulin	Pancreas	Decreases appetite	Circulating levels are frequently high.
Ghrelin	Stomach (primarily)	Stimulates appetite ↑ after food deprivation ↓ in response to the presence of food in the stomach	Normal postprandial decline does not occur; increased appetite and overeating may result.
Peptide YY	Descending colon and rectum	Inhibits appetite by slowing GI motility and gastric emptying	Circulating levels are decreased; release is decreased after eating.
Cholecystokinin	Duodenum Jejunum	Inhibits gastric emptying and sends satiety signals to hypothalamus	Role is unknown.

GI, gastro-intestinal.

Adipocytes are not just a storage unit for triglycerides; they are also endocrine cells known to produce at least 100 different proteins. These proteins are secreted as enzymes, adipokines, growth factors, and hormones that contribute to the development of insulin resistance and atherosclerosis.

Environmental Factors.

Environmental factors play an important role in obesity. In today's culture, there is greater access to food, particularly prepackaged and fast foods, as well as soft drinks, all of which have poor nutritional quality. Portion size of meals has also increased (Table 43-4). Individuals with obesity tend to underestimate food and caloric intake. Eating outside of the home impedes the ability to control the composition and the quality of food.

TABLE 43-4
PORTION SIZES: PAST VERSUS PRESENT

Food	20 Years Ago	Today
Turkey sandwich	320 cal 	820 cal 
Bagel	7.6 cm diameter: 140 cal 	15.2 cm diameter: 350 cal 
Cheeseburger	333 cal 	590 cal 
Soft drink	237 mL: 105 cal 	591 mL: 250 cal 

Lack of physical activity is another factor that contributes to weight gain and obesity. The amount of physical activity people engage in has decreased, both in the workplace and at home. With increases in technology and labour-saving devices, Canadians are expending less energy in their everyday lives. Numerous initiatives have been enacted in Canada to address inactivity and resultant obesity throughout the lifespan, such as ParticipACTION (see the Resources at the end of the chapter), but further measures are needed.

Socioeconomic status can affect obesity in a variety of indirect ways. People with low incomes may buy food that is less expensive but often has poorer nutritional quality and greater caloric content, for example, prepackaged foods rather than fresh meats and produce. This population may also live in environments that do not accommodate outdoor activities

(e.g., safe playgrounds, walking tracks, tennis courts, swimming pools). Gyms tend to be attended by more affluent individuals.

Psychosocial Factors.

People use food for many reasons beyond nutritional maintenance. Many food associations begin in childhood, such as using food for comfort and reward. Furthermore, when overeating begins in childhood and continues into adulthood, a person's ability to sense fullness, or *satiety,* is compromised. Whether the desire to eat is triggered by specific foods or by the availability of a wide variety, some people consume food beyond their body's needs. The social component of eating occurs due to the association of food with pleasure. Food has become the central focus of most social events and celebrations. All these factors must be included when considering the etiology and treatment of obesity.

Health Risks Associated With Obesity

Many health conditions are more prevalent among people with obesity (Figure 43-3). The mortality rate rises as the rate of obesity increases, especially when obesity is associated with visceral fat. Among people with a BMI of 30 kg/m^2 or higher, the mortality rates from all causes—especially from cardiovascular disease—are generally 50% to 100% higher than the rates for people with BMIs in the normal range. The number of years lived with obesity also has a direct link to the risk for mortality (Abdullah, Wolfe, Stoelwinder, et al., 2011). In addition to these problems, patients with obesity have a reduced quality of life. Fortunately, most of these conditions can improve with weight loss. Loss of 5% to 10% of excess body weight can significantly improve obesity-related comorbid conditions (Lau, 2007).

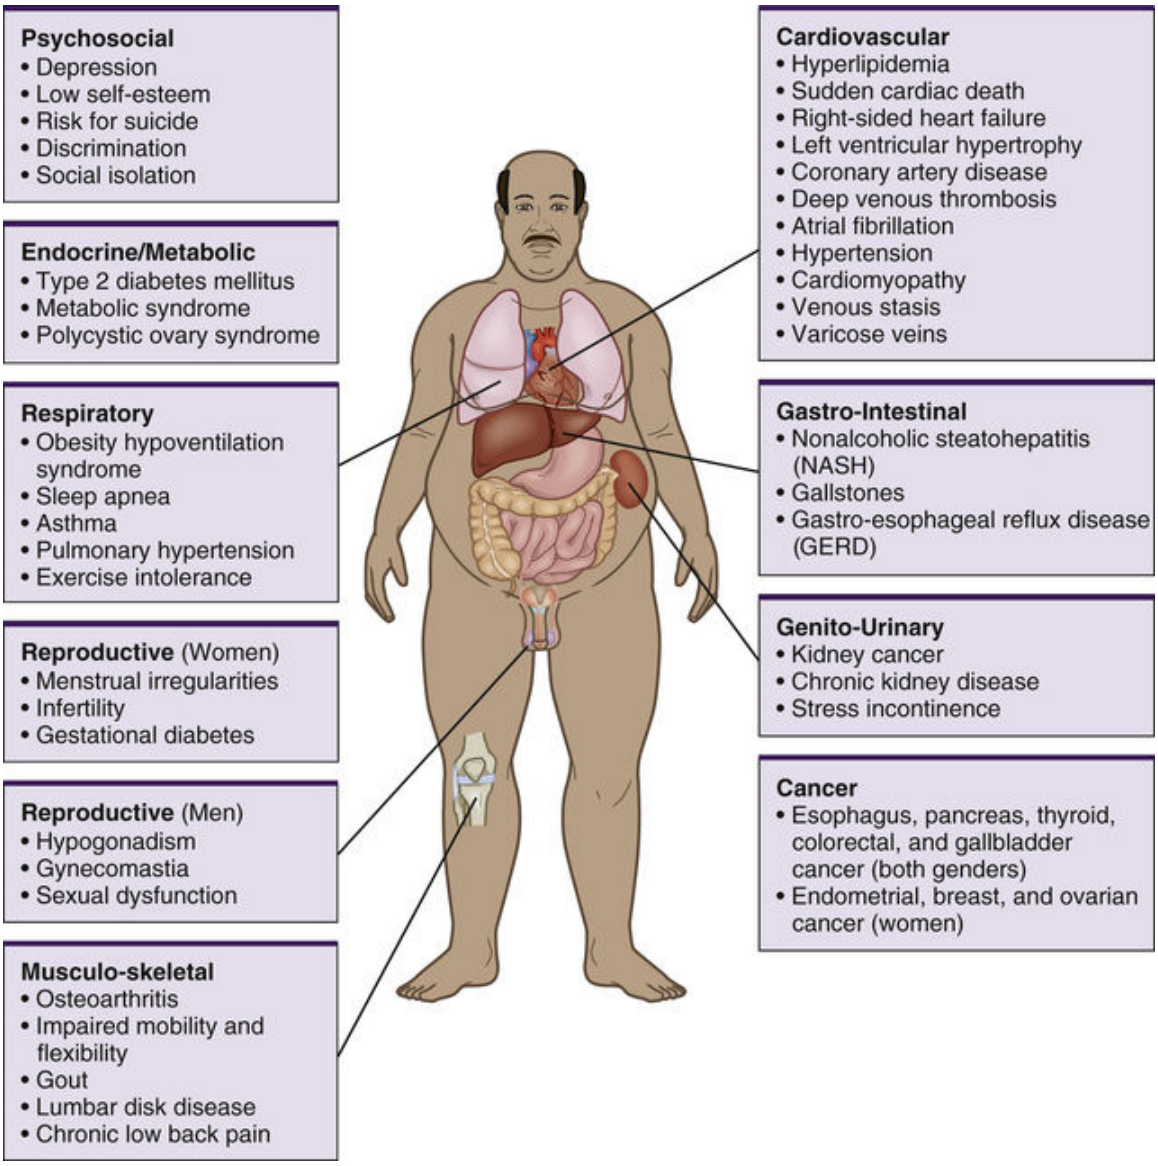

FIGURE 43-3 Health risks associated with obesity.

Metabolic Syndrome

Metabolic syndrome—also known as *syndrome X, insulin resistance syndrome,* and *dysmetabolic syndrome*—is a collection of risk factors that increase an individual's chance of developing cardiovascular disease and diabetes mellitus. The Canadian Heart Health Surveys, completed between 1986 and 1992, remain the most recent representative Canadian source of measured anthropometry and cardiovascular risk factors. Metabolic syndrome is diagnosed if an individual has three or more of the conditions listed in Table 43-5.

TABLE 43-5

DIAGNOSTIC CRITERIA FOR METABOLIC SYNDROME*

Measurement	Categorical Cutoff Point
Waist circumference	Men: ≥102 cm Women: ≥88 cm
Triglyceride levels	≥1.7 mmol/L *or* Drug treatment for elevated triglyceride levels
HDL cholesterol level	Men: <1.0 mmol/L Women: <1.3 mmol/L *or* Drug treatment for reduced HDL cholesterol level
BP	≥130 mm Hg systolic *or* ≥85 mm Hg diastolic *or* Drug treatment for hypertension
Fasting glucose level	≥5.6 mmol/L *or* Drug treatment for elevated glucose level

*At least three of the five measures must exceed the cutoff level for a diagnosis of metabolic syndrome.

BP, blood pressure; *HDL,* high-density lipoprotein.

Joint scientific statement: Harmonizing the metabolic syndrome: A joint interim statement of the International Diabetes Federation Task Force on Epidemiology and Prevention; National Heart, Lung, and Blood Institute; American Heart Association; World Heart Federation; International Atherosclerosis Society; and International Association for the Study of Obesity. *Circulation*, *120*, 1640–1645.

Etiology and Pathophysiology

The main underlying risk factor for metabolic syndrome is insulin resistance related to excessive visceral fat (Figure 43-4). In a person with insulin resistance, the body's cells have a diminished ability to respond to the actions of insulin. To compensate, the pancreas secretes more insulin, which results in hyperinsulinemia.

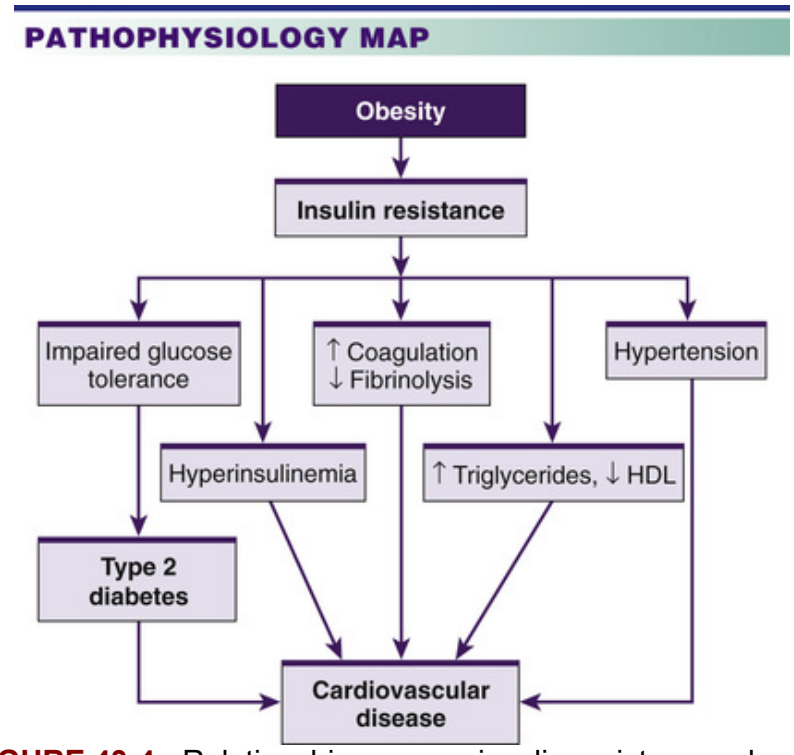

FIGURE 43-4 Relationships among insulin resistance, obesity, diabetes mellitus, and cardiovascular disease. *HDL,* high-density lipoprotein.

Other characteristics associated with metabolic syndrome include hypertension, increased risk of clotting, and abnormalities in cholesterol levels. Most people with metabolic syndrome are overweight or obese; however, genetics and environment also have important roles in the development of metabolic syndrome.

Patients diagnosed with metabolic syndrome typically have diabetes and cannot maintain a proper level of glucose, have hypertension and secrete a large amount of insulin, or they have survived a heart attack and have hyperinsulinemia.

Nursing and Collaborative Management Metabolic Syndrome

Lifestyle therapies are the first-line interventions to reduce the risk factors for metabolic syndrome. Management or reversal of metabolic syndrome can be achieved by reducing the major risk factors of cardiovascular disease: lowering low-density lipoprotein (LDL) cholesterol level, quitting smoking, lowering blood pressure (BP), and reducing glucose levels. For long-term reduction of risk, weight should be decreased, physical activity increased, and healthy dietary habits established.

No specific treatment for metabolic syndrome is available. Nurses can assist patients by providing information on healthy diets, physical activity, and positive lifestyle changes. The diet should be low in saturated fats and promote weight loss. Although low-carbohydrate diets may offer short-term weight loss, there is no strong evidence to support long-term weight loss with such diets. Weight reduction and maintenance of a lower weight should be the first priority in patients with abdominal obesity and metabolic syndrome.

Because sedentary lifestyles contribute to metabolic syndrome, increasing regular physical activity reduces a patient's risk factors. In addition to assisting in weight reduction, regular physical activity has been found to decrease the triglyceride level and increase the HDL cholesterol level in patients with metabolic syndrome.

Patients who are unable to reduce their risk factors with lifestyle therapies alone and those at high risk for a coronary event or diabetes may be considered for drug therapy. Although there is no medication for metabolic syndrome, cholesterol-lowering medication and antihypertensives can be used. Metformin (Glucophage) has also been used to prevent diabetes by lowering glucose levels and enhancing the cells' sensitivity to insulin.

Cardiovascular Problems.

Obesity is a significant risk factor for predicting cardiovascular disease in both men and women. The WHR is the best predictor of these risks. Obesity, especially android obesity, is connected with increased levels of LDLs and triglycerides and decreased levels of HDLs. Obesity is also associated with hypertension. Hypertension can occur because of

increased circulating blood volume, abnormal vasoconstriction, decreased vascular relaxation, and increased cardiac output. Measurement of BP in a patient with obesity requires the use of a larger cuff size to avoid artifactual increases.

Respiratory Problems.

Severe obesity may be connected with sleep apnea and obesity hypoventilation syndrome. Affected patients also have reduced chest wall compliance, increased work in breathing, and decreased total lung capacity and functional residual capacity. Weight loss can bring substantial improvement in lung function.

Diabetes Mellitus.

Hyperinsulinemia and insulin resistance are common features of obesity. Insulin resistance is more strongly related to visceral fat than to fat in other locations. Obesity is a major risk factor for type 2 diabetes (see Figure 43-4). As many as 90% of cases of type 2 diabetes are associated with excess weight (Wilding, 2014). Weight loss and exercise are linked with improved glucose control in diabetes.

Musculo-Skeletal Problems.

Obesity is correlated with an increased incidence of osteoarthritis as a result of stress put on weight-bearing joints. Hyperuricemia and gout are often found in people who are obese and in those who have metabolic syndrome.

Gastro-Intestinal and Liver Problems.

Gastro-esophageal reflux disease (GERD; also called *acid reflux*) and gallstones are prevalent among people with obesity. Gallstones occur when bile becomes supersaturated with cholesterol. Nonalcoholic steatohepatitis (NASH) is more common in people with obesity. In people with NASH, lipids are deposited in the liver, resulting in a fatty liver. NASH is associated with increased production of hepatic glucose and can eventually progress to cirrhosis and be fatal. Weight loss can improve NASH.

Cancer.

Overweight and obesity not only increase the risk for cardiovascular disease and type 2 diabetes mellitus but also are now known risk factors for a variety of cancer types (Schmandt, Iglesias, Co, et al., 2011). The risk for breast, endometrial, ovarian, and cervical cancer is increased in women with obesity, possibly because of the increased estrogen levels (estrogen is stored in fat cells) associated with obesity in postmenopausal women. Colorectal cancer has been linked to hyperinsulinemia. Increased waist circumference and WHR, indicators of abdominal obesity, are associated with increased risk for colon cancer in both men and women. Men with obesity have higher mortality rates with cancer of the prostate. Obesity often leads to GERD, which increases the risk for esophageal cancer because of the irritation and inflammation caused by frequent or constant exposure of the esophageal lining to stomach acid and bile.

Psychosocial Issues.

The consequences of obesity extend beyond physical changes and often affect the individual's emotional well-being. Clear and consistent stigmatization of people with obesity and, in some cases, discrimination occur in three important areas of living: employment, education, and health care (Budd & Peterson, 2014). In addition to dealing with the negative social impact, many people with obesity have low self-esteem, withdraw from social interaction, and experience major depression.

Nursing and Conservative Collaborative Management Patients With Obesity

Nursing Assessment

The nurse, working closely with the health care team, plays a major role in the planning and management of care for patients with obesity. Information that can assist nurses in understanding patients with obesity and provide a basis for intervention is presented in Table 43-6. Because many individuals with obesity have experienced weight bias in the past, nurses should ensure that their approach and actions are free of any possible interpretation of continued insensitivity. By being sensitive when asking specific and leading questions, nurses can often obtain information that patients may otherwise withhold out of embarrassment or shyness (Table 43-7). Nurses must provide acceptable reasons for asking personally intrusive questions, respond to patients' concerns about diagnostic tests, and interpret test outcomes. A patient's answers to questions must be treated with respect, understanding, and a nonjudgemental attitude. Knowledge regarding assessment and stepwise management for the treatment of obesity (Figure 43-5) can help nurses, in conjunction with the interdisciplinary team, to guide patients and their families through weight-loss interventions.

TABLE 43-6

NURSING ASSESSMENT
Patient With Obesity

Subjective Data
Important Health Information
Past health history: Time of obesity onset; diseases related to metabolism and obesity (e.g., hypertension, cardiovascular problems, stroke, cancer, chronic joint pain, respiratory problems, diabetes mellitus, cholelithiasis, metabolic syndrome); family history of obesity; history of weight gain and loss *Medications:* Prescription and over-the-counter (including supplements and herbal products) *Surgery or other treatments:* Prior bariatric surgery, other weight-reduction procedures, or other major surgical procedures related to risk factors precipitated by obesity
Medical History
• Comorbid conditions (time since diagnosis, current treatment, and current symptoms) • Drowsiness, somnolence; dyspnea on exertion, orthopnea, paroxysmal nocturnal dyspnea • History or symptoms of mental illness (feelings of depression, guilt, rejection, isolation) • Psychosocial history (income, housing, supports) • Menstrual irregularity, heavy menstrual flow in women, infertility • Altered sexual activity or function • Barriers to performing activities of daily living • Nutritional status
Objective Data
General
BMI ≥30 kg/m^2; waist circumference: woman, >88 cm; man, >102 cm
Respiratory
Increased work in breathing; wheezing; rapid, shallow breathing, sleep apnea, neck circumference (<42 cm = low risk)
Cardiovascular
Hypertension, tachycardia, dysrhythmias, hyperlipidemia
Musculo-Skeletal
Decreased joint mobility and flexibility; knee, hip, and low back pain
Reproductive
Menstrual irregularities and infertility in women; gynecomastia and hypogonadism in men
Possible Findings
Elevated levels of serum glucose, cholesterol, triglycerides, and A_{1c}; chest radiograph demonstrating an enlarged heart; ECG tracing showing dysrhythmia; abnormal results of liver function tests, radiograph evidence of osteoarthritis

BMI, body mass index; *ECG*, electrocardiogram.

TABLE 43-7

ASSESSING A PATIENT WITH OBESITY

When assessing a patient with obesity, the nurse should consider asking several different types of questions, such as the following:

- What is the patient's history with weight gain and weight loss?
- Is the patient interested in losing weight or managing weight differently?
- What does the patient think contributes to his or her weight?
- What barriers does the patient feel impede weight-loss efforts?
- What does food mean to the patient? How does the patient use food (e.g., to relieve stress, provide comfort)?
- Is the patient's food intake influenced by hunger?
- Are other family members overweight?
- Are there environmental or genetic factors influencing the weight gain?

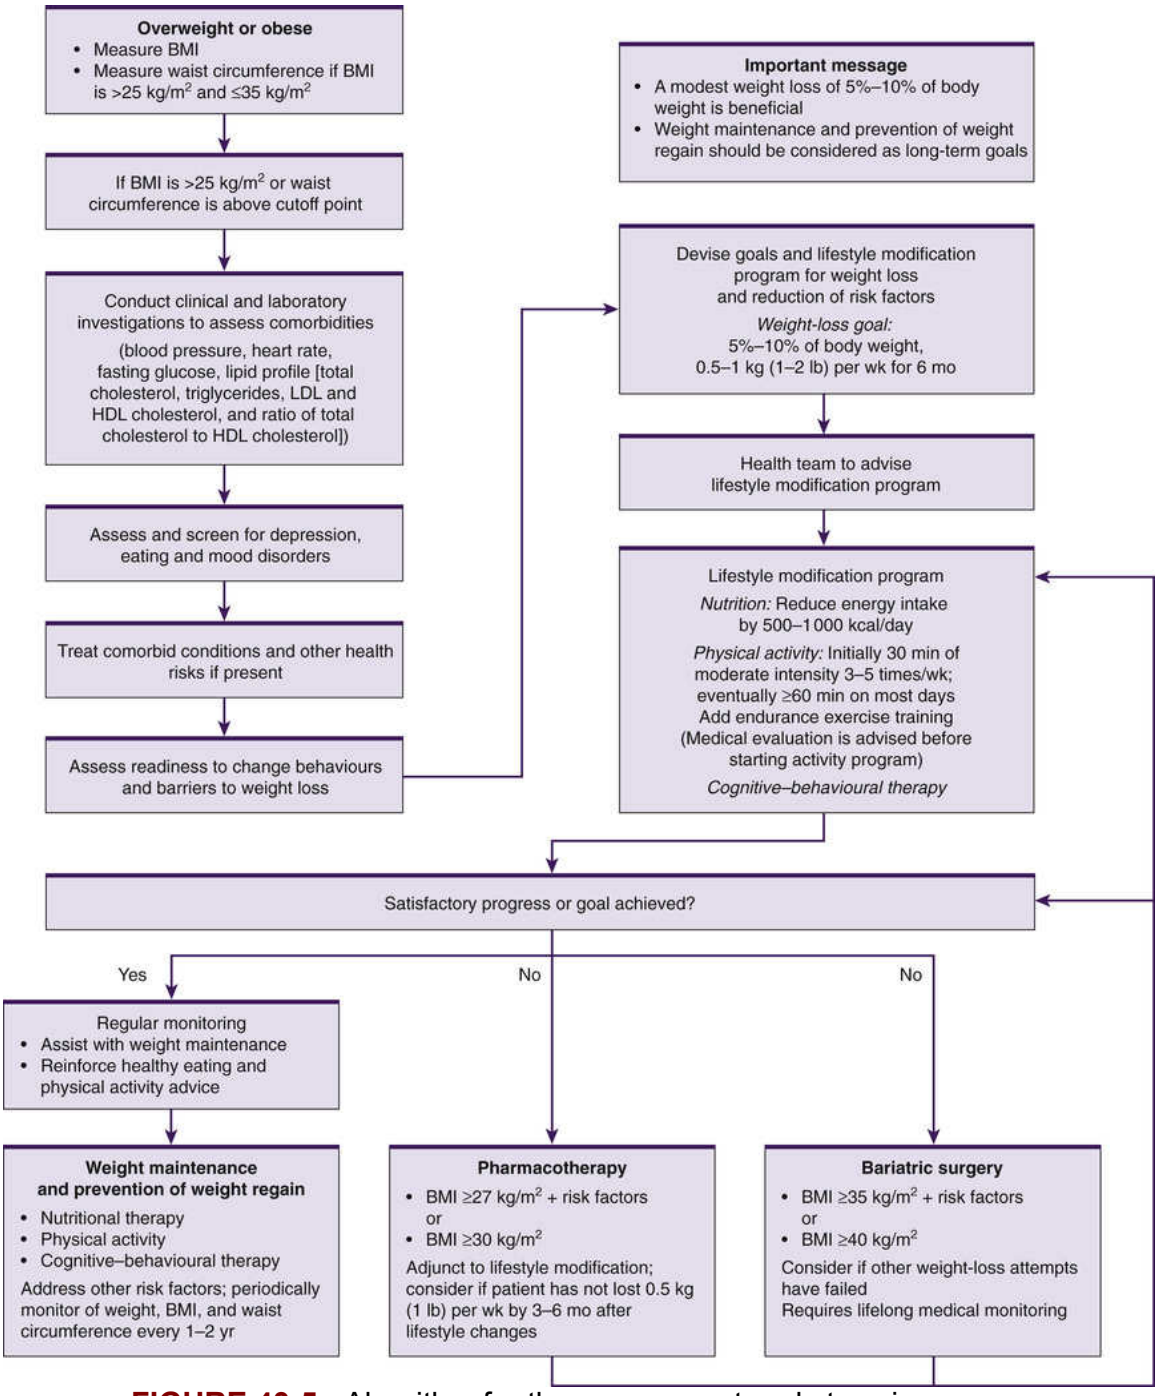

FIGURE 43-5 Algorithm for the assessment and stepwise management of adults who are overweight or obese. *BMI*, body mass index; *HDL,* high-density lipoprotein; *LDL,* low-density lipoprotein. Source: Adapted from Lau, D. C. W. (2007). Synopsis of the 2006 Canadian clinical practice guidelines on the management and prevention of obesity in adults and children. *Canadian Medical Association Journal, 176*(8), 1103–1106. Copied under licence from Access Copyright. Further reproduction, distribution or transmission is prohibited except as otherwise permitted by law.

The health care provider should explore genetic and endocrine factors such as hypothyroidism, hypothalamic tumours, Cushing's syndrome, hypogonadism in men, and polycystic ovary disease in women. Laboratory tests of liver function, fasting glucose level, lipid panel (triglyceride level and LDL and HDL cholesterol levels) assist in evaluating the cause and effects of obesity.

As part of the initial nursing history and physical examination, each body system should be examined, with particular attention to the organ system in which the patient has expressed a problem or concern. Measurements used with people with obesity may include skin fold thickness, height, weight, and BMI. Specific documentation of these measurements assists the health care provider with a more in-depth history and physical examination.

Nursing Diagnoses

Nursing diagnoses for the patient with obesity include but are not limited to the following:

- *Ineffective breathing pattern* related to *obesity* (decreased lung expansion)
- *Obesity* related to *energy expenditure below energy intake based on standard assessment*
- *Impaired skin integrity* related to *moisture, pressure over bony prominence*
- *Chronic low self-esteem* related to *cultural incongruence, inadequate respect from others, inadequate belonging*
- *Impaired physical mobility* related to *body mass index (BMI) >75th percentile appropriate for age and gender*
- *Disturbed body image* related to *alteration in self-perception*

Planning

The overall goals are that the patient with obesity will (a) modify eating patterns, (b) participate in a program of regular physical activity, (c)

achieve weight maintenance (stop historic pattern of continued weight gain over time) or achieve weight loss to a specified level, (d) maintain weight loss at a specified level, and (e) minimize or prevent health problems related to obesity.

Nursing Implementation

The nurse, working closely with the other members of the health care team, plays a major role in the planning and management of the care of a patient with obesity. To be effective, nurses must be aware of their own perceptions of and beliefs about obesity and obesity interventions. Although health care for patients with obesity has inherently greater demands, health care providers often fail to address these needs, and people with obesity underutilize health care opportunities available to them. In addition, health care providers are reluctant to counsel patients about obesity, often citing a lack of time during appointments, lack of professional reward for weight management, lack of reimbursement for weight-management services, and a lack of knowledge of or faith in the effectiveness of weight-management interventions. If a health care provider associates obesity with lack of willpower and with overindulgence, patients can experience shame in a setting that claims to be a caring one. Nurses are in a pivotal position to help people with overweight and obesity deal with negative experiences and to educate other health care providers to eliminate their bias.

Before selecting a weight-loss strategy with the patient, the following questions should be asked:

- What is the patient's motivation for losing weight?
- Is the patient experiencing any major stresses that will make it difficult to focus on weight control?
- Does the patient have any psychiatric illnesses—such as severe depression, substance abuse, or a binge-eating disorder—that will derail weight-loss efforts?
- Can the patient devote the minimal amount of time for physical activity (e.g., at least 15 to 30 minutes per

day for the next 6 months) that is needed for a serious weight-loss effort?

A patient's motivation should be assessed because it is essential for a favourable outcome. Lack of motivation is a huge barrier to change. However, patients should be encouraged to focus on the reasons for wanting to lose weight as they face the challenges in dealing with obesity.

When no organic cause for obesity (e.g., hypothyroidism) can be found, it should be considered a complex, chronic illness. A multipronged approach with attention to multiple factors—including nutrition therapy, physical activity, cognitive–behavioural therapy, and perhaps pharmacotherapy and bariatric surgery—should be used (see Figure 43-5). Focusing on more than one aspect probably provides better balance to weight-loss and weight-control efforts. All opportunities for patient education should stress healthy eating habits and adequate physical activity as lifestyle patterns. A comprehensive, patient-centred, and collaborative approach should be the goal of the health care team (Lau, Douketis, Morrison, et al., 2007).

Even with a comprehensive action plan, there is a high rate of weight regain among people in all age groups, which is discouraging considering the amount of time and effort expended in the process of attempting to lose weight. For successful management of obesity, it helps to view obesity as a chronic condition that necessitates day-to-day attention to losing weight and maintaining weight loss. It is essential that the nurse take a nonjudgemental approach in helping patients manage their problems related to obesity.

Nutritional Therapy.

Restricted food intake is a cornerstone for any weight loss or maintenance program. A good weight-loss plan should promote healthy eating using Canada's Food Guide (Health Canada, 2011; see Chapter 42, Figure 42-1). Nutrition interventions should be developed with a qualified and experienced health care provider, preferably a registered dietitian (Lau, 2007). To support a negative energy balance, it is recommended that energy intake be reduced by 500 to 1 000 kcal per day below estimated energy needs to achieve a 0.5 to 1 kg weight loss per week (Lau, Douketis, Morrison, et al., 2007). Diets may be classified as low-calorie (800–1 200 kcal/day) or very-low-calorie (less than 800 kcal/day). Although an example of a low-calorie diet is presented in Table 43-8, it is important for

the nurse to be aware that dietitians work with patients to develop diets that are based on the patients' current caloric consumption, with subsequent incremental reductions, because the diet must be sustainable over time for the resultant weight loss to be maintained. Once the patient has achieved one goal, subsequent progressive goals are set.

TABLE 43-8

NUTRITIONAL THERAPY
Sample 1 200-Calorie Weight Reduction Diet*

General Principles	
1. Eat regularly. Do not skip meals. 2. Measure foods to determine the correct portion size. 3. Avoid concentrated sweets, such as sugar, candy, honey, pies, cakes, cookies, and regular soft drinks. 4. Reduce fat intake by baking, broiling, or steaming foods. 5. Maintain a regular physical activity program for successful weight loss.	
Meal	**Menu Plan**
Breakfast	30 g (¾ cup) dry cereal (unsweetened) 1 small banana 250 mL (1 cup) non-fat milk Coffee, black, unsweetened
Lunch	Beef and cheese enchiladas (made with 35 g cheese and 57 g lean ground beef) 2 corn tortillas with shredded lettuce 10 mL (2 tsp) chili sauce 175 g (1 cup) sliced tomatoes and cucumbers 30 mL (1 tbsp) low-fat salad dressing 90 g (approx 12) grapes 500 mL (2 cups) water
Dinner	75 g baked chicken breast (no skin) 5 mL (1 tsp) margarine 350 g (2 cups) tossed salad and 30 mL (1 tbsp) low-fat salad dressing 90 g (½ cup) strawberries 90 g (½ cup) whole grain rice 250 mL (1 cup) non-fat milk

*For 1 500 calories, add one meat and alternatives serving and two vegetable and fruit servings, and include one serving of the daily recommended oil and fats. For 1 800 calories, add one grain product serving, one milk and alternative, two meat and alternative servings, two vegetable and fruit servings, and an additional serving of oil and fats.

People on low-calorie and very-low-calorie diets need frequent professional monitoring because the severe energy restriction places them at risk for deficiency of multiple nutrients. A diet that includes adequate amounts of fruits and vegetables provides enough bulk to prevent constipation and meets daily vitamin A and vitamin C requirements. Lean meat, fish, and eggs provide sufficient protein, as well as B-complex vitamins. Restricting dietary intake so that it is below energy requirements is an effective way to reduce body weight.

Most overweight people have at some time attempted to lose weight. Some have had limited and temporary success, and others have met only with failure. Many individuals attempt weight loss by trying out a least one of the many fad diets that offer the enticement of quick weight loss with little effort. Often these fad diets advocate for the elimination of one or more categories of foods (e.g., carbohydrates) and should not be followed. Low-carbohydrate diets, for example, do produce a rapid weight loss, but they also may not allow for adequate amounts of fibre, vitamins, and minerals. These diets are difficult to maintain in the long term because of their restrictive nature. It is best to recommend a dietary approach in which caloric restriction includes all food groups. Patients find it easier to incorporate such changes into their lifestyles and do not become bored with their food options. The nurse must work to support patients' understanding that following a well-balanced, low-calorie diet is an essential part of weight loss and is superior to fad diets in achieving and supporting weight loss and sustained weight maintenance. The degree of success of any reducing diet depends in part on the amount of weight to be lost. People with moderate obesity attain the goal more easily than people with morbid obesity. Perhaps because men have a higher percentage of lean body mass, men are able to lose weight more quickly than women. Women have a higher percentage of body fat, which is metabolically less active than muscle tissue. Postmenopausal women are particularly prone to weight gain, including increased abdominal fat.

Assessing and supporting readiness for change and patient motivation are essential steps in successful weight-loss interventions. The patient must understand the need for weight loss and weight control and the advantages that will occur. The nurse can assist by helping the patient track eating patterns with a diet diary. A frank discussion of eating habits helps the patient realize that eating is often the result of bad habits picked up with time and not the result of hunger. The bad habits must be changed, or weight loss will be only temporary.

Setting a realistic and healthy goal, such as losing 0.5 to 1 kg per week, must be mutually agreed on at the outset. Trying to lose too much too fast usually results in a sense of frustration and failure for the patient. The nurse can help the patient understand that losing large amounts of weight in a short period causes skin and underlying tissue to lose elasticity and tone, resulting in loose folds of skin and tissue. Inevitably, the patient reaches plateau periods during which no weight is lost. These plateaus may last from several days to several weeks. It is especially important for the patient to realize that these are normal occurrences during weight

reduction so as to prevent discouragement, frustration, and giving up of the prescribed dietary plan. A weekly check of body weight is a good method of monitoring progress. Daily weighing is not recommended because of the frequent fluctuations resulting from retained water (including urine) and elimination of feces. Instruct the patient to record his or her weight at the same time of the day, wearing the same type of clothing.

There is no firm agreement on the number of meals to be eaten when a person is on a diet; however, breakfast should not be missed. Some nutritionists advocate several small meals per day because the body's metabolic rate is temporarily increased immediately after eating. However, when several small meals are ingested per day, more calories may be consumed. The patient should be instructed to carefully adhere to portion sizes and stay within the total daily calorie allotment. There seems to be general agreement that consumption of most of the daily caloric intake at a large evening meal results in less weight loss than when the calories are evenly distributed throughout the day.

When a person first begins a weight reduction program, food portion sizes must be carefully determined to stay within the dietary guidelines. Portion sizes have increased considerably since the 1990s (Wright & Aronne, 2012; see Table 43-4). Food portions can be weighed on a scale, or everyday objects can be used as a visual cue to determine portion sizes; for example, the size of a woman's fist or a baseball is equivalent to one serving of vegetables or fruit. A serving of meat is about the size of an adult's palm or a deck of cards. A serving of cheese is about the size of a thumb or six dice (see the Alberta Health Services website listed in the Resources section at the end of this chapter for a sample patient teaching tool). A test on portion sizes is also available online (see the Resources at the end of this chapter). A food journal is an important tool for understanding eating habits and bringing awareness to the patient regarding actual food consumed. Journalling also aids the dietitian in setting goals when working with patients learning proper eating habits.

As identified in Chapter 42, Canada's Food Guide provides a solid example of a balanced diet and instruction to assist individuals with making healthy choices, with appropriate portions from each of the food groups. Patients can be further assisted in understanding and exercising good portion control and choosing appropriate proportions from each of the food groups by describing a healthy meal by how portions fit on a plate (Figure 43-6). Half of a “healthy plate” consists of vegetables and

fruit, one-fourth consists of meat and meat alternatives, and one-fourth consists of grain products.

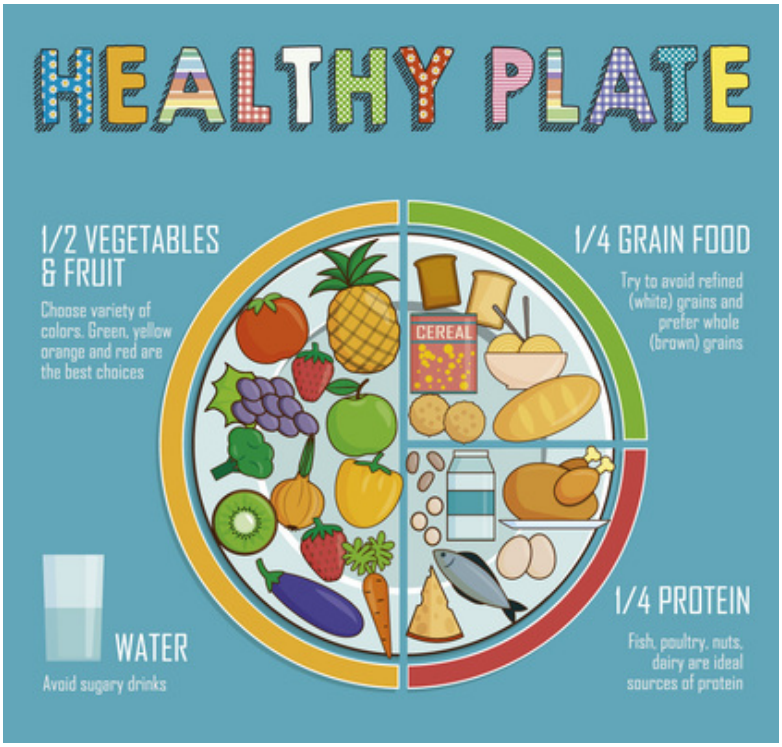

FIGURE 43-6 The sizes of healthy portions on a plate. Source: medejaja/Shutterstock.com.

A list of healthy, low-calorie foods serves as a good reference and enables patients to eat an occasional meal at a restaurant. Patients who carefully follow the prescribed diet may not need to take vitamin supplements. Appropriate fluid intake should be encouraged. Alcoholic beverages are usually not permitted on a reducing diet because they increase the caloric intake and have low nutritional value.

Physical Activity.

Physical activity is an essential part of a weight-control program. Current recommendations state that, to achieve health benefits, people need 150 minutes of moderate to vigorous aerobic activity per week (Canadian Society for Exercise Physiology, 2012). There is no evidence that increased activity promotes an increase in appetite or leads to dietary excess. In fact, physical activity frequently has the opposite effect. The addition of physical activity produces more weight loss than does dieting alone.

Increasing physical activity has a favourable effect on body fat distribution with a reduction in WHR. Physical activity is especially important in maintaining weight loss in people with overweight and obesity.

The nurse and the patient should explore possible ways to increase physical activity in daily routines. It may be as simple as parking farther from a patient's place of employment or taking the stairs rather than the elevator. The patient should be encouraged to wear a pedometer to track daily activity, with a goal of 10 000 steps a day. However, initial success may be walking a third of the recommended steps, with incremental increases over time.

Joining a health club can be one mechanism of getting physical activity. Walking, swimming, and cycling are sensible forms of physical activity and have long-term benefits. Engaging in weekend exercise only or in spurts of strenuous activity is not advantageous and can actually be dangerous. When large muscles are involved in the physical activity program, a primary benefit is cardiovascular conditioning. Overweight men and women who are active and fit have lower rates of morbidity and mortality than overweight people who are sedentary and unfit. Therefore, physical activity is of benefit to overweight people even if it does not make them lean.

An increased physical activity program offers many psychological benefits. Patients can achieve reduction in tension and stress, better-quality sleep and rest, increased stamina and energy, improved self-concept and self-confidence, better attitudes toward work and play, and increased optimism about the future.

Behaviour Modification.

The assumption behind cognitive–behavioural modification is two-fold: (a) that obesity is a learned disorder caused by overeating and (b) that the critical difference between a person with obesity and a person of normal weight is in the cues that regulate eating behaviour. Therefore, most behaviour-modification programs de-emphasize the diet and focus on how and when the person eats. Participants often are taught to restrict their eating to designated meals and to increase the amount of physical activity in their lives. People who have undergone behaviour therapy are more successful in maintaining their losses over an extended time than are those who do not participate in such training.

Common behavioural techniques included in weight-management interventions are (a) self-monitoring, (b) stimulus control, and (c) rewards.

Self-monitoring may involve the person keeping a record of what and when foods are eaten, as well as how the person was feeling when the foods were consumed. *Stimulus control* is aimed at separating events that trigger eating from the act of eating. *Rewards* may be used as incentive for weight loss. Short- and long-term goals are useful benchmarks for earning rewards. It is important that the reward for a specified weight loss not be associated with food, such as dinner out or a favourite treat. Reward items do not have to have a monetary component. For example, time for a hot bath or an hour of pleasure reading would be an enjoyable reward for many people. People may participate in group or individual sessions or both as they work toward their goals.

Support Groups.

Patients may benefit from joining a support group that includes professional counselling. Many self-help groups are available to people who want to learn more about successful dieting and who like the support of others who have the same problems and similar experiences. Take Off Pounds Sensibly (TOPS) is the oldest nonprofit organization of this type in the world. Behaviour modification is an integral part of the program, along with nutrition education. Weight Watchers International, Inc. is probably the most successful commercial weight-reduction enterprise. Weight Watchers offers a food plan that is nutritionally balanced and practical to follow and its programs have included behaviour-modification techniques since 1974.

Commercial weight-reduction centres have proliferated across the nation. Many of these programs are staffed by nurses or dietitians or both, and candidates must undergo an initial physical examination by a health care provider before being accepted for weight reduction. Although behaviour-modification training is often incorporated within these programs, they are often costly, and the cost may be prohibitive for people with limited financial resources. In addition, many of these programs offer special prepackaged foods and supplements that must be purchased as part of the weight-reduction plan. Only these prescribed foods and drinks are to be consumed until an agreed-on amount of weight is lost. The patient is encouraged to buy the same type of foods for the maintenance phase of the program, which lasts from 6 months to 1 year. This is problematic for reasons beyond just the associated costs. Obesity, as with all chronic diseases, resumes its course when the intervention stops. Patients are often frustrated to find that the weight they lost is regained

once they stop participating in the commercial program. Individuals who discontinue such programs must be supported to learn to adjust their diet appropriately to maintain their intervention and the resultant weight loss.

Many places of employment have started programs on health teaching and maintenance. The rationale for such programs is that better health repays the cost of the programs through improved work performance, decreased absenteeism, and eventually less hospitalization. Weight-reduction and hypertension-reduction programs have been instituted and are popular with employees.

Drug Therapy

Drugs have been used to treat obesity but only as adjuncts to nutrition, physical activity, and behaviour-modification therapies. Pharmacotherapy should be reserved for patients with a BMI ≥27 kg/m^2 who have existing comorbid conditions (e.g., hypertension, dyslipidemia, coronary artery disease, type 2 diabetes mellitus, and sleep apnea) and for those with a BMI ≥30 kg/m^2. Currently, drugs approved for weight loss in Canada are the kind that decrease nutrient absorption. Drugs that decrease food intake by reducing appetite or increasing satiety (e.g., sibutramine [Meridia]) and drugs that increase energy expenditure (e.g., ephedrine) are not approved for weight loss in Canada at this time.

Nutrient Absorption–Blocking Drugs

Orlistat (Xenical), a drug that was developed for weight loss and maintenance, works by blocking fat breakdown and absorption in the intestine. It inhibits the action of intestinal lipases. The undigested fat is excreted in the feces. Although this medication has a high safety profile, levels of some fat-soluble vitamins may decrease, and those vitamins may have to be supplemented. Orlistat is associated with leakage of stool, flatulence, diarrhea, and abdominal bloating, which is accentuated if a high-fat diet is consumed. These adverse effects limit its acceptance as a weight-loss tool (Kang & Park, 2012). Liraglutide (Saxenda) is an injectable drug newly used for weight management. It works by blocking GLP1 (glucagon-like peptide). Normally, liraglutide is used for the treatment of type 2 diabetes, but higher doses have been found to help with weight loss in those following a calorie-reduced diet and a physical activity regimen (Pi-Sunyer, Astrup, Fujioka, et al., 2015). In February 2015, Health Canada approved the use of liraglutide (Saxenda) for weight management in patients with BMI >27 kg/m^2 and one or more health-related comorbidities or with a BMI >30 kg/m^2. Adverse effects of liraglutide include nausea and diarrhea as well as increased risk for pancreatitis and gallbladder disease (Novo Nordisk, 2016).

Drugs do not cure obesity, and the patient must understand that without substantial changes in food intake and increased physical activity, weight will be regained when short-term drug therapy is stopped. Supervised long-term drug therapy with safe compounds can contribute to weight management as well as weight loss. As with any

pharmacological treatment, there are adverse effects. Careful evaluation for the presence of other medical conditions can help determine which drugs, if any, would be advisable for a given patient.

The role of the nurse in relation to drug therapy should centre on teaching the patient about proper administration and adverse events and how the drug fits into the larger weight-loss plan. Modifying the dosage without consulting a health care provider can have detrimental effects. The nurse should re-emphasize that the diet and physical activity regimens are the cornerstones of permanent weight loss. Drugs may be helpful, but they do not change the patient's eating behaviour. The purchase of over-the-counter diet aids should be discouraged.

Collaborative Surgical Therapy

Bariatric surgery is an invasive procedure used to treat morbid obesity. Bariatric surgery is currently the only treatment that has been found to help sustain weight loss in individuals who are severely obese. The majority of patients who undergo bariatric surgery have successfully improved their overall quality of life. A great deal of excess weight is lost, comorbid conditions resolve, and patients' appearance, social opportunities, and economic opportunities are improved (Dunham, 2013).

Criteria guidelines for bariatric surgery include having a BMI of 40 kg/m^2 or higher or a BMI of 35 kg/m^2 or higher plus one or more severe obesity-related comorbid conditions (e.g., hypertension, type 2 diabetes mellitus, heart failure, or sleep apnea). Many adults meet these criteria, and additional recommendations must be taken into account, including a documented history of conventional weight loss attempts that have been unsuccessful over time; a demonstrated history of accountability and responsibility marked by attending appointments regularly, practising self-monitoring, completing laboratory tests, regularly taking medications, and making time for healthy eating and activity. The patient must have full understanding of the benefits and limitations of a surgical procedure to assist with the management of obesity, and the risk of the surgical procedure must be lower than the risks of not providing the treatment (Karmali, Johnson Stoklossa, Sharma, et al., 2010). Table 43-9 describes exclusion criteria for bariatric surgery.

TABLE 43-9
EXCLUSION CRITERIA FOR BARIATRIC SURGERY

Patients *who are* or *who have* any of the following characteristics should not be offered bariatric surgery:
• BMI <35 kg/m^2 • Age <18 yr or >65 yr • A medical condition that makes surgery too risky • Clinically significant or unstable mental health concerns • An unrealistic postsurgical target weight • Unrealistic expectations of a surgical procedure • Not tried or optimized lifestyle or medical treatments • A history of poor compliance with lifestyle, medical, or mental health interventions • Pregnant, lactating, or plan for pregnancy within 2 yr of potential surgical treatment • Lack of safe access to abdominal cavity or gastro-intestinal tract • Smokers (All smokers, regardless of their weight status, should quit smoking for at least 8 weeks before surgery as a goal of risk-factor management. All patients should be encouraged to remain nonsmokers or participate in smoking cessation programs.)

BMI, body mass index.

Source: Karmali, S., Johnson Stoklossa, C., Sharma, A., et al. (2010). Bariatric surgery: A primer. *Canadian Family Physician*, *56*, 874.

Patients are not good candidates for bariatric surgery if they (a) are obese as a result of a treatable disorder (e.g., hypothyroidism); (b) have untreated depression or psychosis, binge-eating disorder, or bulimia; (c) currently abuse drugs or alcohol; (d) have severe cardiac disease with prohibitive anaesthetic-related risks; (e) have severe coagulopathy; or (f) are unable to comply with nutritional requirements. Bariatric surgeries fall into one of three broad categories: restrictive, malabsorptive, or a combination of malabsorptive and restrictive (Table 43-10 and Figure 43-7). In restrictive procedures, the stomach is reduced in size (less food eaten), and in malabsorptive procedures, the length of the small intestine is decreased (less food absorbed).

TABLE 43-10
SURGICAL INTERVENTIONS FOR MORBID OBESITY*

Procedure	Anatomical Changes	Advantages	Complications
Restrictive Surgery			
Adjustable gastric banding (AGB) (Lap-Band, Realize band)	Band encircles the stomach, creating a stoma and a gastric pouch with 10- to 15-mL capacity	Food digestion occurs through normal process Band can be adjusted to ↑ or ↓ restriction Surgery can be reversed Absence of dumping syndrome Lack of malabsorption	Low complication rate Some nausea and vomiting initially Problems with adjustment device Band may slip or erode into stomach wall Gastric perforation
Vertical sleeve gastrectomy	About 85% of stomach removed, leaving a sleeve-shaped stomach with 60- to 150-mL capacity	Function of stomach preserved No bypass of intestine Avoids complications of obstruction, anemia, vitamin deficiencies	Possible limitation to weight loss Leakage related to stapling
Vertical banded gastroplasty (VBG)	Band placed around stomach, and staples used above band to create a small gastric pouch	No surgical anastomosis More normal anatomy and physiology maintained Lower risk for infection	High complication rate Slow weight loss Rupture of staple line Dilated pouch Dumping syndrome (nausea, vomiting, diarrhea, or a combination of these related to ingestion of sweets, high-calorie liquids, or dairy products)
Malabsorptive Surgery			
Biliopancreatic diversion (BPD) with or without duodenal switch	70% of the stomach removed horizontally Anastomosis between the stomach and the intestine Decreases the amount of small intestine available for nutrient absorption Duodenal switch cuts the stomach vertically so stomach is shaped like a tube	Increased amount of food intake Less food intolerance Greater long-term weight loss Rapid weight loss	Abdominal bloating, diarrhea, and foul-smelling gas (steatorrhea) Three or four loose bowel movements a day Malabsorption of fat-soluble vitamins Iron deficiency Protein-calorie malnutrition† Dumping syndrome†
Combination of Restrictive and Malabsorptive Surgery			

Procedure	Anatomical Changes	Advantages	Complications
Roux-en-Y gastric bypass (RYGB)	Restrictive surgery on stomach, creating small gastric pouch connected to jejunum Remaining stomach and first segment of small intestine are bypassed	Better weight loss results than with gastric restrictive procedures Lower incidence of malnutrition and diarrhea Rapid improvement of weight-related comorbidities	Leak at site of anastomosis Anemia: iron deficiency, cobalamin deficiency, folic acid deficiency Calcium deficiency Dumping syndrome

*See Figure 43-7.

†Less common with duodenal switch.

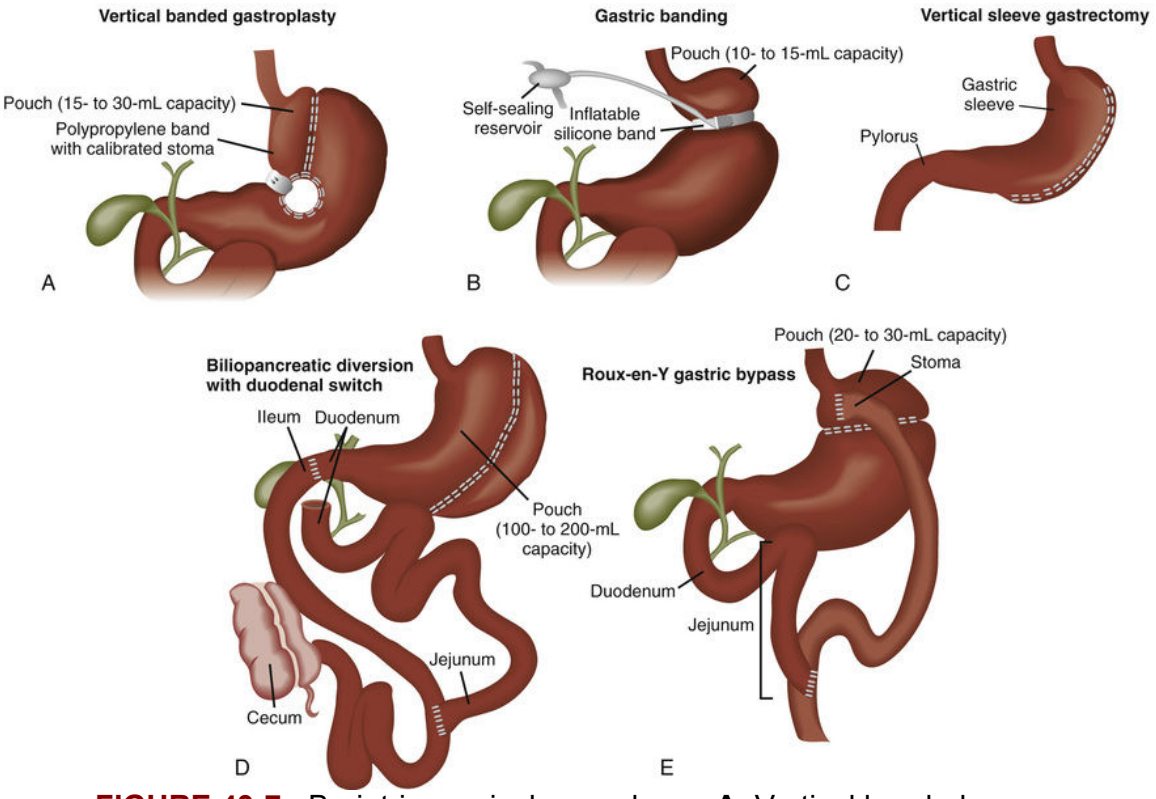

FIGURE 43-7 Bariatric surgical procedures. **A,** Vertical banded gastroplasty involves creating a small gastric pouch. **B,** Adjustable gastric banding involves the use of a band to create a gastric pouch. **C,** Vertical sleeve gastrectomy involves creating a sleeve-shaped stomach by removing approximately 85% of the stomach. **D,** Biliopancreatic diversion with duodenal switch procedure involves creating an anastomosis between the stomach and intestine. **E,** Roux-en-Y gastric bypass procedure involves constructing a gastric pouch whose outlet is a Y-shaped limb of small intestine.

Restrictive Surgeries

Restrictive bariatric surgery reduces either the size of the stomach, which causes the patient to feel full more quickly, or the amount allowed to enter the stomach. The stomach and the intestine digest and absorb food normally when restrictive gastro-intestinal surgery is performed. Because digestion is not altered, the risk for anemia or cobalamin deficiency is low. These procedures can be performed using a laparoscopic approach, which decreases the rate of wound infection and hernia formation. Weight loss is typically more gradual with these procedures. Several restrictive procedures are available. The most common are discussed below.

Vertical Banded Gastroplasty.

Vertical banded gastroplasty involves partitioning the stomach into a small pouch in the upper portion along the lesser curvature of the stomach. This small pouch drastically limits capacity. In addition, the stoma opening to the rest of the stomach is banded to delay emptying of solid food from the proximal pouch. This procedure has been replaced by other procedures because of lack of sustained or desired weight loss and the high incidence of complications.

Adjustable Gastric Banding.

With *adjustable gastric banding,* the stomach size is limited by an inflatable band placed around the fundus of the stomach. This restrictive procedure can be done using the Lap-Band system or the Realize band system. The band is connected to a subcutaneous port and can be inflated or deflated (by fluid injection in the health care provider's office) to change the stoma size to meet the patient's needs as weight is lost. The procedure can be done laparoscopically and can be modified or reversed after the initial procedure. Adjustable gastric banding is the procedure most commonly performed, and it is the preferred option for patients who are at surgical risk because it is a less invasive approach.

Malabsorptive Surgery

In malabsorptive surgery to reduce weight, the surgeon bypasses various lengths of the small intestine so that less food is absorbed.

Biliopancreatic Diversion.

Biliopancreatic diversion (BPD) involves removing approximately 75% of the stomach to produce both restriction of food intake and reduction of acid output. The remaining portion of the stomach is connected to the lower portion of the small intestine. Nutrients pass without being digested. The patient loses weight because most of the calories and nutrients are routed into the colon, where they are not absorbed.

This procedure can increase the risk for gallstone formation and may necessitate removal of the gallbladder. Patients should be aware of the possibilities of intestinal irritation and ulcers. Other risks from BPD include abdominal bloating and foul-smelling stool or gas. During the period when the intestines adjust, bowel movements can be very liquid

and frequent. This condition may lessen over time, but it may be a lifelong condition. Patients should also monitor their protein, iron, and cobalamin intake to ensure that they do not develop malnutrition or anemia. Supplements and vitamins should be taken to offset these risks.

Biliopancreatic Diversion With Duodenal Switch.

A variation of the BPD procedure involves a duodenal switch in which the surgeon leaves intact a larger portion of the stomach, as well as a small part of the duodenum. This procedure also enables sparing of the pyloric valve, which helps prevent dumping syndrome. (Dumping syndrome is discussed in the next section and in Chapter 44.)

Combination of Restrictive and Malabsorptive Surgery

Roux-en-Y Surgical Procedure.

The Roux-en-Y gastric bypass procedure is a combination of restrictive and malabsorptive surgery. Complication rates with this procedure are low, patient tolerance is excellent, and the procedure has proved to sustain long-term weight loss. Because of this, the Roux-en-Y gastric bypass procedure is the bariatric surgery most commonly performed. In this procedure, the stomach size is decreased with a gastric pouch anastomosis that empties directly into the jejunum. This surgery can be performed through an open abdominal incision or through laparoscopy. Variations of this procedure include (a) stapling the stomach without transection to create a small gastric pouch (capacity of 20–30 mL); (b) creating an upper and a lower gastric pouch that are totally disconnected from each other; and (c) creating an upper gastric pouch and completely removing the lower pouch. After the procedure, food bypasses 90% of the stomach, the duodenum, and a small segment of jejunum.

Weight loss is usually greatest during the first year after surgery. Weight tends to stabilize after 18 months. Outcomes include increased glucose tolerance, decreased BP, decreased levels of cholesterol and triglycerides, decreased incidence of GERD, and decreased sleep apnea. A complication of this procedure is *dumping syndrome,* in which gastric contents empty too rapidly into the small intestine, overwhelming its ability to digest nutrients (see Chapter 44). Symptoms can include vomiting, nausea, weakness, sweating, faintness, and, on occasion, diarrhea. To avoid dumping syndrome, patients are discouraged from eating sugary foods

after surgery. Because sections of the small intestine are bypassed, poor absorption of iron can cause iron-deficiency anemia. The patient needs to take a multivitamin with iron and calcium supplements. Chronic anemia caused by cobalamin deficiency may also occur. This problem usually can be managed with cobalamin injections or intranasal cobalamin preparations.

Cosmetic Surgeries to Reduce Fatty Tissue and Skin Folds

Lipectomy.

Lipectomy (adipectomy) is performed to remove unsightly loose folds of adipose tissue for cosmetic reasons. In some patients, up to 15% of the total fat cells can be removed from the breasts, the abdomen, and the lumbar and femoral areas. There is no evidence that adipose tissue regenerates at the surgical sites. However, it must be emphasized to the patient that surgical removal does not prevent obesity from recurring, especially if lifetime eating habits remain the same. Although body image and self-esteem may be enhanced by such procedures, these operations are not without complications. In patients with obesity, the effects of anaesthetics can be dangerous, and wound healing has the potential to be poor. It is more useful for the majority of patients contemplating a lipectomy to be instructed in preventive health measures, such as slow weight reduction to maintain and preserve tissue integrity, the value of physical activity, and behaviour-modification techniques.

Liposuction.

Another surgical procedure is *liposuction,* or suction-assisted lipectomy. The current use is for cosmetic purposes and not for weight reduction. This surgical intervention helps improve facial appearance and body contours. A good candidate for this type of surgery is a person who has achieved weight reduction but has excess fat under the chin, along the jawline, in the nasolabial folds, over the abdomen, or around the waist and upper thighs. A long, hollow, stainless steel cannula is inserted through a small incision over the fatty tissue to be suctioned. The purpose of this type of surgery is to improve body appearance, thereby enhancing body image and self-concept. It is not usually recommended for older patients because the skin is less elastic and does not accommodate the new underlying shape.

Nursing Management Patient With Obesity Undergoing Surgery

Nursing Implementation

Perioperative Care.

Many patients with a BMI greater than 35 kg/m^2 have several other medical conditions related to obesity that increase their surgical risk factors and affect their care before, during, and after surgery. This section discusses general nursing considerations for the care of patients with obesity who are having surgery. (General care of patients before, during, and after surgery is discussed in Chapters 20 to 22.)

Preoperative Care.

There are special care considerations for patients with obesity admitted to the hospital for surgical treatment, especially the ones who have morbid obesity. Before surgery, it is important to conduct a preoperative interview with the patient to obtain past and current health information and to ensure that the patient understands the surgical procedure that he or she is scheduled to undergo. If the patient has a disease other than obesity, care may need to be coordinated with the patient's cardiologist, pulmonologist, gynecologist, gastro-enterologist, or other specialist.

Every effort should be made to ensure the patient's dignity and privacy before admission. Most nursing units are not prepared to meet the needs of a patient who may be too large for a typical hospital bed or who does not fit into standard patient care gowns. To eliminate embarrassment for the patient and frustration for the staff, plans should be made to meet particular needs. Oversized BP cuffs should be ready for use when the patient arrives. A single-bed room may be necessary for the privacy of the patient and to accommodate the bed and sitting arrangements. A strongly reinforced trapeze bar should be placed over the bed to facilitate movement and positioning. In some cases, a bariatric chair may have to be built and beds joined together to allow the patient to sit and sleep in comfort.

The nurse must consider how the patient will be weighed and transported within the hospital and in what ways simple physical assessment strategies may have to be adjusted. Bariatric equipment such

as an oversized wheelchair, bariatric bed, walker, and various lifting devices should be made available in the hospital and used.

Bathing, turning, and ambulating the patient may require extra staff, and a plan to meet this need should be in place before the patient's admission. Routine physical assessment strategies do not work well with patients with morbid obesity, who have numerous layers of skin folds covering areas that must be assessed. If alternative or unique methods of dealing with this problem are not identified, assessment of respiratory status and bowel sounds or even wound inspection could be awkward for the nurse and embarrassing for the patient. Wound infection is one of the most common complications after surgery. Because of the many layers of skin folds, especially in the abdominal area, preoperative skin preparation is important. Many patients are instructed to take several showers a day for a few days before admission to the hospital. Careful cleansing with soap and warm water of the abdominal area from the breasts to below the waist is emphasized.

Obesity can cause a patient's breathing to become shallow and rapid. The extra adipose tissue in the chest and the abdomen compresses the diaphragmatic, thoracic, and abdominal structures. This compression restricts the chest's ability to expand, causing the lungs to not work as efficiently as they would otherwise. Thus, the patient retains more carbon dioxide. In addition, less oxygen is delivered to the lungs, resulting in hypoxemia, pulmonary hypertension, and polycythemia. Instruct the patient in the proper coughing technique, deep breathing, and methods of turning and positioning to prevent pulmonary complications after surgery. Introduce the use of spirometry before surgery. Use of the spirometer helps prevent and alleviate postoperative lung congestion. Practising these strategies preoperatively can aid the patient in performing them correctly after surgery. Furthermore, if the patient uses a continuous positive airway pressure (CPAP) device at home for sleep apnea, make arrangements for use of a CPAP machine while the patient is in the hospital. (See Chapter 68 for further discussion on CPAP; see Chapter 9 for more information on sleep apnea and the use of CPAP.)

Obtaining venous access may also be complicated by excess adipose tissue. An assistant may be needed to help. If a patient has pitting edema or excess fat, the nurse should firmly, with pressure, hold a finger over the spot. The nurse may also want to mark the spot of injection with a sterile skin marker once a vein is found. Edema can become worse if the nurse chooses to anchor the catheter by taping the arm. This action can further impede venous return, causing venous stasis, pooling of intravenous

fluids, extravasation, or infiltration. The nurse may also want to use multiple tourniquets to distend veins and hold back excess tissue. To avoid aggravating the edema, the tourniquet should be removed as soon as it is no longer needed. The nurse may also need a longer catheter (longer than 2.5 cm) to traverse overlying tissue. The cannula must reach far enough into the vein to ensure that it does not become dislodged or cause infiltration.

The use of anaesthetic agents during the surgery increases the patient's risk for failure to wean from mechanical ventilation. The patient must be informed of this risk so that he or she can know what to expect upon waking up from the anaesthesia.

Special Considerations for Bariatric Surgery.

The hospital experience will depend on the type of procedure and the surgical approach. The nurse should prepare the patient before surgery for the possibility of returning to the room with one or more of the following: urinary catheter, intravenous (IV) catheter, compression stockings, and a nasogastric (NG) tube. The nurse should emphasize that vital signs will be checked and general assessment conducted frequently to monitor for immediate complications. Furthermore, the patient must understand that he or she will be assisted with ambulation soon after surgery and encouraged to deep-breathe to prevent pulmonary complications. Liquids will be started soon after surgery but only after the patient is fully awake and no anastomotic leaks are found.

Postoperative Care.

The initial postoperative care focuses on careful assessment and immediate intervention for cardiopulmonary complications, thrombus formation, anastomotic leaks, and electrolyte imbalances. The transfer of the patient from surgery may require many trained staff members. During the transfer, the patient's airway should remain stabilized, and pain should be managed at a tolerable level. Maintain the head of the patient at a 35- to 40-degree angle to reduce abdominal pressure and increase tidal flow. If the patient has severe obesity, the nursing team should closely monitor for rapid oxygen desaturation. The body stores anaesthetic agents in adipose tissue; thus the patient with excess adipose tissue is at risk for resedation. As adipose cells release anaesthetic back into the bloodstream, the patient may become sedated after surgery. If this happens, the nursing care team should be prepared to perform a head-tilt or jaw-thrust

manoeuvre and keep the patient's oral and nasal airways opened. Early ambulation is essential for the postoperative bariatric patient. Preoperative teaching facilitates the patient's cooperation with what will be an uncomfortable activity. The patient should be informed that typically the evening after surgery, he or she will be assisted to walk and then be ambulated at least three or four times each day. The dangers of thrombophlebitis and the measures to counteract its development are a routine part of preoperative teaching. The patient should know that sequential compression devices or elastic compression stockings will be applied to the legs and that active and passive range-of-motion exercises will be a frequent part of daily care. Low-dose heparin may be ordered. Depending on the size of the patient and the amount of pain he or she is experiencing, the patient may not be able to assist the nurse in turning. Extra nurses may be needed to help turn the patient safely.

The patient should also be informed that the nursing care team will assess the patient's skin for delayed wound healing and the development of seromas, hematomas, wound dehiscence, wound evisceration, and wound infection. Skin folds should be kept clean and dry to prevent dermatitis and secondary bacterial or fungal infections.

Special Considerations for Bariatric Surgery.

The patient experiences considerable abdominal pain after bariatric surgery. Pain medications should be given as frequently as necessary during the immediate postoperative period (first 24 hours). The nurse must be diligent in assessing pain and be aware that pain could be caused by an anastomotic leak rather than typical surgical pain.

Abdominal wounds must be observed frequently for the amount and type of drainage, condition of the sutures, and signs of infection. The nurse must protect the incision against undue straining that accompanies turning and coughing. Wound dehiscence and impaired wound healing are potential problems for patients with obesity. Monitoring the vital signs assists in identifying problems such as infection.

If an NG tube is inserted, the nurse must monitor it for correct positioning. However, the NG tube must never be inserted or repositioned by the nurse. Vomiting with an NG tube in place requires repositioning the tube, so the surgeon should be notified immediately. The upper gastric pouch is small, and irrigating the tube with too much solution or manipulating tube position can lead to disruption of the anastomosis or the staple line.

Skin care should be performed several times each shift. Perspiration may be excessive at times. The many layers of skin should be kept clean and dry so that this source of irritation is eliminated. For the patient who has an in-dwelling catheter, perineal care is important to prevent urinary tract infection.

During the immediate postoperative period (first 24 hours), water and sugar-free clear liquids are administered (30 mL every 2 hours while the patient is awake). Before discharge, the patient should be instructed about a measured amount of a high-protein liquid diet. The patient is taught to eat slowly and to stop when feeling full and not to consume liquids with solid food. Vomiting is a common complication during this time. A dietitian is typically a part of the bariatric team and assists with the patient's transition to the new diet.

Ambulatory and Home Care

Special Considerations for Bariatric Surgery.

The patient who has undergone major surgical treatment for obesity has not, in the past, been successful in following or maintaining a prescribed diet. Now the patient is forced to reduce the oral intake as a result of the anatomical changes brought about by the operation. The patient finds that adherence to a regimen of reduced intake is necessary because of the concern for abdominal distension, cramping abdominal pain, and perhaps diarrhea.

Weight loss is considerable during the first 6 to 12 months. During this time, the patient must learn to adjust intake sufficiently to maintain a stable weight. Although behaviour modification was not an intended outcome when these surgical procedures were devised, it has become an unexpected and beneficial secondary benefit. The diet generally prescribed should be high in protein and low in carbohydrates, fat, and roughage, and consist of six small feedings daily. Fluids should not be ingested with the meal, and, in some cases, fluids should be restricted to less than 1 000 mL per day. Fluids and foods high in carbohydrates tend to promote diarrhea and symptoms of dumping syndrome. In general, calorically dense foods (foods high in fat) should be avoided to enable more nutritionally sound food to be consumed.

Proper diet must be clearly understood by the patient. Late complications can be anticipated after gastric bypass or gastroplasty, including anemia, vitamin deficiencies, diarrhea, and psychiatric problems. Failure to lose weight or loss of too much weight may be caused

by the surgical formation of a stomach pouch that is too large or of an outlet that is much too small, respectively. Peptic ulcer formation, dumping syndrome, and small bowel obstruction may occur late in the recovery and rehabilitative stages.

Long-term follow-up care must be stressed, in part because of complications late in the recovery period. Encourage the patient to adhere strictly to the prescribed diet and to keep the health care provider informed of any changes in physical or emotional condition. Some patients have been known to overeat when they return home and gain rather than lose weight.

The nurse must anticipate and recognize several potential psychological problems after surgery. Some patients express guilt because the only way they could lose weight was by surgical means rather than by the "sheer willpower" of reduced dietary intake. The nurse should be ready to provide support so that such patients do not dwell on negative feelings.

Many patients with morbid obesity who blamed their feelings of social inferiority or inadequacies on their appearance before bypass surgery may suffer from episodes of depression (see the "Evidence-Informed Practice" box). By 6 to 8 months after surgery, considerable weight loss will have occurred, and patients are able to see clearly how much their appearance has changed. Massive weight loss often leaves the patient with large quantities of loose skin that can cause problems related to altered body image. Reconstructive surgery at least 1 full year after the initial surgery may alleviate this situation. Reduction of breasts, upper arms, thighs, and excess abdominal skin folds are possible solutions. Discussion of this possible outcome with the patient before surgery and again during the rehabilitation phase of recovery helps facilitate the patient's adjustment to a new body image and social reintegration.

Evidence-Informed Practice

Translating Research Into Practice

William Giles is a 35-yr-old male patient weighing 166.4 kg with a BMI of 54.3 kg/m^2. He underwent gastric bypass surgery and is now ready for discharge. The bariatric program at the hospital he is in recommends attendance at support groups after surgery. Mr. Giles informs the nurse that he does not feel comfortable in group settings and will not be attending these meetings.

Best Available Evidence	Clinician Expertise	Patient Preferences and Values
Patients attending psychotherapeutic interventions or support groups in combination with bariatric surgery experience greater weight-loss results than patients treated with only bariatric surgery.	The nurse has heard from several former bariatric patients who have maintained their weight loss after surgery and attributed this success, in part, to their participation in the support group offered at the facility.	Patient does not feel comfortable in group settings.

Decision and Action

The nurse explores Mr. Giles's feelings about groups and shares the reports from former patients with him. He continues to be firm about his unwillingness to attend any support groups. The nurse discusses with him that it is his decision and assures him that his progress will be monitored. The nurse also gently reminds him that he can change his decision at any time. The physician is informed of the patient's choice.

Evaluation

The following outcomes are expected for patients with obesity after surgery:

- The patient will experience long-term weight loss.
- The patient will experience improvement in obesity-related comorbid conditions.
- The patient will integrate healthy practices into daily routines.
- The patient will monitor for adverse effects of surgical therapy.
- The patient will have an improved self-image.

Age-Related Considerations

Obesity in Older Adults

The prevalence of obesity is increasing in all age groups, including older people (CIHI & PHAC, 2011). The number of older adults with obesity has risen markedly because of both an increase in the total number of older people and an increase in the percentage of people who are obese. Obesity is more common in older women than in older men. A decrease in energy expenditure is an important contributor to a gradual increase in body fat with increasing age.

Obesity in older adults can exacerbate age-related declines in physical function and lead to frailty and disability. Excess body weight places more demands on arthritic joints; mechanical strain on weight-bearing joints can lead to premature immobility. Older adults may find that excess intra-abdominal weight causes urinary incontinence. Excess weight may also contribute to hypoventilation and sleep apnea. Obesity is associated with shortened lifespan: individuals who are obese live 6 to 7 years less than do people of normal weight.

Obesity affects quality of life for older adults. Weight loss can improve quality of life and physical function and lessen obesity-related health complications. The same therapeutic approaches to obesity discussed earlier also apply to older adults.

Case Study

Obesity

Source: Antonio Gravante/Shutterstock.com.

Patient Profile

Mrs. Stella Roman is a 60-year-old woman.

Subjective Data

- Reports gradual weight gain of 30 kg during past 40 years
- Spends most of her free time watching television
- Reports health problems related to type 2 diabetes mellitus, shortness of breath, hypertension, chest pressure, and osteoarthritis
- Underwent knee replacement surgery at age 56 for osteoarthritis

Objective Data

Physical Examination

- Height: 162.5 cm; weight: 105 kg
- Has obese, nontender, soft abdomen
- Blood pressure: 160/100 mm Hg

Laboratory Results

- Fasting blood glucose level: 13.9 mmol/L
- Total cholesterol level: 5.3 mmol/L
- Triglyceride level: 3.36 mmol/L
- HDL cholesterol level: 0.8 mmol/L

Discussion Questions

1. What are Mrs. Roman's risk factors for obesity?
2. What is her estimated BMI?
3. Of the possible complications of obesity, which ones does Mrs. Roman have? Why did she develop them?
4. ***Priority decision:*** How would the nurse assist Mrs. Roman in designing a successful program for weight loss and weight management?
5. What are Mrs. Roman's risk factors for metabolic syndrome?

6. Is Mrs. Roman a candidate for surgical intervention for obesity? If so, why? If not, why not?
7. ***Priority decision:*** On the basis of the assessment data presented, what are the priority nursing diagnoses? Are there any collaborative problems?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. Which of the following statements best describes the etiology of obesity?
   a. Obesity results primarily from a genetic predisposition.
   b. Psychosocial factors can override the effects of genetics in the etiology of obesity.
   c. Obesity is the result of complex interactions between genetic and environmental factors.
   d. Genetic factors are more important than environmental factors in the etiology of obesity.
2. Which obesity classification is *most* often associated with cardiovascular health problems?
   a. Primary obesity
   b. Secondary obesity
   c. Gynoid fat distribution
   d. Android fat distribution
3. Health risks associated with obesity include which of the following? *(Select all that apply)*
   a. Colorectal cancer
   b. Rheumatoid arthritis
   c. Polycystic ovary disease
   d. Nonalcoholic steatohepatitis
   e. Systemic lupus erythematosus
4. What is the best nutritional therapy for a person with obesity?
   a. Low-carbohydrate diet
   b. High-protein diet
   c. Low-sugar diet
   d. Foods from the basic food groups
5. Which bariatric surgical procedure involves creating a stoma and gastric pouch that is reversible and does not involve malabsorption?
   a. Vertical gastric banding
   b. Biliopancreatic diversion

c. Roux-en-Y gastric bypass

d. Adjustable gastric banding

6. A client with obesity has undergone Roux-en-Y gastric bypass surgery. In planning postoperative care, what should the nurse anticipate?

a. The client may have severe diarrhea early in the postoperative period.

b. The client will not be allowed to ambulate for 1 to 2 days postoperatively.

c. The client will require nasogastric suction until healing of the incision occurs.

d. The client may have only liquids orally, and in very limited amounts, during the early postoperative period.

7. Which of the following criteria must be met for a diagnosis of metabolic syndrome? *(Select all that apply)*

a. Hypertension

b. Elevated triglyceride levels

c. Elevated plasma glucose level

d. Increased waist circumference

e. Decreased LDL levels

1. c; 2. d; 3. a, c, d; 4. d; 5. d; 6. d; 7. a, b, c, d.

CHAPTER 44

Nursing Management

Upper Gastro-Intestinal Problems

Written by, Paula P. Cox-North

Adapted by, Françoise Verville

LEARNING OBJECTIVES

1. Describe the etiology, complications, collaborative care, and nursing management of nausea and vomiting.
2. Describe the etiology, clinical manifestations, and treatment of common oral inflammations and infections.
3. Describe the etiology, clinical manifestations, complications, collaborative care, and nursing management of oral cancer.
4. Explain the types, pathophysiology, clinical manifestations, complications, and collaborative care, including surgical therapy, and nursing management of gastro-esophageal reflux disease and hiatal hernia.
5. Describe the pathophysiology, clinical manifestations, complications, and collaborative care of esophageal cancer, diverticula, achalasia, and esophageal strictures.
6. Differentiate between acute and chronic gastritis, including the etiology, pathophysiology, collaborative care, and nursing management.

7. Explain the common etiology, clinical manifestations, collaborative care, and nursing management of upper gastro-intestinal bleeding.
8. Compare and contrast gastric and duodenal ulcers, including the etiology and pathophysiology, clinical manifestations, complications, collaborative care, and nursing management.
9. Describe the clinical manifestations, collaborative care, and nursing management of gastric cancer.
10. Identify the common types of food poisoning and the nursing responsibilities related to food poisoning.

vomiting, p. 1013

Nausea and Vomiting

Nausea and vomiting are the most common manifestations of gastro-intestinal (GI) diseases. **Nausea** is a feeling of discomfort in the epigastrium with a conscious desire to vomit. **Vomiting** is the forceful ejection of partially digested food and secretions *(emesis)* from the upper GI tract. Vomiting is a complex act that requires the coordinated activities of several structures: closure of the glottis, deep inspiration with contraction of the diaphragm in the inspiratory position, closure of the pylorus, relaxation of the stomach and lower esophageal sphincter (LES), and contraction of the abdominal muscles with increasing intra-abdominal pressure. These simultaneous activities force the stomach contents up through the esophagus, into the pharynx, and out the mouth. Although nausea and vomiting can occur independently, they are usually closely related and usually treated as one problem.

Etiology and Pathophysiology

Nausea and vomiting occur in a wide variety of GI disorders, as well as in conditions that are unrelated to GI disease. Such conditions include pregnancy, infectious diseases, central nervous system (CNS) disorders (e.g., meningitis, CNS tumour), cardiovascular problems (e.g., myocardial infarction, heart failure), metabolic disorders (e.g., Addison's disease, uremia), adverse effects of drugs (e.g., opioids digitalis), allergies, and psychological factors (e.g., stress, fear).

In general, nausea occurs before vomiting and is characterized by contraction of the duodenum and by slowing of gastric motility and emptying. A single episode of nausea accompanied by vomiting may not be significant. However, if vomiting occurs several times, it is important that the cause be identified.

A vomiting centre in the brainstem coordinates the multiple components involved in emesis. This centre receives input from various stimuli. Neural impulses reach the vomiting centre via afferent pathways through branches of the autonomic nervous

system. Visceral receptors for these afferent fibres are located in the GI tract, the kidneys, the heart, and the uterus. When stimulated, these receptors relay information to the vomiting centre, which then initiates the vomiting reflex (Figure 44-1).

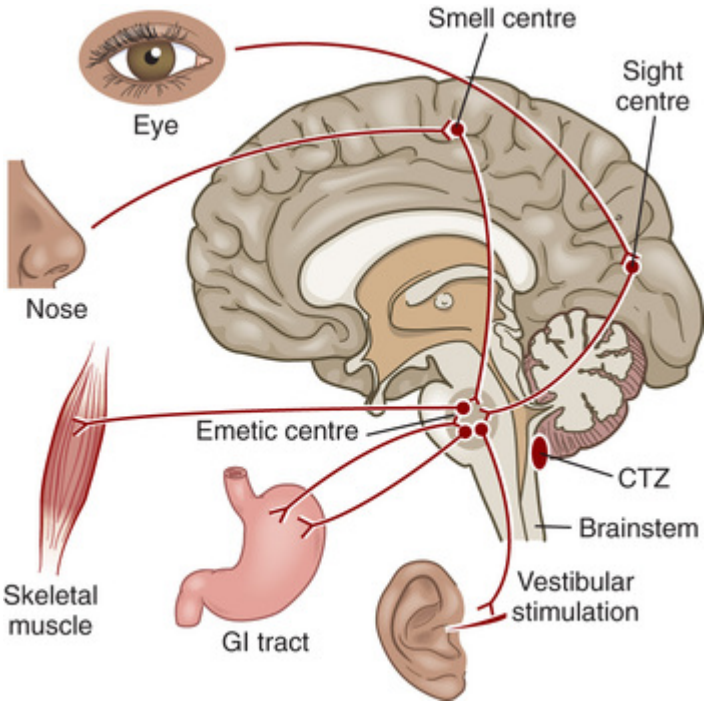

FIGURE 44-1 Stimuli involved in the act of vomiting. *CTZ*, chemoreceptor trigger zone; *GI*, gastro-intestinal. Source: Modified from McKenry, L., Tessier, E., & Hogan, M. (2006). *Mosby's pharmacology in nursing* (22nd ed.). St. Louis: Mosby.

In addition, the chemoreceptor trigger zone (CTZ), located on the floor of the fourth ventricle in the brain, responds to chemical stimuli of drugs and toxins. The CTZ also plays a role in emesis when it is caused by labyrinthine stimulation (e.g., motion sickness). Once stimulated, the CTZ transmits impulses directly to the vomiting centre.

Vomiting also can occur when the GI tract becomes overly irritated, excited, or distended. It can be a protective mechanism to rid the body of spoiled or irritating foods and liquids. Immediately before the act of vomiting, the person becomes aware of the need to vomit. The autonomic nervous system is activated, resulting in both

parasympathetic and sympathetic nervous system stimulation. Sympathetic activation produces tachycardia, tachypnea, and diaphoresis. Parasympathetic stimulation causes relaxation of the lower esophageal (cardiac) sphincter, an increase in gastric motility, and a pronounced increase in salivation. These manifestations are experienced immediately before emesis.

Clinical Manifestations

Nausea is a subjective complaint. *Anorexia* (lack of appetite) usually accompanies nausea and is brought on by unpleasant stimulation involving any of the five senses. When nausea and vomiting are prolonged, dehydration can develop rapidly. In addition to water, essential electrolytes (e.g., potassium, sodium, chloride, hydrogen) are also lost. As vomiting persists, the patient may suffer severe electrolyte imbalances, loss of extracellular fluid volume, decreased plasma volume, and eventually circulatory failure. Metabolic alkalosis can result from loss of gastric hydrochloric acid (HCl). (The word *acid* contained in the shorthand of the chemical formula is a concept important for an understanding of GI chemistry and function.) Metabolic acidosis can occur because of the loss of bicarbonate when contents from the small intestine are vomited. However, metabolic acidosis is a less common result of severe vomiting than is metabolic alkalosis. Weight loss resulting from fluid loss is evident in a short time when vomiting is severe.

The threat of pulmonary aspiration is a concern when vomiting occurs in a patient who is an older adult, is unconscious, or has other conditions that impair the gag reflex. A patient who cannot adequately manage self-care should be put in a semi-Fowler's or side-lying position to prevent aspiration.

Collaborative Care

The goals of collaborative care are to determine and treat the underlying cause of the nausea and vomiting and to provide symptomatic relief. Determining the cause is often difficult because nausea and vomiting are manifestations of many conditions of the GI tract and of disorders of other body systems. An interprofessional

approach to management of patients involving pharmacists, dietitians, and social workers should be considered.

The history must include important information regarding times when the vomiting occurs, precipitating factors, and a description of the contents of the vomitus or emesis. There are sex-related differences in risk for nausea and vomiting associated with both surgical procedures and motion sickness. Women are more likely than men to experience nausea and vomiting (Kovac, 2013). In all patients, vomiting, regurgitation, and projectile vomiting must be differentiated. *Regurgitation* is a process in which partially digested food is slowly brought up from the stomach. Retching or vomiting seldom precedes it. *Projectile vomiting* is a very forceful expulsion of stomach contents without nausea and is a characteristic of CNS tumours.

The presence of fecal odour and bile after prolonged vomiting indicates intestinal obstruction below the level of the pylorus. The presence of bile in the emesis may suggest obstruction below the ampulla of Vater or bile reflux gastritis. The presence of partially digested food several hours after a meal is indicative of gastric outlet obstruction or delay in gastric emptying.

The colour of the emesis aids in determining the presence and the source of bleeding. Vomitus with a "coffee grounds" appearance is associated with bleeding in the stomach, where blood changes to dark brown as a result of its interaction with gastric acid. Bright red blood indicates active bleeding, which is suggestive of a tear in the mucosal lining of the lower esophagus or the fundus of stomach, bleeding gastric or duodenal ulcer or neoplasm, or bleeding esophageal varices.

Drug Therapy.

The choice of drugs in the treatment of nausea and vomiting depends on the cause of the problem. Many different drugs can be used (Table 44-1). Because the cause cannot always be readily determined, drugs must be administered with caution. Antiemetics used before the cause of the vomiting is established can mask the underlying disease process and delay diagnosis and treatment.

Many of the antiemetic drugs act on the CNS at the level of the CTZ. In general, they block the neurochemicals that appear to trigger nausea and vomiting.

TABLE 44-1
DRUG THERAPY
Nausea and Vomiting

Classification	Drug
Dopamine antagonists	• Domperidone (Motilium) • Haloperidol (Haldol) • Metoclopramide
Antihistamine	• Cyclizine • Dimenhydrinate (Gravol) • Diphenhydramine (Benadryl)
Serotonin antagonist	• Dolasetron (Anzemet) • Granisetron (Kytril) • Ondansetron (Zofran)
Antimuscarinic (anticholinergic)	• Scopolamine (hyoscine)
Phenothiazine	• Chlorpromazine (Largactil) • Prochlorperazine (Stemetil) • Promethazine (Phenergan)
Benzodiazepine	• Clonazepam (Clonapam) • Diazepam (Valium) • Lorazepam (Ativan)
Others	• Aprepitant (Emend) • Corticosteroids • Dexamethasone (Decadron)

Many drugs that control nausea and vomiting—antimuscarinics, antihistamines, and phenothiazines—have anticholinergic actions, and their use is contraindicated in patients with glaucoma, prostatic hyperplasia, pyloric or bladder neck obstruction, or biliary obstruction. They share many common adverse effects, which include dry mouth, hypotension, sedative effects, rashes, and GI disturbances such as constipation. Consultation with a pharmacist may be indicated before these drugs are administered to a patient with multiple medical problems.

Metoclopramide and domperidone (Motilium) act both centrally and peripherally on dopamine receptors. Peripherally, they enhance the release of acetylcholine, which results in increased gastric emptying. Because of this effect, these drugs are considered prokinetics. However, about 10% to 20% of patients taking

metoclopramide experience adverse CNS effects ranging from anxiety to hallucinations. Extrapyramidal adverse effects, including tremor and dyskinesias similar to those of Parkinson's disease, may also occur. Domperidone does not cross the blood–brain barrier and thus produces fewer adverse effects than does metoclopramide.

Drug Alert

Metoclopramide

- Chronic use or high doses of metoclopramide carry the risk of tardive dyskinesia.
- Tardive dyskinesia is a neurological condition characterized by involuntary and repetitive movements of the body (e.g., extremity movements, lip smacking).
- With discontinuation of the drug, the tardive dyskinesia persists.

Antagonists to specific serotonin (5-HT) receptors have been found to act both centrally and peripherally to reduce nausea and vomiting. In particular, antagonists to the 5-HT3 receptor are effective in reducing cancer chemotherapy–induced vomiting, vomiting caused by total body irradiation, GI motility disturbances, carcinoid syndrome, and nausea and vomiting related to migraine headache and anxiety. Serotonin antagonists, including ondansetron (Zofran), granisetron (Kytril), and dolasetron (Anzemet), act both centrally in the vomiting centre and peripherally to enhance gastric emptying.

Dexamethasone is used in the management of cancer chemotherapy–induced emesis, usually in combination with other antiemetics. Dexamethasone alone or in combination with ondansetron reduces both acute and delayed chemotherapy-induced nausea and vomiting. Aprepitant (Emend), a substance P/neurokinin-1 receptor antagonist, is used for the prevention of

chemotherapy-induced nausea and vomiting, as well as prevention of postoperative nausea and vomiting. Coadministration with warfarin results in decreased prothrombin time, and so the international normalized ratio (INR) must be closely monitored. The efficacy of hormonal contraceptives may also be reduced, which necessitates an alternative method during treatment and for 1 month after the last dose. Benzodiazepines have no direct antiemetic effect but may be useful as adjunct therapy in the treatment of chemotherapy-induced nausea and vomiting.

Nutritional Therapy.

Patients with severe vomiting require intravenous (IV) fluid therapy with electrolyte and glucose replacement until they are able to tolerate oral intake. In some cases, a nasogastric (NG) tube and suction are used to decompress the stomach. Keeping the stomach empty reduces the stimulus to vomit. The NG tube should be stabilized to eliminate its movement in the nose and back of the throat because this can stimulate nausea and vomiting.

Once the symptoms have subsided, oral nourishment is started with clear liquids. Extremely hot or cold liquids are not usually well tolerated. Carbonated beverages, at room temperature and with the carbonation gone, and warm tea are more easily tolerated. The addition of dry toast or crackers may alleviate the feeling of nausea and help prevent vomiting. Water is the initial fluid of choice for rehydration by mouth.

As the patient's condition improves, a diet high in carbohydrates and low in fatty foods should be provided. Items such as a baked potato, plain gelatin, cereal with milk and sugar, and hard candy may be added. Foods that are known to be poorly tolerated include coffee, spicy foods, and highly acidic foods. Food should be eaten slowly and in small amounts to prevent overdistension of the stomach. When solid foods have been reintroduced, fluids should be taken between meals rather than with meals. It is advised that the patient avoid physical activity and sit upright for approximately 1 hour after meals. A dietitian may be consulted about appropriate

foods that will maintain nutritional health and are well tolerated by the patient during the recovery process.

Complementary & Alternative THERAPIES

Nausea and Vomiting

A number of studies have demonstrated that acupressure or acupuncture at specific points is effective in reducing postoperative nausea and vomiting (Holmér Pettersson & Wengström, 2012).

Some patients use herbs such as ginger and peppermint oil for nausea and vomiting. Breathing exercises, massage, changing body position, self-hypnosis, guided imagery, biofeedback, music therapy, or exercise may be helpful for some patients (Canadian Cancer Association, 2015a).

Nursing Implications

- Patients taking anticoagulant therapy, digoxin, or hypoglycemic agents should not use ginger. Ginger also should not be used if a patient has gallstones or heart failure.

Nursing Management Nausea and Vomiting

Nursing Assessment

Each patient with a history of prolonged and persistent nausea or vomiting requires a thorough nursing assessment before a specific plan of care is developed. Although the conditions associated with nausea and vomiting are numerous, the nurse should have a basic understanding of the more common conditions and should be able to identify a patient who is at high risk of complications from nausea and vomiting. Knowledge of the physiological mechanisms involved in nausea and vomiting and the demonstration of a genuine regard for the patient are essential. Table 44-2 lists subjective and objective data that should be obtained from a patient with nausea and vomiting, regardless of the underlying cause.

TABLE 44-2

NURSING ASSESSMENT
Nausea and Vomiting

Subjective Data
Important Health Information
Past health history: GI disorders, chronic indigestion, food allergies, pregnancy, infection, CNS disorders, recent travel, bulimia, metabolic disorders, cancer, cardiovascular disease, renal disease *Medications:* Use of antiemetics, digitalis, opioids, ferrous sulphate, ASA (Aspirin), aminophylline, alcohol, antibiotics; general anaesthetic; chemotherapy *Surgery or other treatments:* Recent surgery
Symptoms
• Emesis, dry heaves, dry mouth, anorexia, weight loss • Weakness, fatigue • Abdominal tenderness or pain
Objective Data
General
Lethargy, sunken eyeballs
Integumentary
Pallor, dry mucous membranes, poor skin turgor
Gastro-intestinal
Amount, frequency, character (e.g., projectile), content (undigested food, blood, bile, feces), and colour of vomitus (red, "coffee grounds," green-yellow)
Urinary
Decreased output, concentrated urine
Possible Findings
Altered serum electrolyte levels (especially hypokalemia), metabolic alkalosis, abnormal upper GI findings on endoscopy or abdominal radiographs

ASA, acetylsalicylic acid; *CNS*, central nervous system; *GI*, gastro-intestinal.

Nursing Diagnoses

Nursing diagnoses for the patient with nausea and vomiting may include, but are not limited to, the following:

- *Nausea* related to *noxious environmental stimuli, noxious taste, unpleasant visual stimuli*
- *Deficient fluid volume* related to *insufficient fluid intake* (prolonged vomiting)
- *Imbalanced nutrition: less than body requirements* related to *insufficient dietary intake* (nausea and

vomiting)

Additional information on nursing diagnoses is presented in Nursing Care Plan (NCP) 44-1, available on the Evolve website.

Planning

The overall goals are that the patient with nausea and vomiting will (a) experience minimal or no nausea and vomiting, (b) have normal electrolyte levels and hydration status, and (c) return to a normal pattern of fluid balance and nutrient intake.

Nursing Implementation

Acute Intervention.

The majority of individuals with nausea and vomiting can be managed at home. However, when nausea and vomiting persist regardless of home treatment strategies, hospitalization may be necessary for diagnosis of the underlying problem. Until a diagnosis is confirmed, the patient is kept on nothing-by-mouth (NPO) status and given IV fluids. An NG tube connected to suction may be necessary for a patient with persistent vomiting and for a patient in whom the possible diagnosis may be bowel obstruction or paralytic ileus.

With prolonged vomiting, there is a probability of dehydration and of acid–base and electrolyte imbalances. The nurse plans care that includes accurate recording of intake and output, monitoring vital signs, assessing for signs of dehydration, proper positioning to prevent possible aspiration by a susceptible patient, and observing for changes in the patient's general physical comfort and mentation. The nurse takes responsibility for providing physical and emotional support; maintaining a quiet, odour-free environment; and giving explanations regarding any diagnostic tests or procedures performed.

Patients who are hospitalized for other health problems may be prone to episodes of nausea and vomiting. These individuals include patients who are recovering immediately after surgery from the

effects of the procedure, anaesthesia, and pain. Nausea and vomiting are common adverse effects in patients with cancer receiving chemotherapeutic drugs. (Nursing care of patients with cancer is discussed in Chapter 18 and in NCP 18-2, available on the Evolve website.)

Ambulatory and Home Care.

The patient and caregiver may need instructions on (a) how to deal successfully with the unpleasant sensations of nausea, (b) methods of preventing nausea and vomiting, and (c) strategies to maintain fluid and nutritional intake. The occurrence of nausea or vomiting may be minimized if measures are taken to keep the immediate environment quiet, free of noxious odours, and well ventilated. Sudden changes of position and unnecessary activity should be avoided. Use of relaxation techniques, acupressure, frequent rest periods, and diversional tactics help prevent nausea and vomiting and facilitate a more rapid recovery from their effects. Cleansing the face and the hands with a cool washcloth and mouth care between episodes increase the person's comfort level. When the symptoms occur, all foods and drugs should be stopped until the acute phase is past.

If a medication is suspected as the cause, the health care provider should be notified immediately so that either the dosage can be altered or a different drug can be prescribed. The patient should be reminded that stopping a prescribed drug without consulting the health care provider may eliminate the immediate cause of the nausea and vomiting but may also have detrimental effects on health or the disease state.

When food is identified as the precipitating cause of nausea and vomiting, the nurse should help the patient solve the problem. What food was it? When was it eaten? Has this food caused problems in the past? Is anyone else in the family sick?

When the patient believes some foods and fluids can be tolerated, the nurse might suggest that it would be helpful to begin with clear liquids or warm beverages, Gatorade, tea or broth, dry crackers or toast, and then plain gelatin. Bland foods, such as pasta, rice, and

cooked chicken, are generally well tolerated in small amounts. An antiemetic drug should be taken only if prescribed by the health care provider. Taking over-the-counter (OTC) drugs for relief of symptoms may make the condition worse. Patients should be asked to describe any use of nontraditional preparations.

Evaluation

The following are expected outcomes for the patient with nausea and vomiting:

- The patient will be comfortable with minimal or no nausea and vomiting.
- The patient will maintain body weight.
- The patient's electrolyte levels will be within normal range.
- The patient will be able to maintain adequate intake of fluids and nutrients.
- The patient will maintain normal urine volume.

Age-Related Considerations

Nausea and Vomiting

Older adult patients experiencing nausea and vomiting require careful assessment and monitoring, particularly during periods of fluid loss and subsequent rehydration therapy. Older adults are more likely to have cardiac or renal insufficiency, which increases their risk for life-threatening fluid and electrolyte imbalances. In addition, excessive replacement of fluid and electrolytes may result in adverse consequences for an older adult who has heart failure or renal disease. Moreover, older adults with a decreased level of consciousness may be at high risk for aspiration of vomitus. Close monitoring of the patient's physical status and level of consciousness during episodes of vomiting must be a primary concern for the nurse.

In addition, older adults are particularly susceptible to the CNS adverse effects of antiemetic drugs; these drugs may produce confusion. Dosages should be reduced and efficacy closely evaluated. Safety precautions also should be instituted for these patients.

Foodborne Illness

Foodborne illness and *food poisoning* are nonspecific terms that describe acute GI symptoms such as nausea, vomiting, diarrhea, and colicky abdominal pain caused by the intake of contaminated food. Food most commonly causes illness if it is contaminated with microorganisms or their products. The GI tract is frequently the portal of entry for the microorganisms. The epidemiology of foodborne illness is changing. There are new organisms, and many have spread worldwide. The two main types of food poisoning are (a) acute gastro-enteritis from bacteria and (b) neurological symptoms from botulism. Bacteria account for most foodborne illnesses. Raw foods that have become contaminated during growing, harvesting, processing, storing, shipping, or final

preparation are the most common source. When food is uncooked and left out for more than 2 hours at room temperature, bacteria can multiply quickly. The most common bacterial causes of food poisoning are listed in Table 44-3.

TABLE 44-3
BACTERIAL FOOD POISONING

Causative Agent	Sources	Onset of Symptoms	Clinical Manifestations	Treatment	Prevention
Staphylococcal					
Toxin from *Staphylococcus aureus*	Meat, bakery products, cream fillings, salad dressings, milk; skin and respiratory tract of food handlers	30 min–7 hr	Vomiting, nausea, abdominal cramping, diarrhea	Symptomatic, fluid and electrolyte replacement, antiemetics	Immediate refrigeration of foods, monitoring of food handlers
Clostridial					
Clostridium perfringens	Meat or poultry dishes cooked at lower temperature (stew or pot pie), rewarmed meat dishes, gravies, improperly canned vegetables	8–24 hr	Diarrhea, nausea, abdominal cramps, vomiting (rare); midepigastrium pain	Symptomatic, fluid replacement	Correct preparation of meat dishes, serving of food immediately after cooking, or rapid cooling of food
***Salmonella* Organisms**					
Salmonella typhimurium (grows in gut)	Improperly cooked poultry, pork, beef, lamb, and eggs	8 hr to several days	Nausea and vomiting, diarrhea, abdominal cramps, fever and chills	Symptomatic, fluid and electrolyte replacement	Correct preparation of food
Botulism					

Causative Agent	Sources	Onset of Symptoms	Clinical Manifestations	Treatment	Prevention
Toxin from *Clostridium botulinum;* ingested toxin is absorbed from gut and blocks acetylcholine at neuro-muscular junction	Improperly canned or preserved food, home-preserved vegetables, preserved fruits and fish, canned commercial products	12–36 hr	GI symptoms: nausea, vomiting, abdominal pain, constipation, distension Central nervous system symptoms: headache, dizziness, muscular incoordination, weakness, inability to talk or swallow, diplopia, breathing difficulties, paralysis, delirium, coma	Maintenance of ventilation, polyvalent antitoxin, guanidine HCl (enhances acetylcholine release)	Correct processing of canned foods, discarding suspect canned goods
Escherichia coli					
E. coli serotype O157:H7	Contaminated beef, pork, milk, cheese, fish, prepackaged cookie dough	Varies by strain: 8 hr–1 wk	Bloody stools, hemolytic uremic syndrome, abdominal cramping, profuse diarrhea	Symptomatic, fluid and electrolyte replacement	Correct preparation of food
***Listeria* Organisms**					
Gram-positive rod-shaped bacterium	Most cases associated with ingesting contaminated dairy products, poultry, and meat	1–90 days	In immuno-competent host: fever, diarrhea Immuno-compromised host (pregnant women, older adults, immuno-compromised persons at greatest risk): meningitis ± septicemia	Ampicillin and trimethoprim-sulphamethoxazole or erythromycin	Pasteurization, proper washing, refrigeration, and cooking of foods potentially contaminated with animal manure or sewage

GI, gastro-intestinal.

Poisonous chemicals, such as mercury, arsenic, zinc, and potassium chlorate, may contaminate foods. Poisoning can also occur from ingestion of poisonous plants (e.g., certain mushroom species).

Prevention of occurrence is the focus of interventions. Teaching should include correct food preparation and cleanliness, adequate cooking, and refrigeration. If the patient is hospitalized, care focuses on correction of fluid and electrolyte imbalance from diarrhea and vomiting. With botulism, additional assessment and care relative to neurological symptoms are indicated (see Chapter 63).

Escherichia coli O157:H7 Poisoning

Escherichia coli O157:H7 causes hemorrhagic colitis and kidney failure, and in young children and older adults, *E. coli* O157:H7 infection can be life-threatening (Centers for Disease Control and Prevention, 2015). *E. coli* O157:H7 is found primarily in undercooked meats, particularly poultry and hamburger. *E. coli* outbreaks have also been observed with contaminated leafy vegetables, fruits, and nuts. Person-to-person contact in families, nursing homes, and child care centres is also an important mode of transmission. Infection can also occur after drinking raw milk, unpasteurized juice, or contaminated fruit juices and after swimming in or drinking sewage-contaminated water.

Most strains of *E. coli* are harmless and live in the intestines of healthy humans and animals. *E. coli* O157:H7 produces a powerful toxin and can cause severe illness. The clinical manifestations of *E. coli* O157:H7 infection include diarrhea and abdominal cramping pain for 2 to 8 days (on average, 3–4 days) after the organism is swallowed. The diarrhea is variable, ranging from mild to bloody. The diarrhea may start out as watery but may progress to bloody. Systemic complications, including hemolytic uremia and thrombocytopenic purpura, and even death can occur.

Infection with *E. coli* O157:H7 is diagnosed when the bacteria are detected in the stool. All people who suddenly have diarrhea with blood should get their stool tested (stool culture) for *E. coli* O157:H7.

Treatment involves supportive care to maintain blood volume. The use of antibiotics remains controversial. Most affected people recover without antibiotics or other specific treatment. Patients should avoid antidiarrheal agents, such as loperamide (Imodium). Other therapies may include dialysis and plasmapheresis.

In approximately 2% to 7% of infections, particularly in young children and older adults, hemolytic uremic syndrome (HUS) occurs, in which the red blood cells (RBCs) are destroyed and kidney function fails. HUS is a life-threatening condition and approximately 3% to 5% of patients with HUS die. About one third of people with HUS have abnormal kidney function many years after the onset, and a few require long-term dialysis. Additional long-term complications of HUS include hypertension, seizures, blindness, and paralysis.

Oral Inflammations and Infections

Oral infections and inflammations may be manifestations of specific mouth diseases, or they may occur in the presence of some systemic diseases such as leukemia or vitamin deficiency. Oral inflammations and infections can severely impair the ingestion of food and fluids. Common inflammations and infections of the oral cavity are listed in Table 44-4. Patients who are immuno-suppressed (e.g., those with acquired immune deficiency syndrome [AIDS] and those receiving chemotherapy) are most susceptible to oral infections. Patients receiving corticosteroid inhalant treatment for asthma are at risk for oral infections, especially candidiasis.

TABLE 44-4
INFECTIONS AND INFLAMMATION OF THE MOUTH

Condition	Etiology	Clinical Manifestations	Treatment
Gingivitis	Neglected oral hygiene, malocclusion, missing or irregular teeth, faulty dentistry, eating of soft rather than fibrous foods	Inflamed gingivae and interdental papillae; bleeding during toothbrushing; development of pus; formation of abscess with loosening of teeth (periodontitis)	Prevention through health teaching, dental care, gingival massage, professional cleaning of teeth, fibrous foods, conscientious brushing habits with flossing
Vincent's infection (acute necrotizing ulcerative gingivitis, trench mouth)	Fusiform bacteria; Vincent's spirochetes; predisposing factors of stress, excessive fatigue, poor oral hygiene, nutritional deficiencies (vitamins B and C)	Painful, bleeding gingivae; eroding necrotic lesions of interdental papillae; ulcerations that bleed; increased saliva with metallic taste; fetid mouth odour; anorexia, fever, and general malaise	Rest (physical and mental); avoidance of smoking and alcoholic beverages; soft, nutritious diet; correct oral hygiene habits; topical applications of antibiotics; mouth rinses with hydrogen peroxide and saline solutions
Oral candidiasis (moniliasis or thrush)	*Candida albicans* (a yeastlike fungus), debilitation, prolonged high-dose antibiotic or corticosteroid therapy	Pearly, bluish-white "milk-curd" membranous lesions on mucosa of mouth and larynx; sore mouth; yeasty halitosis	Nystatin suspension or fluconazole as oral therapy, good oral hygiene
Herpes simplex (cold sore, fever blister)	Herpes simplex virus type 1 or 2; factors predisposing to upper respiratory infections, excessive exposure to sunlight, food allergies, emotional tension, onset of menstruation	Lip lesions, mouth lesions, vesicle formation (single or clustered); shallow, painful ulcers	Spirits of camphor, corticosteroid cream, mild antiseptic mouthwash, viscous lidocaine; removal or control of predisposing factors, antiviral agents (e.g., acyclovir [Zovirax])
Aphthous stomatitis (canker sore)	Recurrent and chronic form of infection secondary to systemic disease, trauma, stress, or unknown causes	Ulcers of mouth and lips, causing extreme pain; ulcers surrounded by erythematous base	Corticosteroids (topical or systemic), tetracycline oral suspension
Parotitis (inflammation of parotid gland, surgical mumps)	Usually *Staphylococcus* species, occasionally *Streptococcus* species, debilitation and dehydration with poor oral hygiene, NPO status for an extended time	Pain and swelling in area of gland and ear, absence of salivation, purulent exudate from gland, erythema, ulcers	Antibiotics, mouthwashes, warm compresses; preventive measures such as chewing gum, sucking on hard candy, adequate fluid intake
Stomatitis (inflammation of mouth)	Trauma; pathogens; irritants (tobacco, alcohol); renal, liver, and hematological diseases; adverse effect of many cancer chemotherapy drugs and irradiation	Excessive salivation, halitosis, sore mouth	Removal or treatment of cause, oral hygiene with soothing solutions, topical medications; soft, bland diet

NPO, nothing by mouth.

Oral infections may predispose to infections in other body organs. For example, the oral cavity can be considered a potential reservoir for respiratory pathogens. Oral pathogens have also been associated with heart disease.

An important element in reducing the incidence of oral infections and inflammation is good oral hygiene. Management of oral infections and inflammation is focused on identification of the cause, elimination of infection, provision of comfort measures, and maintenance of nutritional intake.

Oral Cancer

Oral (or oropharyngeal) cancer may occur on the lips or anywhere within the mouth (e.g., tongue, floor of the mouth, buccal mucosa, hard palate, soft palate, pharyngeal walls, tonsils). It was estimated that 4 700 new cases of oral cancer would be diagnosed in Canada in 2017, and that 1 250 persons would die from the disease (Canadian Cancer Society, 2017). It is more common after 45 years of age. It is more common in men (male-to-female ratio, 2 : 1). Squamous cell carcinoma is the most common oral malignant tumour (95% of cases of oral cancer). Mortality rates have been decreasing since the early 1980s. The rate of 5-year survival for all stages of cancer of the oral cavity and pharynx combined is 63%.

Most of the oral malignant lesions occur on the lower lip. Other common sites are the lateral border and undersurface of the tongue, the labial commissure, and the buccal mucosa. Carcinoma of the lip has the most favourable prognosis of any of the oral tumours. This is probably because lip lesions are more apparent to the patient than other oral lesions and are usually diagnosed earlier.

Etiology and Pathophysiology

Although the definitive cause of oral cancer is unknown, there are a number of predisposing factors (Table 44-5). Factors that influence the development of oral cancer include tobacco use (e.g., cigar, cigarette, pipe, snuff), excessive alcohol intake, human

papillomavirus infection, chewing betel quid or areca nut, precancerous conditions of the oral cavity (e.g., leukoplakia), and a family history of squamous cell carcinoma. A positive history of tobacco and alcohol use, in the past or currently, is the most significant etiological factor in oral cancer. Constant overexposure to ultraviolet radiation from the sun is also a factor in the development of cancer of the lip. Irritation from the pipe stem resting on the lip is a factor in pipe smokers.

TABLE 44-5
TYPES AND CHARACTERISTICS OF ORAL CANCER

Location	Predisposing Factors	Clinical Manifestations	Treatment
Lip	Constant overexposure to sun, ruddy and fair complexions, recurrent herpetic lesions, irritation from pipe stem, syphilis, immuno-suppression	Indurated, painless ulcer	Surgical excision, radiation therapy
Tongue	Tobacco, alcohol, chronic irritation, syphilis	Ulcer or area of thickening; soreness or pain; increased salivation, slurred speech, dysphagia, toothache, earache (later signs)	Surgery (hemiglossectomy or glossectomy), radiation therapy
Oral cavity	Poor oral hygiene, tobacco usage (pipe and cigar smoking, snuff, chewing tobacco), chewing betel nut, chronic alcohol intake, chronic irritation (jagged tooth, ill-fitting prosthesis, chemical or mechanical irritants), exposure to HPV	Leukoplakia; erythroplakia; ulcerations; sore spot; rough area; pain, dysphagia, difficulty in chewing and speaking (later signs)	Surgery (mandibulectomy, radical neck dissection, resections of buccal mucosa), internal and external radiation therapy

HPV, human papillomavirus.

Clinical Manifestations

The common manifestations of oral cancer are leukoplakia, erythroplakia, ulcerations, a sore that bleeds easily and does not heal, and a rough area (felt with the tongue). **Leukoplakia,** called "white patch" or "smoker's patch," is often considered a precancerous lesion; approximately 3% to 17.5% of these lesions actually transform into malignant cells within 15 years. It is a whitish patch on the mucosa of the mouth or the tongue that results from

chronic irritation, especially from smoking. The patch becomes *keratinized* (hard and leathery) and is sometimes described as *hyperkeratosis. Erythroplasia* (erythroplakia), which is seen as a red velvety patch on the mouth or tongue, is also considered a precancerous lesion. Areas of erythroplakia have a 51% chance of becoming malignant. Later symptoms of oral cancer are pain, **dysphagia** (difficulty swallowing), and difficulty in moving the jaw (e.g., chewing and speaking).

Cancer of the lip usually appears as an indurated, painless ulcer on the lip. The first sign of carcinoma of the tongue is an ulcer or area of thickening. Soreness or pain of the tongue may occur, especially when hot or highly seasoned foods are eaten. Cancerous lesions are most likely to develop in the proximal half of the tongue. Some patients experience limitation of movement of the tongue. Later symptoms of cancer of the tongue include increased salivation, slurred speech, dysphagia, toothache, and earache. Approximately 30% of patients with oral cancer have an asymptomatic neck mass.

Diagnostic Studies

Endoscopic examination in combination with biopsy of the suspected lesion with cytological examination is the best definitive diagnostic study for oral cancer. Oral exfoliative cytological study involves scraping the suspect lesion and spreading this scraping on a slide. In contrast to biopsy, a negative result of a cytological smear does not reliably rule out the possibility of a malignant condition, but it may be used as an initial screening test. The definitive diagnosis of cancer is based on biopsy and histological findings. Once cancer is diagnosed, radiographs, computed tomography, and magnetic resonance imaging (MRI) are useful in the staging of oral cancer (Canadian Cancer Society, 2015b).

Collaborative Care

Collaborative care of patients with oral carcinoma usually consists of surgery, radiation therapy, chemotherapy, or a combination of these (Table 44-6).

TABLE 44-6
COLLABORATIVE CARE
Oral Cancer

Diagnostic	Collaborative Therapy*

• History and physical examination
• Biopsy
• Oral exfoliative cytological study
• Radiographs, CT, and MRI
	• Surgery
	  • Surgical excision of the tumour
	  • Radical neck dissection
	• Radiation therapy (internal or external)
	• Combined surgical resection with radiation therapy
	• Chemotherapy

*Any of these approaches may be used, depending on the primary lesion and the extent of metastasis.

CT, computed tomography; *MRI,* magnetic resonance imaging.

Surgical Therapy.

Surgery remains the most effective treatment, especially for removing the central core of the tumour. Various surgical procedures may be performed, depending on the location and the extent of the tumour. Many of the operations are radical procedures involving extensive resections. Some examples are partial *mandibulectomy* (removal of the mandible), *hemiglossectomy* (removal of half of the tongue), *glossectomy* (removal of the tongue), resections of the buccal mucosa and the floor of the mouth, and radical neck dissection. Composite resections, which are combinations of the various surgical procedures, may be performed.

Because cancers of the oral cavity metastasize early to the cervical lymph nodes, a radical neck dissection is commonly performed. It includes wide excision of the involved primary lesion with removal of the regional lymph nodes, the deep cervical lymph nodes, and their lymphatic channels. In addition, the following structures may also be removed or transected (depending on the extent of the primary lesion): sternocleidomastoid muscle and other closely associated muscles, internal jugular vein, mandible, submaxillary gland, part of the thyroid and parathyroid glands, and spinal accessory nerve. A tracheostomy is commonly performed along with the radical neck dissection. Drainage tubes are inserted into the

surgical area and connected to the suction device to remove fluid and blood.

Nonsurgical Therapy.

Chemotherapy and radiation therapy are used together when the lesions are more advanced or involve several structures of the oral cavity. Chemotherapy may also be used when surgery and radiation therapy fail or as the initial therapy for smaller tumours (see Chapter 18).

Palliative treatment may be the best management when the prognosis is poor, the cancer is inoperable, or the patient decides against surgery. The aim of palliation is to treat the symptoms and make the patient more comfortable. If it becomes difficult for the patient to swallow, a gastrostomy may be performed to allow for adequate nutritional intake. (Gastrostomy is discussed in Chapter 42.) Analgesic medication should be given freely to such a patient. Frequent suctioning of the oral cavity becomes necessary when swallowing becomes difficult. (Other nursing measures for terminally ill patients are discussed in Chapter 13.)

Nutritional Therapy.

Because of depression, alcoholism, or presurgery radiation treatment, patients may be malnourished even before surgery. After radical neck surgery, the patient may be unable to take in nutrients through the normal route of ingestion because of swelling, location of sutures, or difficulty with swallowing. Parenteral fluids are given for the first 24 to 48 hours. After this time, tube feedings are usually given via an NG tube or a nasointestinal tube that was placed during surgery. Sometimes a temporary feeding gastrostomy may be used. (NG and gastrostomy feedings are described in Chapter 42.) Cervical esophagostomy and pharyngostomy have also been used. The nurse must observe for tolerance of the feedings and (in consultation with a dietitian) adjust the amount, the time, and the formula if nausea, vomiting, diarrhea, or distension occurs. The patient is instructed about the tube feedings. When the patient can swallow, small amounts of water are given. Close observation for choking is essential. Suctioning may be necessary to prevent aspiration.

Nursing Management Oral Cancer

Nursing Assessment

Subjective and objective data that should be obtained from a patient with oral cancer are listed in Table 44-7.

TABLE 44-7

NURSING ASSESSMENT
Oral Cancer

Subjective Data
Important Health Information
Current health history: Use of alcohol or tobacco, pipe smoking, poor oral hygiene *Past health history:* Recurrent oral herpetic lesions, syphilis, exposure to sunlight, HPV infection or vaccination *Medications:* Immuno-suppressants *Surgery or other treatments:* Removal of prior tumours or lesions
Symptoms
• Reduced oral intake, weight loss, difficulty in chewing or swallowing food; increased salivation; intolerance to certain foods or temperatures of food • Mouth or tongue soreness or pain, toothache, earache, neck stiffness, difficulty speaking
Objective Data
Integumentary
Indurated, painless ulcer on lip; painless neck mass
Gastro-intestinal
Areas of thickening or roughness, ulcers, leukoplakia, or erythroplakia on the tongue or the oral mucosa; limited movement of the tongue; increased salivation, drooling; slurred speech; poor oral hygiene, foul breath odour
Possible Findings
Positive result of exfoliative cytological smear (microscopic examination of cells removed by scraping); positive biopsy findings

HPV, human papillomavirus.

Nursing Diagnoses

Nursing diagnoses for patients with oral cancer may include, but are not limited to, the following:

- *Imbalanced nutrition: less than body requirements* related to *insufficient dietary intake* (oral pain,

difficulty chewing and swallowing, surgical resection, and radiation treatment)
- *Chronic pain* related to *injury agent* (tumour, surgery, or radiation treatment)
- *Anxiety* related to *stressors, threat of death, threat to current status* (diagnosis of cancer, potential for disfiguring surgery)

Planning

The overall goals are that the patient with carcinoma of the oral cavity will (a) have a patent airway, (b) be able to communicate, (c) have adequate nutritional intake to promote wound healing, and (d) have relief of pain and discomfort.

Nursing Implementation

Health Promotion.

The nurse has a significant role in early detection and treatment of oral cancer. The nurse must provide the patient with information regarding predisposing factors, such as constant overexposure to the sun, tobacco, and other irritants, such as chewing betel nuts. Smoking and the long-term use of smokeless tobacco are the major risk factors for oral cancer. A patient identified as a smoker should be informed about smoking cessation programs available in the community. (Smoking cessation is discussed in Chapter 11. See also the link to the CAN-ADAPTT *Canadian Smoking Cessation Clinical Practice Guideline* in the Resources at the end of this chapter.)

It is important that adolescents and teenagers be informed about the danger of using snuff and chewing tobacco. In addition, oral cancers have an increased chance of recurrence if risk factors are not reduced. The nurse should also teach correct oral hygiene and dental care and encourage the patient to seek preventive dental care. Risk factors should be identified. Because early detection of oral cancer is important, the patient should be taught to examine the mouth and to

recognize danger signals of oral cancer. If any of these signals are present, the patient should be instructed to visit a health care provider. Danger signals include unexplained pain or soreness in the mouth, unusual bleeding from the oral cavity, dysphagia, and swelling or lump in the neck.

Any individual with an ulcerative lesion that does not heal within 2 to 3 weeks should be referred to a health care provider, and a biopsy of the lesion should probably be performed. The nurse should inspect the patient's oral cavity to detect suspect lesions.

Acute Intervention.

Preoperative care for a patient who is to undergo a radical neck dissection involves consideration of the patient's physical and psychosocial needs. Physical preparation is the same as for any major surgery, with special emphasis on oral hygiene. Alcohol intake should be assessed thoroughly, and measures should be implemented early to assess and treat withdrawal if it is a problem. Explanations and emotional support are of special significance and should include postoperative measures relating to communication and feeding. The surgical procedure should be explained to the patient, and the nurse should make sure that the patient understands the information. (Radical neck dissection and related nursing management are discussed in Chapter 29 and in NCP 29-2, available on the Evolve website.)

Evaluation

The following are expected outcomes for the patient with oral cancer:

- The patient will have no respiratory complications.
- The patient will be able to communicate.
- The patient will participate in regular follow-up examinations.

- The patient will maintain adequate nutritional intake to promote wound healing and overall health.
- The patient will experience minimal pain and discomfort with eating, drinking, and talking.

Esophageal Disorders

Gastro-esophageal Reflux Disease

Etiology and Pathophysiology

Gastro-esophageal reflux disease (GERD) is not a disease but a syndrome. GERD is defined as any clinically significant symptomatic condition or histopathological alteration presumed to be secondary to reflux of gastric contents into the lower esophagus. In Canada, GERD is the most prevalent acid-related disorder; for approximately 13% of Canadians, GERD symptoms occur at least once a week (Canadian Society of Intestinal Research, 2015).

There is no single cause of GERD. Several factors or a combination of factors can be involved (Figure 44-2). It results when the defences of the lower esophagus are overwhelmed by the reflux of stomach acidic contents into the esophagus. Predisposing conditions include hiatal hernia, incompetent LES, decreased esophageal clearance (ability to clear liquids or food from the esophagus into the stomach) as a result of impaired esophageal motility, and decreased gastric emptying. The acidic gastric secretions that are regurgitated up into the lower esophagus result in esophageal irritation and inflammation (esophagitis). In addition, the presence of the gastric enzyme pepsin, intestinal enzymes (e.g., trypsin), and bile salts is corrosive to the esophageal mucosa. The degree of inflammation depends on the amount and the composition of gastric reflux and on the ability of the esophagus to clear the acidic contents.

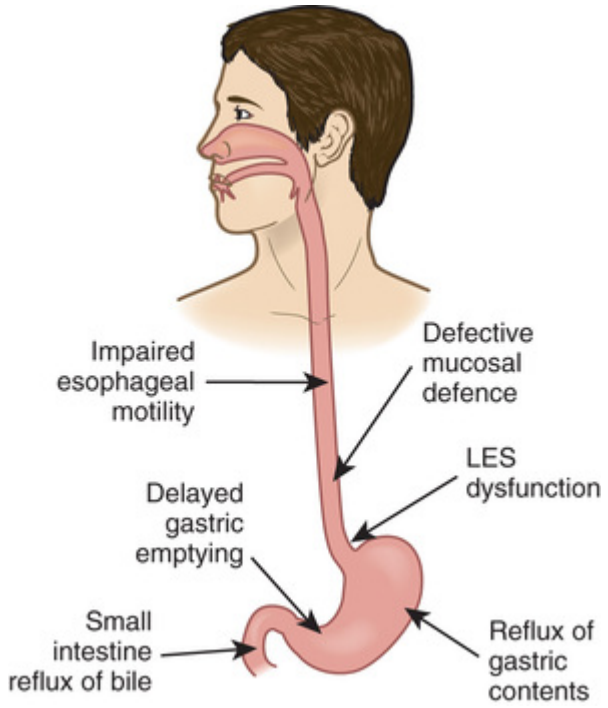

FIGURE 44-2 Factors involved in the pathogenesis of gastro-esophageal reflux disease (GERD). *LES*, lower esophageal sphincter.

One of the primary factors in GERD is incompetence of the LES. An incompetent LES results in a decrease in pressure in the distal portion of the esophagus. As a result, gastric contents are able to move from an area of higher pressure (stomach) to an area of lower pressure (esophagus) when the patient is in a supine position or has an increase in intra-abdominal pressure. Decreases in LES pressure can be caused by certain foods (e.g., caffeine, chocolate) and drugs (e.g., anticholinergics). A common cause of GERD is a hiatal hernia, which is discussed in the next section.

Clinical Manifestations

The symptoms of GERD vary from individual to individual, but the diagnosis can usually be made on the basis of history and physical examination. Heartburn *(pyrosis)* from gastro-esophageal reflux is the most common clinical manifestation. It is caused by irritation of the esophagus by the gastric secretions. Heartburn is described as a burning, tight sensation that is felt intermittently beneath the lower

sternum and spreads upward to the throat or the jaw. Approximately once a week, the majority of patients with GERD have mild symptoms, including heartburn, after a meal, with no evidence of mucosal damage.

Heartburn may occur after ingestion of food or drugs that decrease the LES pressure or are directly irritating to the esophageal mucosa (Table 44-8). An individual with GERD may also report respiratory symptoms, including wheezing, coughing, and dyspnea. Otolaryngological symptoms include hoarseness, sore throat, a globus sensation (sensation of a lump in the throat), and choking. *Regurgitation* (effortless return of food or gastric contents from the stomach into the esophagus or mouth) is a fairly common manifestation of GERD. It is often described as hot, bitter, or sour liquid coming into the throat or mouth. Gastric symptoms—including early satiety, bloating after a meal, nausea, and vomiting—are related to delayed gastric emptying. Symptoms that would prompt endoscopic evaluation include dysphagia (solid food, progressive), odynophagia (painful swallowing), bleeding and subsequent anemia, weight loss, and persistent vomiting. Further investigation is indicated if suspected GERD symptoms are actually cardiac in origin, if the patient has respiratory symptoms secondary to reflux, or for individuals who do not respond to medical therapy after 8 weeks (Richter, 2014).

TABLE 44-8

COMMON FOODS/DRUGS AFFECTING LOWER ESOPHAGEAL SPHINCTER PRESSURE

Increase Pressure
• Bethanechol (Duvoid) • Metoclopramide
Decrease Pressure

• Alcohol
• Chocolate (theobromine)
• Fatty foods
• Nicotine
• Peppermint, spearmint
• Tea, coffee (caffeine)
• Drugs
  • Anticholinergics
  • β-Adrenergic blockers
  • Calcium channel blockers
  • Diazepam (Valium)
  • Morphine sulphate
  • Nitrates
  • Progesterone
  • Theophylline

Complications

Complications of GERD are related to the direct local effects of gastric acid on the esophageal mucosa. **Esophagitis** (inflammation of the esophagus) is a frequent complication of GERD. Other risk factors for esophagitis include hiatal hernia, chemical irritation from lye, and physical irritants such as smoking, cold or hot liquids, and excessive alcoholic intake. Trauma to the esophagus may also produce inflammation. The appearance of esophagitis with esophageal ulcerations is shown in Figure 44-3.

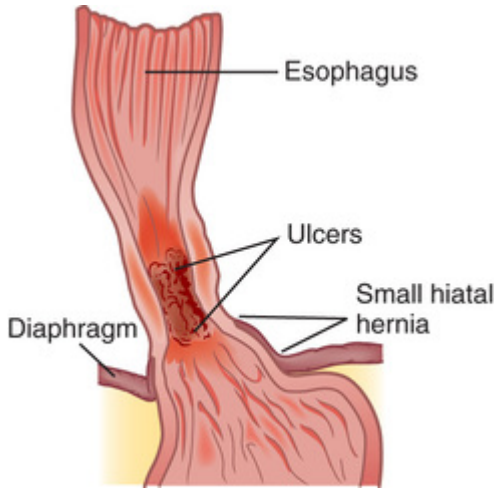

FIGURE 44-3 Esophagitis with esophageal ulcerations.

Repeated exposure may cause scar tissue formation and decreased distensibility of the esophagus *(esophageal stricture).* This may result in dysphagia.

Another complication of GERD is **Barrett's esophagus** (esophageal metaplasia). Barrett's esophagus is considered a precancerous lesion and increases the risk for esophageal cancer. In Barrett's esophagus, the normal squamous epithelium of the esophagus is replaced with columnar epithelium. These cell changes are thought to be related to chronic reflux esophagitis. Signs and symptoms of Barrett's esophagus can range from none to mild to bleeding and perforation. Because patients with Barrett's esophagus are at higher risk for adenocarcinoma, they may need to be monitored on a regular basis (every 2.5 years) with endoscopy and biopsy (Almond & Barr, 2014).

Respiratory complications of GERD include bronchospasm, laryngospasm, and cricopharyngeal spasm. These complications are caused by irritation of the upper airway by gastric secretions. With GERD, there is also the potential for pneumonia as a result of aspiration of gastric contents into the respiratory system. Dental erosion, especially in the posterior teeth, may result from acid reflux into the mouth.

Diagnostic Studies

Diagnostic studies are performed to determine the cause of the GERD, such as hiatal hernia (Table 44-9). Barium swallow studies

may be done to determine whether there is protrusion of the upper part of the stomach (called the *gastric fundus*). Endoscopy is useful in assessing the competence of the LES and the extent of inflammation (if present), potential scarring, and strictures (Canadian Society of Intestinal Research, 2014). Biopsy and cytological specimens can be obtained to differentiate carcinoma of the stomach or esophagus from Barrett's esophagus. Esophageal manometric studies can be performed to measure pressure in the esophagus, as well as in the LES. The pH may be determined with the use of specially designed probes in the laboratory or ambulatory monitoring systems, which may demonstrate the presence of acid in the normally alkaline esophagus. Radionuclide tests may also be performed to detect reflux of gastric contents and the rate of esophageal clearance.

TABLE 44-9
COLLABORATIVE CARE
Gastro-Esophageal Reflux Disease and Hiatal Hernia

Diagnostic • History and physical examination • Barium swallow • Motility (manometry) studies • pH monitoring (laboratory or 24-hr ambulatory) • Upper GI endoscopy with biopsy and cytological analysis **Collaborative Therapy** ***Conservative*** • Elevation of head of bed on 10- to 15-cm blocks • High-protein, low-fat diet with avoidance of foods and fluids that decrease LES pressure or irritate acid-sensitive esophagus	Drug Therapy • Antacids • Antisecretory agents • Cholinergic drugs • H_2-receptor blockers* • Proton pump inhibitors* • Prokinetic drug therapy* ***Surgical Therapy*** • Belsey fundoplication • Hill gastropexy • Nissen fundoplication • Toupet fundoplication ***Endoscopic Therapy*** • Intraluminal valvuloplasty • Radiofrequency therapy • Stretta device

*See Table 44-10.

GI, gastro-intestinal; *LES,* lower esophageal sphincter.

Collaborative Care

Most cases of GERD can be successfully managed by lifestyle modifications and drug therapy. These are long-term approaches requiring patient education and adherence to therapeutic regimens. When these therapies are ineffective, surgery is an option (see Table 44-9).

Lifestyle Modifications.

Patients with GERD are taught to avoid factors that aggravate symptoms. Particular attention is given to diet and drugs that may affect the LES, acid secretion, or gastric emptying. Patients who are overweight or obese are encouraged to lose weight. Patients who smoke are encouraged to stop.

Nutritional Therapy.

Diet does not cause GERD, but food can aggravate symptoms. No specific diet is necessary, but foods that cause reflux should be avoided. Fatty foods stimulate the release of cholecystokinin, a hormone from the duodenum that decreases LES pressure. High-fat foods also decrease the rate of gastric emptying. Foods that decrease LES pressure, such as chocolate, peppermint, and caffeinated beverages (coffee, cola, and tea; see Table 44-8), should be avoided because they are conducive to reflux. Milk products should be avoided, especially at bedtime, because milk increases gastric acid secretion. To prevent overdistension of the stomach, small, frequent meals are advised. The patient should avoid late-evening meals and nocturnal snacking. Fluids should be taken between rather than with meals to reduce gastric distension. Certain foods (e.g., tomato-based products, orange juice) may irritate the acid-sensitive esophagus and may have to be avoided. To reduce intra-abdominal pressure, weight reduction is recommended if the patient is overweight.

Drug Therapy.

Drug therapy for GERD is focused on improving LES function, increasing esophageal clearance, decreasing volume and acidity of reflux, and protecting the esophageal mucosa (Table 44-10). There are two approaches to drug therapy. In the "step-up" approach, therapy starts with antacids and OTC histamine (H_2)-receptor (H_2R) blockers; then prescription H_2R blockers and, finally, proton pump inhibitors (PPIs) are included. The "step-down" approach involves starting with a PPI and, over time, titrating down to prescription H_2R blockers and, finally, to OTC H_2R blockers and antacids.

TABLE 44-10

DRUG THERAPY
Gastro-Esophageal Reflux Disease (GERD)

Mechanism of Action	Examples
Increase Lower Esophageal Sphincter Pressure	
Cholinergic	Bethanechol (Duvoid)
Promotility	
Prokinetic	Metoclopramide
Acid-Neutralizing	
Antacids	Aluminum hydroxide and magnesium hydroxide (Maalox, Mylanta)
Antisecretory	
H_2-receptor blockers	Famotidine (Pepcid) Nizatidine (Axid) Ranitidine (Zantac)
Proton pump inhibitors	Esomeprazole (Nexium) Dexlansoprazole (Dexilant) Lansoprazole (Prevacid) Omeprazole (Losec) Pantoprazole (Pantoloc) Rabeprazole (Pariet)
Cytoprotective	
Alginic acid-antacid	Aluminum hydroxide + magnesium trisilicate (Gaviscon)
Acid-protective	Sucralfate

Antacids produce quick but short-lived relief of heartburn. They act by neutralizing HCl. They should be taken 1 to 3 hours after meals and at bedtime. OTC antacids with or without alginic acid (e.g., Gaviscon) may be useful in patients with mild, intermittent heartburn. The alginic acid reacts with sodium bicarbonate and forms a viscous solution that floats to the surface of the gastric contents and coats the esophagus, acting as a mechanical barrier to reflux. However, in patients with moderate to severe or frequent symptoms or patients with documented esophagitis, these regimens are not effective in relieving symptoms or healing erosive lesions.

Antisecretory agents decrease the secretion of HCl by the stomach. H_2R blockers (e.g., ranitidine [Zantac]) are available in OTC and prescription formulations. Some formulations include combinations of H_2R blockers and antacids; for example, Pepcid Complete includes famotidine, calcium carbonate, and magnesium hydroxide. In prescription-strength doses, H_2R blockers reduce symptoms and promote esophageal healing in approximately 50% of patients. Many

patients experience relapse (i.e., GERD symptoms return) with discontinuation of the drug.

PPIs also decrease stomach HCl secretion. These drugs act by inhibiting the proton pump mechanism responsible for the secretion of hydrogen ions (H^+). PPIs promote esophageal healing in approximately 80% to 90% of patients but are more expensive than H_2R blockers. PPIs may also be beneficial in decreasing the incidence of esophageal strictures, a complication of chronic GERD. Long-term use of PPIs has been associated with decreased bone density, chronic hypochlorhydria, increased risk of infection with *Clostridium difficile* in hospitalized patients, and pneumonia (Owen, Panesar, Marks, et al., 2014).

Another drug that may be used to treat GERD is sucralfate, an antiulcer drug used for its cytoprotective properties. Cholinergic drugs, such as bethanechol (Duvoid), may be used to increase LES pressure, improve esophageal emptying in the supine position, and increase gastric emptying. However, the value of current cholinergic agents is limited because they also stimulate HCl secretion. Prokinetic (motility-enhancing) drugs such as metoclopramide promote gastric emptying and reduce the risk of gastric acid reflux (see Table 44-10).

Evidence-Informed Practice

Research Highlight

Are Proton Pump Inhibitors Associated With Increased Risk of Diarrhea?

Clinical Question

Among hospitalized patients (P), does the use of proton pump inhibitor drugs (I) increase the risk of *C. difficile*–associated diarrhea (O)?

Best Available Evidence

Meta-analysis of case-control and cohort studies

Critical Appraisal and Synthesis of Evidence

- In 23 studies, researchers examined medical records of 300 000 hospitalized patients for proton pump inhibitor (PPI) exposure and confirmation of acute diarrhea due to *C. difficile*.
- Patients taking PPIs have a greater risk (65%) of *C. difficile*–associated diarrhea (CDAD).

Conclusion

- There is a significant positive association between PPIs and the incidence of CDAD.

Implications for Nursing Practice

- Advise patients taking PPIs of the risk for diarrhea and to contact their health care provider if it does not improve.
- Inform patients that CDAD symptoms include watery stool, abdominal pain, and fever.
- Institute infection control procedures in hospitalized patients suspected of having *C. difficile* infection.

P, Patient population of interest; *I*, intervention or area of interest; *O*, outcomes of interest (see Chapter 1).

Reference for Evidence

Janarthanan S, Ditah I, Adler DG, et al. *Clostridium difficile*–associated diarrhea and proton pump inhibitor therapy: A meta-analysis. *Am J Gastroenterol*. 2012;107(7):1001–1010; 10.1038/ajg.2012.179.

Surgical Therapy.

Surgical therapy (antireflux surgery) may be necessary if long-term conservative therapy fails, in the presence of a hiatal hernia, or in the presence of complications, such as esophageal stricture and stenosis (narrowing), chronic esophagitis, and bleeding. Many surgical procedures are performed laparoscopically. The objective of surgical interventions for GERD is to reduce reflux of gastric contents by enhancing the integrity of the LES. Surgical interventions for GERD are called *antireflux procedures.* In these procedures, the fundus of the stomach is wrapped around the lower portion of the esophagus in varying positions.

A diagram of the Nissen fundoplication is shown in Figure 44-4. Laparoscopically performed Nissen and Toupet fundoplications have become the standard antireflux surgical procedures. The use of laparoscopic antireflux surgery for GERD has reduced complications, overall morbidity, and the cost of hospitalization in comparison with a thoracic or open abdominal approach (Funk, Kanji, Scott Melvin, et al., 2014).

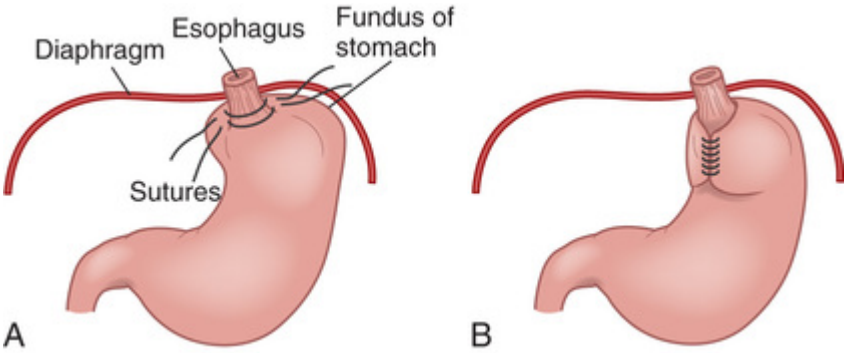

FIGURE 44-4 Nissen fundoplication for repair of hiatal hernia. **A,** The fundus of the stomach is wrapped around the distal esophagus. **B,** The fundus is then sutured to itself.

Source: Modified from Doughty, D. B., & Jackson, D. B. (1993). *Mosby's clinical nursing series: Gastrointestinal disorders.* St. Louis: Mosby.

Endoscopic Therapy.

Alternatives to surgical therapy include endoscopic mucosal resection, photodynamic therapy, cryotherapy, and radiofrequency ablation (image-guided technique that kills cells through heating). For patients with high-grade dysplasia, endoscopic mucosal resection can also be used as a diagnostic test to obtain biopsy samples.

Nursing Management Gastro-esophageal Reflux Disease

Patients with GERD must avoid factors that cause reflux. A patient teaching guide is provided in Table 44-11. Patients who smoke should stop. Smoking causes an almost immediate drop in LES pressure and decreases the ability to clear acid from the esophagus. Patients may need to be referred to other members of the health care team or to community resources for assistance in stopping smoking. (See Chapter 11 for additional information related to smoking cessation.) Substances that decrease LES pressure and tone should be avoided (see Table 44-8). If stress seems to cause symptoms, measures to cope with stress should be discussed. (See Chapter 8 for stress management techniques.) The patient should also be taught possible adverse effects of drugs.

TABLE 44-11

PATIENT & CAREGIVER TEACHING GUIDE
Prevention of Gastro-Esophageal Reflux Disease

The following guidelines should be included when teaching the patient and caregiver about prevention of gastro-esophageal reflux disease. The nurse should:
1. Explain the rationale for a high-protein, low-fat diet. If the patient is overweight or obese, the need for weight loss should be discussed. 2. Encourage the patient to eat small, frequent meals to prevent gastric distension. 3. Explain the rationale for avoiding alcohol, smoking (which causes an almost immediate, marked decrease in LES pressure), and beverages that contain caffeine. 4. Teach the patient not to lie down for 2–3 hrs after eating, not to wear tight clothing around the waist, and not to bend over (especially after eating). 5. Encourage the patient to sleep with head of bed elevated 30 degrees (gravity fosters esophageal emptying). 6. Teach information regarding drugs, including rationale for their use and common adverse effects. 7. Discuss strategies for weight reduction, if appropriate. 8. Encourage patient and caregiver to share concerns about lifestyle changes and living with a chronic problem.

LES, lower esophageal sphincter.

Nursing care for the patient who is having acute symptoms consists mainly of encouraging the patient to follow the necessary regimen, as described in Table 44-11. The patient may be taking

drugs to relieve heartburn, and so the nurse must both observe for adverse effects and evaluate the drugs' effectiveness. Even when symptoms are brought under control, the patient may need to continue taking the drugs because the underlying problem is still present. Because of the link between GERD and metaplastic changes in the lower esophagus (Barrett's esophagus), patients are instructed to see their health care provider if symptoms persist.

The nurse must observe for and instruct the patient about adverse effects of the drugs being taken. Adverse effects with H_2R blockers and PPIs are rare. Antacids have minimal adverse effects: Those that contain aluminum tend to cause constipation, whereas those that contain magnesium tend to cause diarrhea. Several of the antacids are combinations of aluminum and magnesium designed to minimize these adverse effects. If the patient is taking bethanechol (Duvoid), adverse effects to observe for include urinary urgency, increased salivation, and abdominal cramping with diarrhea, nausea, vomiting, and hypotension. Such adverse effects often limit the effectiveness of cholinergic agents in the treatment of GERD. Adverse effects of metoclopramide include restlessness, anxiety, insomnia, and hallucinations. Adverse effects of sucralfate include drowsiness, dizziness, nausea, vomiting, constipation, urticaria, and other types of rash.

Postoperative care focuses on concerns related to prevention of respiratory complications, maintenance of fluid and electrolyte balance, and prevention of infection. If a thoracic approach is used, a chest tube is inserted. Assessment and management related to closed chest drainage are important (see Chapter 30).

If an open abdominal incision is used, respiratory complications can occur in a patient because it is a high abdominal incision. Respiratory assessment should include respiratory rate and rhythm, pulse rate and rhythm, and signs of pneumothorax (e.g., dyspnea, chest pain, cyanosis). Deep breathing is essential to fully expand the lungs.

The patient receives IV fluids and electrolytes until the return of peristalsis. Care should be taken to maintain patency of the NG tube (if present) to prevent the need to reinsert the tube. It is dangerous to attempt to replace the tube because the surgical repair can be

perforated. Immediately after the surgical procedure, the patient cannot voluntarily vomit or belch, and this may cause bloating and abdominal discomfort. When peristalsis returns, only fluids are given initially. Solids are added gradually so that the stomach is not overdistended. The nurse must maintain an accurate recording of intake and output and observe for fluid and electrolyte imbalances (see Chapter 19). (Care of the patient after a laparotomy procedure is described in Chapter 45 and NCP 45-2, available on the Evolve website.)

After surgical therapy, there should be no symptoms of gastric reflux. However, the recurrence rate may range from 10% to 30% over a 20-year period after surgery. The patient should be instructed to report symptoms such as heartburn and regurgitation. Such problems may be temporary and resolve with time. The patient should report persistent dysphagia, sense of epigastric fullness, and bloating. A normal diet is gradually resumed. The patient should avoid foods that are gas forming and should try to prevent gastric distension. Food should be chewed thoroughly.

Hiatal Hernia

Hiatal hernia is herniation of a portion of the stomach into the esophagus through an opening (hiatus) in the diaphragm. It is also referred to as *diaphragmatic hernia* and *esophageal hernia.* The incidence of hiatal hernia is difficult to determine. However, it is the most common abnormality found on radiographic examination of the upper GI tract. Hiatal hernias are common in older adults and are more common in women than in men.

Types

Hiatal hernias are classified into the following two types (Figure 44-5):

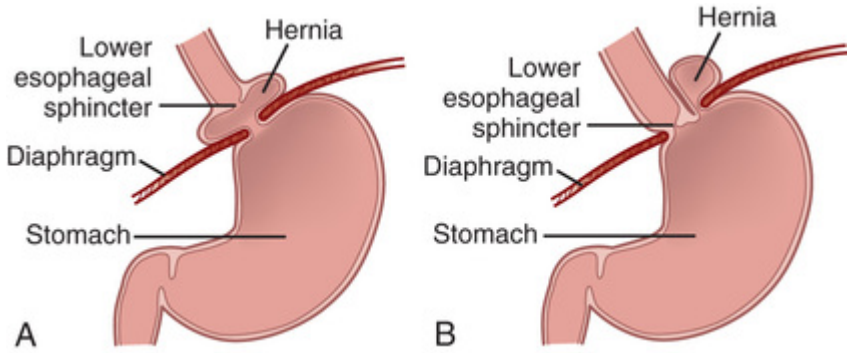

FIGURE 44-5 **A,** Sliding hiatal hernia. **B,** Para-esophageal (rolling) hiatal hernia.

1. *Sliding:* The junction of the stomach and the esophagus is above the hiatus of the diaphragm, and a part of the stomach slides through the hiatal opening in the diaphragm. The stomach "slides" into the thoracic cavity when the patient is supine and usually goes back into the abdominal cavity when the patient is standing upright. This is the most common type of hiatal hernia.
2. *Para-esophageal* or *rolling:* The esophagogastric junction remains in the normal position, but the fundus and the greater curvature of the stomach roll up through the diaphragm, forming a pocket alongside the esophagus.

Etiology and Pathophysiology

Many factors contribute to the development of hiatal hernia. Structural changes, such as weakening of the muscles in the diaphragm around the esophagogastric opening, are usually contributing factors. Factors that increase intra-abdominal pressure, including obesity, pregnancy, ascites, tumours, tight corsets, intense physical exertion, and heavy lifting on a continual basis, may also predispose to development of a hiatal hernia. Other predisposing factors are increased age, trauma, poor nutrition, and a forced recumbent position, as when a prolonged illness confines the person to bed. In some cases, congenital weakness is a contributing factor.

Clinical Manifestations

Hiatal hernia may be asymptomatic. The signs and symptoms of hiatal hernia, when present, are similar to those described for GERD. Heartburn, especially after a meal or after lying supine, is a common symptom. Affected patients may report dysphagia. Frequently, the symptoms of hiatal hernia mimic those of gallbladder disease, peptic ulcer disease (PUD), and angina. Reflux and discomfort are also associated with position, occurring soon or several hours after the person lies down. Bending over may cause a severe burning pain, which is usually relieved by sitting or standing. Other common precipitating factors of pain include consumption of large meals and alcohol and smoking. Nocturnal symptoms of heartburn are common, especially if the person has eaten before going to sleep.

Complications

Complications that may occur with hiatal hernia include GERD, hemorrhage from erosion, stenosis (narrowing of the esophagus), ulcerations of the herniated portion of the stomach, strangulation of the hernia, and regurgitation with tracheal aspiration.

Diagnostic Studies

A barium swallow study is an important diagnostic measure that may reveal the protrusion of gastric mucosa through the esophageal hiatus in a patient with hiatal hernia. Endoscopic visualization of the lower esophagus provides information on the degree of mucosal inflammation or other abnormalities. Other tests are similar to those described in Table 44-9.

Nursing and Collaborative Management Hiatal Hernia

Conservative Therapy

Conservative therapy for hiatal hernia is similar to that described for GERD, including lifestyle modifications (e.g., reduction of intra-abdominal pressure by eliminating constricting garments, avoiding lifting and straining, eliminating alcohol and smoking, elevating the head of the bed) and the use of antacids and antisecretory agents (i.e., PPIs, H_2R blockers). Elevation of the head of the bed on 10- to 15-cm blocks assists gravity in maintaining the stomach in the abdominal cavity and also helps prevent reflux and tracheal aspiration. If the patient is overweight, the patient should be encouraged to lose weight.

Surgical Therapy

The objective of surgical interventions for hiatal hernia is to reduce reflux by enhancing the integrity of the LES. There are four slightly varied procedures: the Nissen fundoplication, the Toupet fundoplication or technique, the Hill gastropexy, and the Belsey fundoplication. These surgical procedures are all variations of fundoplication, which involves wrapping the fundus of the stomach around the lower portion of the esophagus in varying positions. These procedures reduce the hernia, help maintain an acceptable LES pressure, and prevent movement of the gastro-esophageal junction. The Nissen fundoplication is illustrated in Figure 44-4. As with GERD, laparoscopically performed Nissen and Toupet techniques have become the standard antireflux surgeries for hiatal hernia (Funk, Kanji, Scott Melvin, et al., 2014). A thoracic or open abdominal approach may also be used in selected cases.

Age-Related Considerations

Gastro-esophageal Reflux Disease and Hiatal Hernia

Both the incidence of GERD and that of hiatal hernia increase with age. They are associated with weakening of the diaphragm, obesity, kyphosis, and use of corsets or other factors that increase intra-abdominal pressure. In some older adults, hiatal hernia is asymptomatic. The first indications may include esophageal bleeding secondary to esophagitis or respiratory complications (e.g., aspiration pneumonia) related to aspiration of gastric contents. The LES may become less competent with aging in some individuals.

The clinical course and the management of GERD and hiatal hernia in older adults are similar to those for the younger adult. With the increased use of laparoscopic procedures, surgical risks have been reduced. However, an older adult with cardiovascular and pulmonary problems may not be a good candidate for surgical intervention. In addition, changes in lifestyle, including elimination of dietary factors such as caffeine-containing beverages and chocolate, and elevating the head of the bed on blocks, may be more difficult for the older adult.

Esophageal Cancer

Esophageal cancer is a rare malignant neoplasm of the esophagus. There are two main types: squamous cell carcinoma and adenocarcinoma. The rate of 5-year survival is 14% despite multimodal treatment options. Cancer of the esophagus occurs in three times as many men than in women, and the rate has remained relatively stable since the mid-1980s. The incidence of one type of esophageal cancer (esophageal adenocarcinoma), although it is still relatively rare in Canada, doubled from 1986 to 2006 (Otterstatter, Brierley, De, et al., 2012). This may be because of the rising prevalence of obesity and GERD. It was estimated that 2 300 new cases of esophageal cancer would be diagnosed in Canada during

2017 (Canadian Cancer Society, 2017). Adenocarcinomas arise from the glands lining the esophagus and resemble cancers of the stomach and the small intestine, whereas squamous cell carcinoma starts in the squamous cells that line the esophagus. The incidence of esophageal cancer increases with age.

Etiology and Pathophysiology

The cause of esophageal cancer is unknown. Important risk factors are smoking and excessive alcohol intake, chewing betel quid, GERD, tylosis, achalasia, Plummer-Vinson syndrome, chemical injury to the esophagus, exposure to ionizing radiation, and a personal history of oral cancer or a family history of esophageal cancer (Canadian Cancer Society, 2015c). One risk factor for esophageal adenocarcinoma is Barrett's esophagus. (Barrett's esophagus is described in the earlier "Complications" section under "Gastro-esophageal Reflux Disease.")

The majority of esophageal tumours are located in the middle and lower portions of the esophagus. The malignant tumour usually appears as an ulcerated lesion and has often advanced by the time the patient experiences symptoms. The tumour may penetrate the muscular layer and even extend outside the wall of the esophagus. Obstruction of the esophagus occurs in the later stages.

Clinical Manifestations

The onset of symptoms is usually late in relation to the extent of the tumour. Progressive dysphagia is the most common symptom and may be expressed as a substernal feeling as if food is not passing (globus sensation). Initially, the dysphagia occurs only with meat, then with soft foods, and eventually with liquids.

Pain develops late in the course of the disease and is described as occurring in the substernal, epigastric, or back areas and usually increases with swallowing. The pain may radiate to the neck, the jaw, the ears, and the shoulders. If the tumour is in the upper third of the esophagus, symptoms such as sore throat, choking, and hoarseness may occur. Weight loss is fairly common. When

esophageal stenosis is severe, regurgitation of blood-flecked esophageal contents is common.

Complications

Hemorrhage may occur if the cancer erodes through the esophagus and into the aorta. Esophageal perforation with fistula formation into the lung or the trachea sometimes develops. The tumour may enlarge enough to cause esophageal obstruction. Metastases spread via the lymph system, the liver and the lungs being common sites of metastasis.

Diagnostic Studies

A barium swallow study with fluoroscopy may demonstrate a narrowing of the esophagus at the site of the tumour (Table 44-12). Sometimes a crater is visible. Endoscopy with biopsy is necessary to make a definitive diagnosis of carcinoma by identification of malignant cells. Endoscopic ultrasonography is an important tool used to stage esophageal cancer. A bronchoscopic examination may be performed to detect malignant involvement of the lung. Computed tomography and MRI are also used to assess the extent of the disease.

	• Chemotherapy
	• Dilation
	• Laser therapy
	• Palliative therapy
	• Radiation
	• Stent or prosthesis

CT, computed tomography; *MRI,* magnetic resonance imaging.

Collaborative Care

The treatment of esophageal cancer depends on the location of the tumour and whether invasion or metastasis has occurred (see Table 44-12). Esophageal cancer has a poor prognosis, mainly because it is not usually diagnosed until the disease is advanced. The best results may be obtained with a combination of surgery, chemotherapy, and radiation.

The types of surgical procedures that can be performed are (a) removal of part or all of the esophagus *(esophagectomy)* with use of a Dacron graft to replace the resected part, (b) resection of a portion of the esophagus and anastomosis of the remaining portion to the stomach *(esophagogastrostomy),* and (c) resection of a portion of the esophagus and anastomosis of a segment of colon to the remaining portion *(esophagoenterostomy).* The surgical approaches may be thoracic or both abdominal and thoracic. In comparison with the other procedures, minimally invasive esophagectomy (laparoscopic vagal nerve–sparing surgery) has the advantages of smaller incisions, shorter hospital stays, and fewer pulmonary complications. Overall outcomes appear to be similar to open resections of the esophagus. Chemotherapy in combination with radiation treatment before or after surgery is currently used (Canadian Cancer Society, 2015d). Current treatment regimens can be found through the Canadian Cancer Society. If the tumour is in the cervical section (upper third) of the esophagus, radiation treatment is usually indicated. A tumour in the lower third of the esophagus is usually resected surgically.

Palliative therapy consists of restoration of the swallowing function and maintenance of nutrition and hydration. Dilation, stent placement, or both can relieve obstruction. Dilation is accomplished with various types of dilators (e.g., Celestin's tube). Dilation often relieves dysphagia and allows for improved nutrition. Placement of a stent or prosthesis may help when dilation is no longer effective. The prostheses are composed of silicone rubber or nylon-reinforced latex tubes with distal and proximal collars. The prosthesis is placed in the esophagus so that food and fluids can pass through the

stenotic segment of the esophagus. The prosthesis can be placed endoscopically.

Endoscopic laser therapy or vaporization of the tumour may be used in combination with dilation. Obstruction recurs as the tumour grows, but laser therapy can be repeated. Sometimes these procedures are combined with radiation therapy. Other measures for palliation include gastrostomy or esophagostomy tube placements for nutritional support and pain management.

Nutritional Therapy.

After esophageal surgery, parenteral fluids are given. When fluids are allowed, 30 to 60 mL of water is given hourly, with gradual progression to small, frequent bland meals. The patient should be in an upright position to prevent regurgitation of the fluid. The patient is observed for signs of intolerance to the feeding or leakage of the feeding into the mediastinum. Symptoms that indicate leakage are pain, increased temperature, and dyspnea. Symptoms of food intolerance include vomiting and abdominal distension. A gastrostomy may be performed for the purpose of feeding the patient. (Gastrostomy and tube feedings are discussed in Chapter 42.)

Nursing Management Esophageal Cancer

Nursing Assessment

The patient should be asked about any history of GERD, hiatal hernia, achalasia, or Barrett's esophagus. The patient is also questioned regarding tobacco and alcohol use. The patient should be assessed for progressive dysphagia and *odynophagia* (burning, squeezing pain during swallowing). The nurse should question the patient regarding the type of substances ingested that cause dysphagia, such as meat, soft foods, and liquids. The patient is also assessed for pain (substernal, epigastric, or back areas), choking, heartburn, hoarseness, cough, anorexia, weight loss, and regurgitation (sometimes bloody).

Nursing Diagnoses

Nursing diagnoses for the patient with esophageal cancer include, but are not limited to, the following:

- *Chronic pain* related to *injury agent* (compression of tumour on surrounding tissues)
- *Imbalanced nutrition: less than body requirements* related to *insufficient dietary intake* (dysphagia, odynophagia, weakness)
- *Risk for aspiration* related to *decrease in gastro-intestional motility* (difficulty swallowing and regurgitation)
- *Anxiety* related to *threat to current status, threat of death*

Planning

The overall goals are that the patient with esophageal cancer will (a) have relief of symptoms, including pain and dysphagia; (b) achieve optimal nutritional intake; (c) understand the prognosis of the disease; and (d) experience the best possible quality of life during disease progression.

Nursing Implementation

Health Promotion.

Patients with diagnosed GERD and hiatal hernia need to be counselled regarding regular follow-up evaluation. Health counselling should focus on elimination of smoking and excessive alcohol intake, as well as other risk factors for GERD. Maintenance of good oral hygiene and dietary habits (intake of fresh fruits and vegetables) may also be helpful.

Patients with Barrett's esophagus need to be monitored because this is considered a premalignant condition. Early diagnosis of esophageal tumours is important but difficult because the onset of symptoms is usually late in the course of the disease. Patients are encouraged to seek medical attention for any esophageal problems, especially dysphagia. Patients who are at risk for esophageal adenocarcinoma, such as those with evidence of Barrett's esophagus and a diagnosis of achalasia (discussed later in the "Other Esophageal Disorders" section), may need regular endoscopic screening with biopsy and cytological study.

Acute Intervention

Preoperative Care.

In addition to general preoperative teaching and preparation, particular attention to the patient's nutritional needs and oral care is important. Many patients are poorly nourished because of the inability to ingest adequate amounts of food and fluids before surgery. A high-calorie, high-protein diet is recommended. It may have to be in liquid form. Some patients may need IV fluid

replacement or parenteral nutrition. The patient and the family member are instructed on how to keep an intake and output record and how to assess for signs of fluid and electrolyte imbalance. Some treatment protocols necessitate preoperative radiation treatment and chemotherapy.

Meticulous oral care is essential. The mouth, including tongue, gingivae, and teeth or dentures, must be cleaned thoroughly. Milk of magnesia with mineral oil may be used to remove any crusting that has formed. A mixture of mouthwash (nonalcohol), ice, and water makes a refreshing rinse for the patient.

Teaching should include information about chest tubes (if a thoracic approach is used), IV lines, NG tubes, gastrostomy feeding, turning, coughing, and deep breathing. (General preoperative care is presented in Chapter 20.)

Postoperative Care.

After surgery for esophageal cancer, most patients have an NG tube in place, and there may be bloody drainage for 8 to 12 hours. The drainage gradually changes to greenish yellow. Assessment of the drainage, maintenance of the tube, and oral and nasal care are nursing responsibilities. The nurse should not reposition or reinsert the NG tube without consulting with the surgeon.

Because of the location of the incision and the general condition of the patient, special emphasis must be placed on prevention of respiratory complications. Turning and deep breathing should be done every 2 hours. Use of an incentive spirometer helps to prevent respiratory complications.

The patient should be positioned in semi-Fowler's or Fowler's position to prevent reflux and aspiration of gastric secretions. When the patient can drink fluids or eat, the upright position should be maintained for at least 2 hours after eating in order to assist the movement of food through the GI tract.

Ambulatory and Home Care.

Many patients require long-term follow-up care after surgery for esophageal cancer. Patients may undergo chemotherapy and

radiation treatment after surgery. Such patients need encouragement and assistance in maintaining adequate nutrition. A permanent feeding gastrostomy may be necessary. Most of these patients have fears and anxieties about a diagnosis of cancer. The nurse should know what the health care provider has told the patient regarding the prognosis and then provide appropriate counselling.

Referral to a home health nurse may be necessary for continued care of the patient (e.g., gastrostomy teaching, follow-up wound care). (See Chapter 13 for management of terminally ill patients, and Chapter 18 for that of patients with cancer.)

Evaluation

The following are expected outcomes for the patient with esophageal cancer:

- The patient will maintain a patent airway.
- The patient will have relief of pain.
- The patient will be able to swallow comfortably.
- The patient will consume adequate nutritional intake.
- The patient will understand the prognosis of the disease.
- The patient will experience the best possible quality of life during disease progression.

Other Esophageal Disorders

Eosinophilic Esophagitis

Eosinophilic esophagitis is characterized by swelling of the esophagus caused by an infiltration of *eosinophils.* Many people with this condition have a personal or family history of other allergic diseases. The most common food triggers are milk, egg, wheat, rye, and beef.

Environmental allergens—such as pollens; moulds; cat, dog, and dust mite allergens—may be involved in the development of eosinophilic esophagitis.

Clinical manifestations include severe heartburn, difficulty swallowing, food impaction in the esophagus, nausea, vomiting, and weight loss. The diagnosis is based on the symptoms and biopsy findings of eosinophils infiltrating the esophageal tissue obtained from endoscopy.

Allergy skin testing helps determine the person's allergens. A trial of avoidance of the foods to which the person's allergy test results are positive is the initial form of treatment for eosinophilic esophagitis. A variety of treatment approaches, including acid suppression, corticosteroids, and endoscopic dilation, can be used alone or in combination.

Corticosteroids are frequently used to treat eosinophilic esophagitis when avoidance of allergic triggers does not relieve symptoms. Corticosteroids may be used orally (prednisone) or as a topical therapy, as with inhaled corticosteroids (e.g., fluticasone [Flovent]). In asthma, for which fluticasone is typically used, corticosteroids are inhaled. In eosinophilic esophagitis, they are swallowed, and this results in the delivery of the drug directly to the esophagus.

Esophageal Diverticula

Esophageal diverticula are saclike outpouchings of one or more layers of the esophagus. They occur in three main areas: (a) above the upper esophageal sphincter *(Zenker's diverticulum),* which is the most common location; (b) near the esophageal midpoint *(traction diverticulum);* and (c) above the LES *(epiphrenic diverticulum)* (Figure 44-6). Pharyngeal pouches (Zenker's diverticula) occur most commonly in older adults (age >70 yr), and typical symptoms include dysphagia, regurgitation, chronic cough, aspiration, and weight loss. Traction diverticulum may not cause signs and symptoms. However, many affected patients report a sour taste in the mouth and halitosis (bad breath) caused by the decomposition of stagnant food in the diverticulum. Complications include

malnutrition, aspiration, and perforation. A diagnosis is easily established by barium studies.

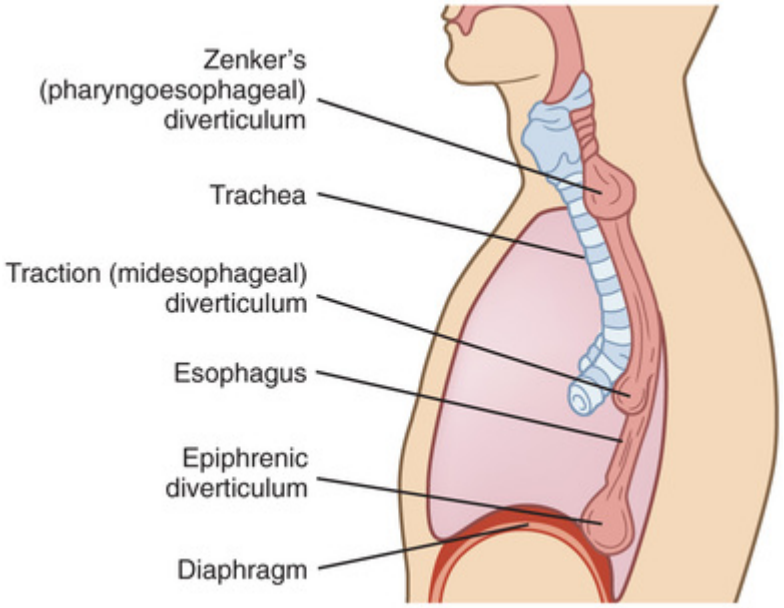

FIGURE 44-6 Possible sites for the occurrence of esophageal diverticula. These hollow outpouchings may occur just above the upper esophageal sphincter (Zenker's, the most common type of diverticulum), near the midpoint of the esophagus (traction), and just above the lower esophageal sphincter (epiphrenic). Source: Modified from Price, S. A., & Wilson, L. M. (2003). *Pathophysiology: Clinical concepts of disease processes* (6th ed.). St. Louis: Mosby.

There is no specific treatment for diverticula. Some patients find they can empty the pocket of food that collects by applying pressure at a point on the neck. The diet may have to be limited to foods that pass more readily (e.g., blenderized foods). Treatment of the diverticulum may be necessary if nutrition becomes disrupted. Treatment is surgical via an endoscopic or external cervical approach and should include a cricopharyngeal myotomy. Open approaches have been associated with significant morbidity because the majority of affected patients are older adults, many of whom have general medical problems.

Esophageal Strictures

The most common cause of esophageal strictures (narrowing) is chronic GERD. The ingestion of strong acids or alkalis, external beam radiation, and surgical anastomosis can also lead to the development of strictures. In addition, trauma such as throat lacerations and gunshot wounds may lead to strictures as a result of scar formation (collagen deposition) from healing. The strictures usually develop over a long time. Strictures can be dilated endoscopically with *bougies* (dilating instruments). Another technique is balloon dilation, which is done under endoscopic guidance and does not necessitate fluoroscopy. Surgical excision with anastomosis is sometimes necessary. The patient may have a temporary or permanent gastrostomy.

Achalasia

Achalasia is the absence of peristalsis of the lower two thirds (smooth muscle) of the esophagus. Pressure in the LES is increased, and relaxation of the LES is incomplete. Obstruction of the esophagus at or near the diaphragm occurs. Food and fluid accumulate in the lower esophagus. The result of this condition is dilation of the lower esophagus (Figure 44-7). The altered peristalsis is a result of impairment of the neurons that innervate the lower esophagus. There is a selective loss of inhibitory neurons, which results in unopposed excitation of the LES. Achalasia affects people of all ages and both sexes. The course of the disease is chronic.

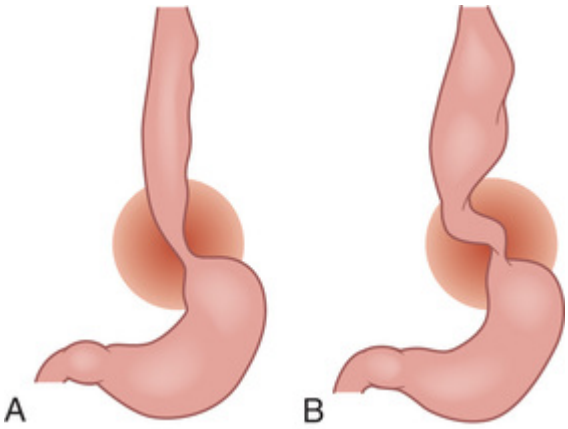

FIGURE 44-7 Esophageal achalasia. **A,** Early stage, showing tapering of lower esophagus. **B,** Advanced stage, showing dilated, tortuous esophagus.

Dysphagia (difficulty swallowing) is the most common symptom and occurs with both liquids and solids. Patients may report a globus sensation. Substernal chest pain (similar to the pain of angina) occurs during or immediately after a meal. *Halitosis* (foul-smelling breath) and the inability to eructate (belch) are other symptoms. Another common symptom is regurgitation of sour-tasting food and liquids, especially when the patient is in a horizontal position. Patients with achalasia also report symptoms (e.g., heartburn) of GERD. Weight loss is typical.

Diagnosis usually involves manometric studies of the lower esophagus and/or endoscopy. The exact cause of achalasia is not known, and so treatment is focused on symptom management. Treatment consists of dilation, surgery, and use of drugs. All these therapies are directed at relieving the stasis caused by the increased LES pressure, the nonrelaxing LES, and the aperistaltic esophagus. Treatment of symptoms consists of a semisoft bland diet, eating slowly and drinking fluid with meals, and sleeping with the head elevated.

Drug therapy is used to manage early achalasia when there is no significant esophageal dilation. Drug therapy is used as a short-term measure and is considered as an alternative only in patients unable to undergo pneumatic dilation or surgery. Endoscopic injection of botulinum toxin (Botox) into the LES can be offered for initial relief of symptoms, but the effects are short term, and symptoms are likely

to recur within 1 year. It works by inhibiting the release of acetylcholine from nerve endings, thereby promoting relaxation of the smooth muscle. This treatment does not carry the risk of perforation that can occur with pneumatic dilation. Repeated injections are required, or the patient must be switched to other therapy. However, there may be subsets of patients, such as older adult patients or those with multiple medical problems, who are poor candidates for more invasive procedures, for whom botulinum toxin injection is the preferred approach. Other classes of drugs used in the management of achalasia include anticholinergics, calcium channel blockers, and long-acting nitrates, which act by relaxing the smooth muscle.

Esophageal dilation *(bougienage)* is an effective treatment measure for many patients. The LES is usually pneumatically dilated with a balloon-tipped dilator passed orally. A variety of different dilators are available for this procedure. All depend on forcible expansion of a balloon in the LES (Figure 44-8). The forceful dilation does not restore normal esophageal motility, but it does provide for emptying of the esophagus into the stomach.

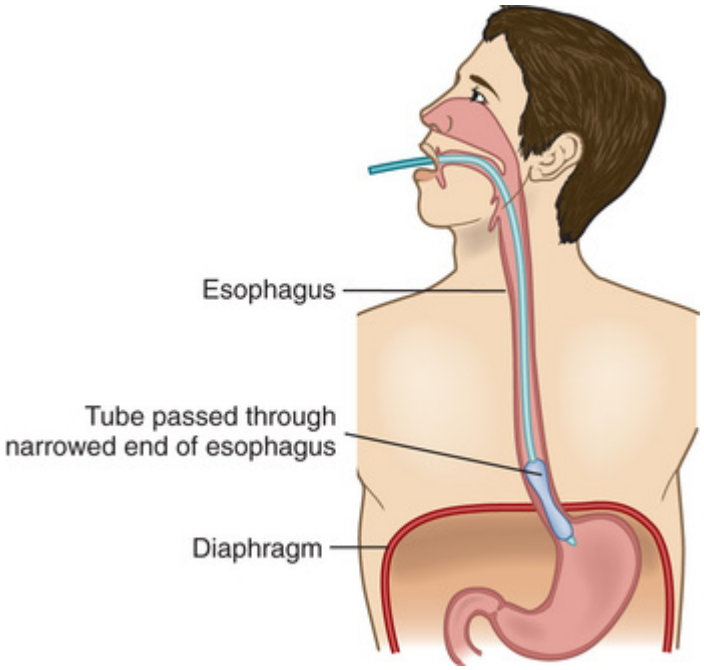

FIGURE 44-8 Pneumatic dilation attempts to treat achalasia by maintaining an adequate lumen and decreasing lower esophageal sphincter tone. Source: Modified from Price, S. A., & Wilson, L. M. (2003). *Pathophysiology: Clinical concepts of disease processes* (6th ed.). St. Louis: Mosby.

Surgical intervention may become necessary. An esophagomyotomy may be performed. In this procedure, the muscle fibres that enclose the narrowed area of the esophagus are divided. This allows the mucosa to pouch out through the division in the muscle layer so that food can be swallowed without obstruction.

A similar procedure is the Heller myotomy (cardiomyotomy), which disrupts the LES and reduces LES pressure. An antireflux procedure is often performed with the myotomy. The Heller myotomy can be performed laparoscopically, which reduces the potential for postoperative complications.

Esophageal Varices

Esophageal varices are veins in the lower portion of the esophagus that become dilated and tortuous as a result of portal hypertension. Esophageal varices are a common complication of liver cirrhosis and are discussed further in Chapter 46.

Disorders of the Stomach and Upper Small Intestine

Gastritis

Types

Gastritis, an inflammation of the gastric mucosa, is one of the most common problems affecting the stomach. Gastritis may be acute or chronic and may be diffuse or localized. Chronic gastritis has been further divided into three subtypes: (a) autoimmune, which involves the body and the fundus of the stomach; (b) diffuse antral, which affects primarily the antrum; and (c) multifocal, which is diffuse throughout the stomach. The causes of gastritis and its relationship to other gastric disorders, such as *Helicobacter pylori* infection and gastric cancer, are the focus of ongoing research.

Etiology and Pathophysiology

Gastritis occurs as the result of a breakdown in the normal gastric mucosal barrier. This mucosal barrier normally protects the stomach tissue from autodigestion by HCl and the proteolytic enzyme pepsin. When the barrier is broken, HCl can diffuse back into the mucosa. The backward diffusion of acid results in tissue edema, disruption of capillary walls with loss of plasma into the gastric lumen, and possibly hemorrhage.

Causes of gastritis are listed in Table 44-13. Drugs such as acetylsalicylic acid (ASA: Aspirin), nonsteroidal anti-inflammatory drugs (NSAIDs), and digitalis have direct irritating effects on the gastric mucosa. In addition, corticosteroids and NSAIDs are known to inhibit the synthesis of prostaglandins that are protective of the gastric mucosa. This leaves the gastric mucosa more susceptible to mucosal damage. NSAID-related gastritis is associated with many of the older drugs, including piroxicam (Pirox), naproxen (Naprosyn), sulindac (Sulin), indomethacin, diclofenac (Voltaren), and ibuprofen (Motrin, Advil). The use of cyclo-oxygenase–2 (COX-2) inhibitors has

been associated with fewer GI adverse effects than the nonselective use of NSAIDs. However, even these agents are associated with an increased risk of upper GI inflammation and bleeding.

TABLE 44-13
CAUSES OF GASTRITIS

Drugs	**Pathophysiological Conditions**
• acetylsalicylic acid (ASA; Aspirin)	• Burns
• Corticosteroid drugs	• Crohn's disease
• Nonsteroidal anti-inflammatory drugs	• Large hiatal hernia
Diet	• Physiological stress
• Alcohol	• Reflux of bile and pancreatic secretions
• Spicy, irritating food	• Renal failure (uremia)
Microorganisms	• Sepsis
• *Helicobacter pylori*	• Shock
• Salmonella organisms	**Other Factors**
• Staphylococcus organisms	• Endoscopic procedures
Environmental Factors	• Nasogastric suction
• Radiation	• Psychological stress
• Smoking	

Dietary indiscretions can also result in acute gastritis. After an alcoholic drinking binge, acute damage to the gastric mucosa can range from local destruction of superficial epithelial cells to desquamation and destruction of the mucosa, with mucosal congestion, edema, and hemorrhage. Prolonged damage induced by repeated alcohol abuse can result in chronic gastritis. Eating large quantities of spicy, irritating foods and metabolic conditions such as uremia can also cause acute gastritis.

An important causative factor in chronic gastritis, in particular in the diffuse antral and multifocal types, is *H. pylori* infection. *H. pylori*–associated gastritis is a common problem in adults, many of whom do not have symptoms of gastritis. It is currently thought that *H. pylori* infection is acquired in childhood. For reasons not clearly understood, *H. pylori* is capable of promoting the breakdown of the gastric mucosal barrier, given certain "triggers" or conditions. Thus, given time, *H. pylori* will eventually have a destructive effect on its host environment. *H. pylori* has been linked to gastric cancer and mucosa-associated lymphoid tissue (MALT) lymphoma of the stomach. (The role of *H. pylori* in ulcer development is discussed in greater detail later in the "Duodenal Ulcers" section.)

Autoimmune atrophic gastritis is a form of chronic gastritis that affects both the fundus and the body of the stomach and is associated with an increased risk of gastric cancer. Approximately 30% of patients with *H. pylori* infection are found to have antigastric antibodies as well. Thus there may be a link between the host's response to the presence of *H. pylori* and the development of autoimmune chronic gastritis.

Other causes of chronic gastritis, although not as common, have been identified. Infections with bacteria, viruses, and fungi, including *Mycobacterium, Cytomegalovirus,* and *Treponema pallidum,* are associated with chronic gastritis. Gastritis can result from reflux of bile salts from the duodenum into the stomach as a result of anatomical changes after surgical procedures such as gastro-duodenostomy and gastro-jejunostomy. Prolonged vomiting may also cause reflux of bile salts. In addition, intense emotional responses and CNS lesions may produce inflammation of the mucosal lining as a result of hypersecretion of HCl or corticosteroids (Cushing's syndrome).

Progressive gastric mucosal atrophy from chronic alterations in the protective mucosal barrier causes the gastric chief and parietal cells to die eventually. With the decrease in the number of acid-secreting parietal cells and atrophy of the gastric mucosa, *hypochlorhydria* (decreased acid secretion) or *achlorhydria* (lack of acid secretion) occurs.

Clinical Manifestations

The symptoms of acute gastritis include anorexia, nausea and vomiting, epigastric tenderness, and a feeling of fullness. Hemorrhage is commonly associated with alcohol abuse and at times may be the only symptom. Acute gastritis is self-limiting, lasting from a few hours to a few days, and the mucosa is expected to heal completely.

The manifestations of chronic gastritis are similar to those described for acute gastritis. Some affected patients have no symptoms directly associated with the gastric lesion. However, when the acid-secreting cells are lost or do not function as a result of

atrophy, the source of *intrinsic factor* is also lost. The loss of intrinsic factor, a substance secreted by the gastric mucosa that is essential for the absorption of cobalamin (vitamin B_{12}, which is essential for the growth and maturation of RBCs) in the terminal ileum, ultimately results in cobalamin deficiency. Over time, the body's storage of cobalamin in the liver is depleted, and a deficiency state exists. Lack of this important vitamin results in the development of anemia and neurological complications. (Cobalamin deficiency anemia is discussed in Chapter 33.)

Diagnostic Studies

Diagnosis of acute gastritis is most often based on a history of drug and alcohol use. The diagnosis of chronic gastritis may be delayed or completely missed because the symptoms are nonspecific. Endoscopic examination with biopsy is necessary to obtain a definitive diagnosis. Breath, urine, serum, and gastric tissue biopsy tests are available for the determination of *H. pylori.* These tests are described later in this chapter in the "Diagnostic Studies" section under "Peptic Ulcer Disease." Radiological studies are not helpful because the superficial mucosa is generally involved, and changes are not clearly visible on radiographs. A complete blood cell count (CBC) may demonstrate the presence of anemia that results from blood loss or lack of intrinsic factor. Stools are tested for the presence of occult blood. A gastric analysis, although currently not used as much, demonstrates the amount of HCl present; achlorhydria is a common sign of severe atrophic gastritis. Serum tests for antibodies to parietal cells and intrinsic factor may be performed. Tissue biopsy with cytological examination is necessary to rule out gastric carcinoma.

Nursing and Collaborative Management Gastritis

Acute Gastritis

Eliminating the cause and preventing or avoiding it in the future are generally all that is needed to treat acute gastritis. The plan of care is supportive and similar to that described for nausea and vomiting. If vomiting accompanies acute gastritis, bed rest, NPO status, and IV fluids may be prescribed. Dehydration can occur rapidly in patients with acute gastritis with vomiting. Fluids and electrolytes lost through vomiting and occasionally diarrhea are replaced. Antiemetics are given for nausea and vomiting (see Table 44-1). In severe cases of acute gastritis, an NG tube may be used, either for lavage of the precipitating agent from the stomach or in conjunction with suction to keep the stomach empty and free of noxious stimuli. Clear liquids are resumed when acute symptoms have subsided, with gradual reintroduction of solid, bland foods.

If hemorrhage is considered likely, vital signs must be checked frequently and the vomitus tested for blood. All of the management strategies discussed later in the "Upper Gastro-intestinal Bleeding" section also apply to severe gastritis.

Drug therapy is focused on reducing irritation of the gastric mucosa and providing relief of symptoms. Antacids are beneficial in the relief of abdominal discomfort by raising intragastric pH to above 6. H_2R blockers or PPIs may be used to reduce gastric HCl secretion. The nurse must have knowledge of the action and the therapeutic effects of PPIs and H_2R blockers to teach the patient and to monitor the effects of the drugs.

Chronic Gastritis

The treatment of chronic gastritis focuses on evaluating and eliminating the specific cause (e.g., cessation of alcohol intake, abstinence from drugs, *H. pylori* eradication). Currently, antibiotic and antisecretory agent combinations are used to eradicate infection with *H. pylori* (Table 44-14). For patients with pernicious anemia, oral

or parenteral administration of cobalamin is needed (see Chapter 33). Discussion of the continued need for this essential vitamin must be included in the plan of care.

TABLE 44-14
DRUG THERAPY
Helicobacter pylori Infection

Treatment	Duration	Eradication Rate
Triple-Drug Therapy (Recommended as First-Line Therapy)		
Proton pump inhibitor* Amoxicillin Clarithromycin (Biaxin)	7–14 days	>70%–85%
Quadruple Therapy		
Proton pump inhibitor* Bismuth subsalicylate Tetracycline Metronidazole (Flagyl)	10–14 days	85%

*See Table 44-10.

The patient undergoing treatment for chronic gastritis may have to adapt to many lifestyle changes and adhere strictly to a drug regimen. A nonirritating diet consisting of six small meals a day and the use of an antacid after meals may help provide relief from symptoms. Smoking is contraindicated. An interdisciplinary team approach in which the physician, the nurse, the dietitian, and the pharmacist provide consistent information and support may increase the patient's success in making these alterations. Because the incidence of gastric cancer is higher among patients who have a history of chronic gastritis, especially atrophic gastritis, close medical follow-up should be emphasized.

Gastric Cancer

Gastric cancer (also called *stomach cancer*) is an adenocarcinoma of the stomach wall (Figure 44-9). It is the second most frequent cause of cancer death worldwide (Thomson & Young, 2011). Although less common in Canada, it was estimated that 3 500 new gastric cancer cases would be diagnosed in 2017 (Canadian Cancer Society, 2017). Gastric cancer is more prevalent in men of the lower socioeconomic

class, primarily those living in urban areas. Gastric cancer is typically at an advanced stage when diagnosed and is not usually amenable to surgical resection. The disease is confined to the stomach in only 10% to 20% of affected patients. The rate of 5-year survival is 25%.

FIGURE 44-9 Gastric cancer. Gross photograph shows an ill-defined, excavated central ulcer surrounded by irregular, heaped-up borders. Source: Kumar, V., Abbas, A. K., Fausto, N., et al. (2010). *Robbins and Cotran pathologic basis of disease* (8th ed.). Philadelphia: Saunders.

Etiology and Pathophysiology

Many factors have been implicated in the development of gastric cancer: *H. pylori* infection; smoking; family history of gastric cancer; inherited conditions (e.g., hereditary diffuse gastric cancer); certain stomach conditions, including gastritis; previous stomach surgery; infection with the Epstein-Barr virus; exposure to ionizing radiation; and type A blood (Canadian Cancer Society, 2015e).

Gastric carcinogenesis probably begins with a nonspecific mucosal injury as a result of aging, autoimmunity, or repeated exposure to irritants such as bile, anti-inflammatory agents, or alcohol. Nutritional or other undetermined genetic deficiencies may impede mucosal repair, which results in chronic gastritis and subsequent proliferation of *H. pylori.* Infection with *H. pylori,* especially at an

early age, is considered a definite risk factor for gastric cancer. It is possible that *H. pylori* and resulting metabolic changes can induce a sequence of transitions from dysplasia to carcinoma in situ. Individuals with MALT lymphoma are at higher risk for gastric cancer.

Other predisposing factors associated with a high incidence of gastric cancer are atrophic gastritis, pernicious anemia, adenomatous polyps, hyperplastic polyps, and achlorhydria. The relationship between chronic gastric ulcers and the development of gastric cancer is still controversial. Malignant transformation of a benign chronic ulcer does occur but accounts for fewer than 5% of all gastric cancers. It is known that people with achlorhydria or pernicious anemia are more likely to develop gastric cancer than are people with normal gastric acid production.

Gastric cancers often spread to adjacent organs before any distressing symptoms occur. The tumour may grow to large dimensions without obstructing the lumen of the stomach simply because the lumen itself is so large. The interval from onset of symptoms to consultation with a health care provider may be as long as 6 months. This long delay is largely attributed to the vague, intermittent abdominal distress experienced by the patient. Unfortunately, these symptoms are nonspecific; most healthy persons at one time or another experience them as a result of dietary indiscretions, nervous tension, and anxiety.

Gastric cancer can occur in any portion of the stomach. Tumours located at the cardia and the fundus are associated with a poor prognosis. These tumours typically infiltrate rapidly to the surrounding tissue, regional lymph nodes, and liver. Patients with tumour growth along the lesser curvature have a better survival rate. Adenocarcinomas account for more than 95% of the cancers, and sarcomas (comprising lymphomas and leiomyomas) make up the rest.

The tumour growth is insidious and follows a pattern of continuous infiltration. Gastric cancer may spread by direct extension along the mucosal surface and infiltrate through the stomach wall. The rich lymphatic plexuses in the stomach facilitate

distant metastasis. Seeding of tumour cells into the peritoneal cavity may occur late in the course of the disease.

Clinical Manifestations

The clinical manifestations exhibited by persons with gastric cancer can be categorized by signs and symptoms of anemia, PUD, or indigestion. Anemia is a common occurrence with gastric cancer. It is caused by chronic blood loss that occurs as the lesion erodes through the mucosa or as a direct result of pernicious anemia, which develops when intrinsic factor is lost. The affected person appears pale and weak and reports fatigue, weakness, dizziness, and in extreme cases, shortness of breath. The stool specimen may be positive for occult blood.

The symptoms of gastric cancer are sometimes identical to those of PUD. The pain and discomfort may be alleviated by belching and by the use of antacids, antisecretory agents, and diet modifications. Manifestations related to indigestion include vague feeling of epigastric fullness with feelings of early satiety after meals. Weight loss, dysphagia, and constipation frequently accompany epigastric distress. When nausea, vomiting, and hematemesis occur, they may indicate gastric outlet obstruction or may be a warning of impending hemorrhage.

With more advanced disease, the physical examination may reveal that the patient is pale and lethargic if anemia is present. When the appetite has been poor and weight loss has been considerable, the patient may appear cachectic. A mass may be detected beneath the abdominal wall and is seen to move with each inspiration. On palpation, the mass may be felt in the epigastrium. Masses that are predominantly in the antrum of the stomach are generally found to the left of the midline. Masses located to the right of midline usually tend to be metastases to the liver or indicate involvement of the perigastric lymph nodes. Supraclavicular lymph nodes that are hard and enlarged and located on the left side are suggestive of metastasis via the thoracic duct from the stomach lesion. The presence of ascites is a poor prognostic sign.

Diagnostic Studies

The diagnostic studies for gastric cancer are presented in Table 44-15.

TABLE 44-15

COLLABORATIVE CARE
Gastric Cancer

Diagnostic Studies	Collaborative Therapy
• History and physical examination • Alpha-fetoprotein measurement • Carbohydrate antigen (CA-) 19-9, CA-125, CA 72-4 assessments • Carcinoembryonic antigen (CEA) assessment • Complete blood cell count • Endoscopic ultrasonography • Endoscopy and biopsy • Exfoliative cytological study • Liver enzyme measurements • Serum amylase measurement • Stool examination • Tumour marker assessment • Upper GI barium study • Urinalysis	***Surgical Therapy*** • Subtotal gastrectomy: Billroth I or II procedure • Total gastrectomy with esophago-jejunostomy ***Adjuvant Therapy*** • Radiation therapy • Chemotherapy • Combination radiation therapy and chemotherapy

GI, gastro-intestinal.

Endoscopic examination of the stomach remains the best diagnostic tool. Lesions that go undetected on the radiograph can be viewed more easily and a biopsy performed when endoscopy is used. The stomach can be distended with air during the procedure so that the mucosal folds can be stretched. Fixation of the mucosa is indicative of malignancy.

Upper GI barium studies may demonstrate alterations in gastric contractility and emptying but do not always reveal small lesions of the cardia and fundus.

Blood chemistry studies assist in the determination of anemia and its severity. Elevations in liver enzymes and serum amylase levels may indicate liver and pancreatic involvement. Stool examination provides evidence of occult or gross bleeding.

Several tumour markers are often present in patients with gastric cancer (see Table 44-15). Serum tests for these markers are commonly performed before surgery for this disease. Serum markers are not used as the only diagnostic tools for gastric cancer because

elevations may be related to other factors such as smoking and the presence of benign lesions. (Carcinoembryonic antigen and other tumour markers are discussed in Chapter 18.)

Collaborative Care

When the diagnosis of gastric cancer has been confirmed, the treatment of choice is surgical removal of the tumour. The preoperative management of the patient with gastric cancer focuses on the correction of nutritional deficits, treatment of anemia, and replacement of blood volume.

Transfusions of packed RBCs correct the anemia. If a gastric lesion has been located at or near the pylorus and is causing gastric outlet obstruction, gastric decompression may be necessary before surgery. When the tumour has extended into the transverse colon, and if partial colon resection is also required, special preparation of the bowel is necessary. This preparation may include a low-residue diet, enemas to cleanse the bowel, and the use of antibiotics to reduce the intestinal bacteria. Correction of malnutrition is important if surgery is planned. Malnutrition is associated with increased rates of postoperative complications and mortality.

Surgical Therapy.

The surgical intervention used in the treatment of gastric cancer may be the same surgical procedures used for PUD. The location and the extent of the lesion, the patient's physical condition, and the preference of the surgeon determine the specific surgery employed. When metastasis is widespread at the time of diagnosis, surgical intervention may be only palliative.

The surgical aim is to remove the tumour by resecting as much of the stomach as necessary and a margin of normal tissue. When the lesion is located in the cardia or high in the fundus, a total gastrectomy with esophago-jejunostomy is performed. This combination of procedures involves anastomosis of the lower end of the esophagus to the jejunum (Figure 44-10). Lesions located in the antrum or the pyloric region are generally treated in either a Billroth I or a Billroth II procedure. When the tumour has metastasized to

adjacent organs, such as the spleen, ovaries, or bowel, the surgical procedures must be modified and extended as necessary.

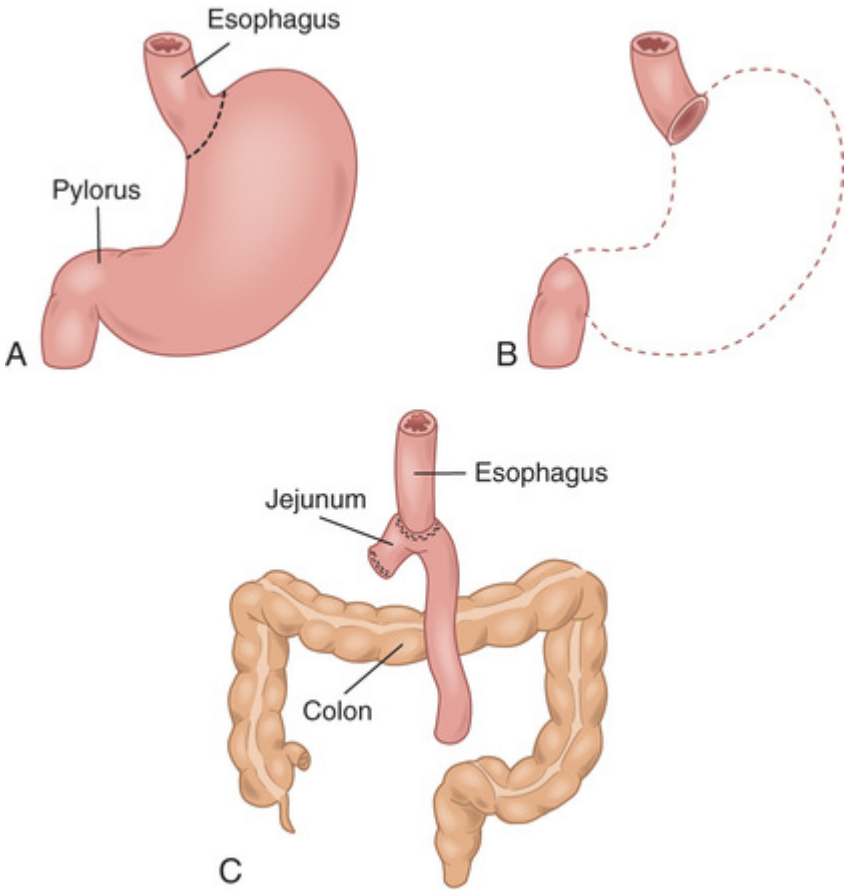

FIGURE 44-10 Total gastrectomy for gastric cancer. **A,** Normal anatomical structure of the stomach. **B,** Removal of the stomach (total gastrectomy). **C,** Anastomosis of the esophagus with the jejunum (esophago-jejunostomy).

The chance of a complete cure by surgical means is decreased considerably when the lymph nodes are involved. Survival is shortened when organs adjacent to the stomach show evidence of invasion at the time of surgery.

Adjuvant Therapy.

Surgery is the only definitive means of achieving a cure. However, when the patient cannot physically withstand a surgical procedure or when surgical cure is not feasible, radiation therapy or

chemotherapy alone or in combination may be used. Neither radiation therapy nor chemotherapeutic agents have been very successful when used as the primary mode of treatment. Because the radiosensitivity of gastric cancers is low, radiation therapy has proved to be of little value. When it is used as a palliative measure, the tumour mass can be decreased, with temporary relief of the cardia or pyloric obstruction.

The combination of chemotherapy and radiation therapy is now being used for patients who are at high risk for disease recurrence after surgery. Single-agent chemotherapy for gastric cancer has traditionally been of little value. Agents that have been identified as having some effect on gastric cancer are a combination of 5-fluorouracil and cisplatin (BC Cancer Agency, 2012). The combination of radiation therapy with chemotherapy involving 5-fluorouracil and leucovorin after surgical resection increases survival. Additional therapies, including intraperitoneal administration of chemotherapeutic agents, are undergoing evaluation. The role of biological therapy is still under investigation for use in gastric cancer. (These therapies are discussed in Chapter 18.)

Nursing Management Gastric Cancer

Nursing Assessment

The assessment of a person with possible gastric cancer is similar to that done for PUD (see Table 44-25). Important information that should be obtained from the patient and the family include data from a nutritional assessment, a psychosocial history, the patient's perceptions of the health problem and the need for hospitalization, and the physical examination of the patient.

The nutritional assessment must elicit information regarding appetite and changes in eating patterns over the previous 6 months. It is necessary to determine the patient's normal weight and any changes that may have occurred in the preceding few months. Unexplained weight loss is common in many types of cancer before diagnosis. A history of vague symptoms of dyspepsia, early satiety, feeling full after consuming even a small amount of food, or symptoms of gas pain should help the nurse differentiate these typical gastric cancer symptoms from those of peptic ulcer. The nurse should determine whether pain is present, where and when it occurs, and how it is relieved. When the pain has been controlled with ingestion of foods, fluids, or antacids for a time but now continues or worsens regardless of interventions, gastric cancer may be the underlying cause.

Psychosocial and demographic data include the patient's age, present or previous occupation, and financial status. Gastric cancer can occur at any age, but the risk increases with age. The majority of new cases occur in people older than 65. A family history of cancer, especially gastric cancer, confers a greater than normal risk.

It is important to determine the patient's personal perception of the health problem and method of coping with hospitalization, diagnostic tests, and procedures. The possibility of a diagnosis of cancer and a treatment regimen that may include surgery, chemotherapy, or radiation treatment is predictive of a prolonged stressful period and a possibly fatal outcome. Therefore, it is important for the nurse to support the patient and the family if tests

result in an unfavourable diagnosis and complex treatment interventions are planned. If surgery is probable, the nurse should assess what the patient expects from surgery (cure or palliation) and how that patient has responded to any previous surgical procedures.

A complete physical examination reveals the patient's current functional abilities, the presence of other health problems, and an estimate of how well the patient may respond to therapy. Cachexia may be evident if the nutritional state has been compromised for an extended time. A malnourished patient does not respond well to chemotherapy or radiation therapy and is a poor candidate for surgery.

Nursing Diagnoses

Nursing diagnoses for the patient with gastric cancer include, but are not limited to, the following:

- *Imbalanced nutrition: less than body requirements* related to *insufficient dietary intake* (inability to ingest, digest, or absorb nutrients)
- *Acute pain* related to *biological injury agent* (underlying disease process)
- *Anxiety* related to *threat to current status, threat of death*

Planning

The overall goals are that the patient with gastric cancer will (a) experience minimal discomfort, (b) achieve optimal nutritional status, and (c) maintain a degree of spiritual and psychological well-being appropriate to the disease stage.

Nursing Implementation

Health Promotion.

The nursing role in the early detection of cancer of the stomach is focused primarily on identification of the patient at risk because of specific disorders such as pernicious anemia and achlorhydria. The nurse should be aware of symptoms associated with gastric cancer, its pattern of spread, and the significant findings on physical examination. The nurse should understand that the cure rate is often quite dismal because symptoms do not arise until late in the course of the disease process, are vague, and often mimic other conditions, such as PUD.

The nurse must be alert to problems suggesting gastric cancer, such as poor appetite, weight loss, fatigue, and persistent gastric distress. If any of these manifestations are present, medical attention should be obtained and the necessary diagnostic tests performed.

In addition, any patient with a positive family history of gastric cancer should be encouraged to undergo diagnostic evaluation if manifestations of anemia, peptic ulcer, or vague epigastric distress are present. It is important that the nurse recognize the possibility of gastric cancer in a patient in whom 3 weeks of prescribed therapy for peptic ulcer fails to provide relief.

Acute Intervention

Preoperative Care.

When the diagnostic tests confirm the presence of a malignancy, patients and their families generally react with shock, disbelief, and depression, regardless of how thoroughly they may have been prepared for this possible outcome. Throughout this period, the nurse must give emotional and physical support, provide information, clarify test results, and maintain a positive attitude with respect to the patient's immediate recovery and long-term survival.

On admission to hospital, the patient may be in poor physical condition. Surgery may have to be delayed while the patient becomes more physically able to withstand the strain of a major operation. A positive nutritional state enhances wound healing, as well as the ability to withstand infection and other possible postoperative complications. Often, the patient is better able to tolerate several small meals a day than three regular meals. The diet

may be supplemented by a variety of commercial liquid supplements (see Chapter 42) and vitamins. The nurse is challenged to find innovative ways of persuading the patient to eat when lack of appetite and state of mind make eating difficult and unrewarding. Enlisting the family's assistance with meals and encouraging intake may be beneficial. If the patient is unable to ingest oral feedings, it may be necessary to provide for nutritional needs with tube feedings or parenteral nutrition.

If needed, blood replacement and fluid volume restoration may be carried out in the preoperative period. Because anemia is usually present, packed RBCs may be administered. Close observation for reactions to the transfusions is important. The hemoglobin and hematocrit levels provide information on the progress of therapy.

The preoperative teaching plan before gastric surgery for cancer is much the same as that for peptic ulcer surgery (see the previous "Collaborative Therapy: Surgical Therapy for Peptic Ulcer Disease" section under "Peptic Ulcer Disease").

Postoperative Care.

Postoperative care of the patient with gastric cancer is similar to that after a Billroth I or II procedure (see the previous "Collaborative Therapy: Surgical Therapy for Peptic Ulcer Disease" section under "Peptic Ulcer Disease"). When the surgical intervention has involved a total gastrectomy, the plan of care is somewhat different. The operation performed usually requires resection of some of the lower esophagus along with the removal of the entire stomach and anastomosis of the esophagus to the jejunum. The chest cavity must be entered, and drainage is accomplished by the insertion of chest tubes. (Chest surgery and drainage tubes are discussed in Chapter 30.) After total gastrectomy, the NG tube does not drain a large quantity of secretions because removal of the stomach has eliminated the reservoir capacity. The NG tube is removed after several days, when intestinal peristalsis has resumed. Small amounts of clear fluid may then be started. The patient requires close observation for signs of leakage of the fluids at the anastomosis, as evidenced by an elevation in body temperature and increasing

dyspnea. When fluids are well tolerated without distress, the amount may be increased and some solid foods added.

As a consequence of a total gastrectomy, patients experience the symptoms of dumping syndrome. Unfortunately, weight loss is very common among such patients, and poor nutritional intake often contributes. Postoperative wound healing may be impaired because of inadequate dietary intake. This necessitates parenteral or oral replacement of vitamins C, D, and K; the B-complex vitamins; and cobalamin. Because these vitamins (with the exception of cobalamin) are absorbed primarily in the upper part of the small intestine, they must be replaced because the duodenum has been bypassed in the surgical procedure.

Postoperative care after a Billroth I or II operative procedure should be the same as that after peptic ulcer surgery. Patients who have undergone these procedures are also subject to the same type of postgastrectomy complications such as dumping syndrome and postprandial hypoglycemia.

Patients with advanced malignant disease can be offered only palliative treatment. When chemotherapy is prescribed, the nurse must have current information regarding the action and adverse effects of the drugs. Patients should be made aware of the potential benefits and hazards that can result from the chemotherapy. Radiation therapy can be used as an adjuvant to surgery or for palliation. In general, patients are quite fearful of radiation therapy and may have many misconceptions regarding its value and dangers. To reassure the patient and ensure completion of the designated number of treatments, the nurse must provide detailed instruction. Because most therapy is completed on an outpatient basis, the nurse should assess each patient's knowledge of radiation therapy, care of the skin, the need for good nutrition and fluid intake during therapy, and the appropriate use of antiemetic drugs. (Specific care of patients receiving chemotherapy and radiation therapy is discussed in Chapter 18 and in NCP 18-1 and NCP 18-2, available on the Evolve website.)

Ambulatory and Home Care.

Before the patient is discharged, the need for teaching should be reviewed. Most dietary measures useful after peptic ulcer surgery are applicable after surgery for gastric cancer. Plans should be made for the relief of pain, including comfort measures and the judicious use of analgesics. Wound care, if needed, must be taught to the primary caregiver in the home situation. Dressings, special equipment, or special services may be required for the patient's continued care at home. A list of community agencies that are available for assistance can be provided before the patient goes home. The services of the Canadian Cancer Society are especially helpful.

When chemotherapy or radiation therapy is to be continued after discharge, a referral for a home health nurse may be beneficial. The home health nurse can assist with recovery, determine the degree of patient adherence, and be a sympathetic health care provider with whom the patient can consult.

Long-term follow-up must be stressed. The patient must be encouraged to comply with the prescribed dietary and drug regimens, to keep appointments for chemotherapy administration or radiation treatments, and to keep the physician informed of changes in physical condition. (Long-term management of patients with cancer is discussed in Chapter 18.)

Evaluation

Expected outcomes are the following for the patient with gastric cancer:

- The patient will experience no or minimal discomfort, pain, or nausea.
- The patient will achieve optimal nutritional status.
- The patient will maintain a degree of psychological well-being appropriate to the disease stage.

Upper Gastro-intestinal Bleeding

Upper GI bleeding represents a significant clinical and societal burden because of the associated morbidity, mortality, and financial implications. Despite advances in critical care, hemodynamic monitoring, and endoscopy, there has been little change in the mortality rate for upper GI bleeding, which has remained approximately 6% to 10% since the 1960s. This is partly because the incidence of upper GI bleeding is higher among older adults, men, and individuals in lower socioeconomic groups (Kurian & Lobo, 2015).

Etiology and Pathophysiology

Although the most serious loss of blood from the upper GI tract is characterized by a sudden onset, insidious occult bleeding can also be a major problem. The severity of bleeding depends on whether the origin is venous, capillary, or arterial. (Types of upper GI bleeding are listed in Table 44-16.) Bleeding from an arterial source is profuse, and the blood is bright red. The bright red colour indicates that the blood has not been in contact with the stomach's acid secretions. In contrast, “coffee grounds” vomitus reveals that the blood and other contents have been in the stomach for some time and have been changed by contact with gastric secretions. A massive upper GI hemorrhage is generally defined as a loss of more than 1 500 mL of blood or of 25% of intravascular blood volume. *Melena* (black, tarry stools) indicates slow bleeding from an upper GI source. The longer the passage of blood through the intestines, the darker the colour of the stool as a result of the degradation of hemoglobin and the release of iron.

TABLE 44-16
TYPES OF UPPER GASTRO-INTESTINAL BLEEDING

Type	Clinical Manifestations
Obvious bleeding	
• Hematemesis	Bloody vomitus appearing as fresh, bright red blood or "coffee grounds" appearance (dark, grainy digested blood)
• Melena	Black, tarry stools (often foul smelling) caused by digestion of blood in the gastro-intestinal tract; the discoloration is caused by the presence of iron
Occult bleeding	Small amounts of blood in gastric secretions, vomitus, or stools not apparent by appearance; detectable by guaiac test

Discovering the cause of the bleeding is not always an easy task. A variety of areas in the GI tract may be involved, and there may be many different reasons for the blood loss. Table 44-17 lists the common causes of bleeding. Although systemic diseases (e.g., leukemia, blood dyscrasias) that interfere with normal blood clotting must be considered whenever upper GI bleeding occurs, the most common sites are the esophagus, stomach, and duodenum.

TABLE 44-17
COMMON CAUSES OF UPPER GASTRO-INTESTINAL BLEEDING

Drug-Induced	**Stomach and Duodenum**
• Corticosteroids	• Gastric cancer
• Nonsteroidal anti-inflammatory drugs	• Hemorrhagic gastritis
• Salicylates	• Peptic ulcer disease
Esophagus	• Polyps
• Esophageal varices	• Stress-related mucosal disease
• Esophagitis	**Systemic Diseases**
• Mallory–Weiss tear	• Blood dyscrasias (e.g., leukemia, aplastic anemia)
	• Liver failure (cirrhosis)
	• Renal failure (uremia)

Esophageal Origin.

Bleeding from an esophageal source is probably the result of chronic esophagitis, a Mallory–Weiss tear, or esophageal varices. Chronic esophagitis can be caused by the ingestion of chemicals, including drugs irritating to the mucosa. Alcohol and smoking are known

irritants of the esophageal mucosa. GERD with or without a hiatal hernia can lead to chronic irritation and erosion. A **Mallory–Weiss tear** is usually caused by severe retching and vomiting. This tear occurs in the esophageal mucosa at the junction of the esophagus and the stomach and results in severe bleeding.

Esophageal varices are usually secondary to cirrhosis of the liver. Anything that may increase the pressure (e.g., coughing, sneezing, trauma) or cause mechanical irritation (e.g., vomiting, irritation, erosion) may result in sudden, massive bleeding. (Esophageal varices are discussed in Chapter 46.)

Stomach and Duodenal Origin.

Bleeding ulcers account for 36% of cases of upper GI bleeding (Mitra, Marrow, & Nayar, 2012). Erosion of a blood vessel by an ulcer located in the stomach or duodenum must always be considered as a possible cause of upper GI bleeding. A gastric ulcer may penetrate the left gastric artery, and a duodenal ulcer may penetrate the superior pancreatico-duodenal artery.

Acute gastritis produced by ingestion of drugs or alcohol or the reflux of bile from the small intestine can result in bleeding. Drugs, either prescribed by the health care provider or OTC, are a major cause of upper GI bleeding. For example, a patient who regularly takes ASA (Aspirin) or ASA-containing compounds may be at risk for bleeding episodes. ASA (Aspirin), NSAIDs (e.g., ibuprofen), and corticosteroids can cause irritation and disruption of the gastric mucosal barrier. ASA-containing products are sold without prescriptions as OTC drugs. A thorough history of all commonly used drugs is therefore necessary whenever upper GI bleeding is suspected.

Stress-related mucosal disease (SRMD), also called *physiological stress ulcers,* occurs in patients who have sustained severe burns or trauma or had major surgery. In SRMD, there is either diffuse superficial mucosal injury or discrete deeper ulcers in the fundus and body portions of the stomach (Figure 44-11). Patients with coagulopathy and those who experience respiratory failure that necessitates mechanical ventilation for more than 48 hours are at highest risk (Pilkington, Wagstaff, & Greenwood, 2012).

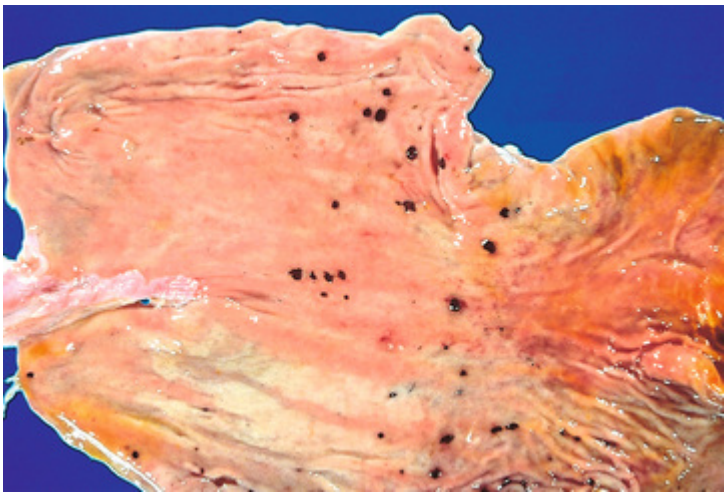

FIGURE 44-11 Multiple stress ulcers of the stomach, highlighted by dark digested blood on their surfaces. Source: Kumar, V., Abbas, A. K., & Fausto, N. (2005). *Robbins and Cotran pathologic basis of disease* (7th ed.). Philadelphia: Saunders.

Emergency Assessment and Management

In approximately 80% to 85% of patients who have massive upper GI hemorrhage, the bleeding stops spontaneously; however, the cause must be identified and treatment initiated immediately. Although a complete history of events leading to the bleeding episode is important in discovering the cause of the blood loss, its documentation should be deferred until emergency care has been initiated. The immediate physical examination must include a systematic evaluation of the patient's condition with emphasis on blood pressure, rate and character of pulse, peripheral perfusion with capillary refill, and observation for the presence or absence of neck vein distension. Vital signs should be monitored every 15 to 30 minutes. Signs and symptoms of shock must be evaluated, and treatment should be started as soon as possible if it occurs (see Chapter 69). The patient's respiratory status is carefully assessed, along with a thorough abdominal examination. The presence or absence of bowel sounds should be assessed and noted. A tense, rigid, boardlike abdomen may indicate the presence of a perforation and peritonitis.

Once the immediate interventions have begun, the patient or the family should answer the following questions: Does the patient have a history of previous bleeding episodes? Has weight loss been a recent problem? Has the patient received blood transfusions in the past, and were there any transfusion reactions? Does the patient have a religious preference that prohibits the use of blood or blood products? Does the patient have any other illnesses that may contribute to bleeding or interfere with treatment (e.g., heart failure, diabetes mellitus)?

Laboratory studies are ordered, including a CBC; prothrombin time measurement; measurements of blood urea nitrogen (BUN), serum electrolytes, blood glucose, liver enzymes, and arterial blood gases; and a type and crossmatch for possible blood transfusions. Vomitus and stools can be tested for the presence of gross and occult blood. A urinalysis provides information on the presence of blood in the urine, and the specific gravity gives an immediate indication of the patient's hydration status.

Intravenous lines, preferably two, with a 16- or 18-gauge needle, should be established for fluid and blood replacement. The type and amount of fluids infused is dictated by physical and laboratory findings. It is generally best to begin with an isotonic crystalloid solution (e.g., lactated Ringer's solution). Whole blood, packed RBCs, and fresh-frozen plasma may be used to replace lost volume in massive hemorrhage. Because of the potential for fluid overload and immunological reactions, packed RBCs are often preferred over whole blood. (The use of blood transfusions is discussed in Chapter 33.) The hemoglobin and hematocrit values are not of immediate assistance in estimating the degree of blood loss, but they provide a baseline for guiding further treatment. The initial hematocrit may be normal and may not reflect the loss until 4 to 6 hours after fluid replacement has taken place because initially the loss of plasma and RBCs is equal. When upper GI bleeding is less profuse, infusion of isotonic saline solution followed by packed RBCs helps restore the hematocrit more quickly and does not create complications related to fluid volume overload. The use of supplemental oxygen may help increase blood oxygen saturation.

For most patients with profuse bleeding, an indwelling urinary catheter is inserted so that urine volume can be accurately assessed every hour. A central venous pressure line may be inserted so that the patient's fluid volume status can be monitored easily. Empirical PPI therapy with high-dose bolus and subsequent infusion is often started before endoscopy.

Diagnostic Studies

Endoscopic procedures allow physicians to identify sources of GI bleeding through direct visualization. For example, the site of bleeding from severe gastritis, an esophageal varix, a gastric or duodenal ulcer, or angiodysplasia can be determined easily and treated effectively. The endoscope is designed to facilitate the passing of various instruments, sclerosing drugs, and probes to control and stop GI bleeding. In addition to using endoscopic procedures to stop bleeding, these procedures also allow direct visualization of the bleeding site. Angiography is used in diagnosing upper GI bleeding only when endoscopy cannot be done. It is an invasive procedure for which preparation and setup time are required, and it may not be appropriate for a patient at high risk for complications whose condition is unstable. In this procedure, a catheter is placed into the left gastric or superior mesenteric artery and advanced until the site of bleeding is discovered.

Collaborative Care

Endoscopic Therapy.

Endoscopic hemostasis is used to identify and stop bleeding. Endoscopy performed within the first 24 hours of bleeding is important for diagnosis and determining the need for surgical or radiologic intervention.

The goal of endoscopic hemostasis is coagulation or thrombosis in the bleeding vessel. Several techniques are used, including (a) thermal (heat) probe, (b) multipolar and bipolar electrocoagulation probe, (c) argon plasma coagulation (APC), and (d) neodymium:yttrium–aluminum–garnet (Nd:YAG) laser. Multipolar

electrocoagulation and thermal probe are the two most commonly used procedures. The heat probe causes tissue coagulation by directly applying a heating element to the bleeding site. Argon plasma coagulation is a noncontact method in which monopolar current is delivered to tissue. For variceal bleeding, other strategies include variceal ligation, injection sclerotherapy, and balloon tamponade.

Surgical Therapy.

Surgical intervention is indicated when bleeding continues despite the therapy provided and when the site of the bleeding has been identified. The site of the hemorrhage determines the choice of operation. In addition, the surgeon must consider the age of the patient because mortality rates are considerably higher among patients older than 60 years.

Drug Therapy.

During the acute phase, drugs are used to decrease bleeding, decrease HCl secretion, and neutralize the HCl that is present. Drug therapy to decrease bleeding is administered during endoscopy. Injection therapy with epinephrine (1 : 10 000 dilution) is effective for acute hemostasis. These agents produce tissue edema and, ultimately, pressure on the source of bleeding. To prevent rebleeding, injection therapy is often combined with other therapies (e.g., thermocoagulation or laser treatment). A sclerosant (an agent that produces inflammation and results in fibrosis of the tissues) such as ethanolamine may be used, especially if the cause of bleeding is esophageal varices.

Antidiuretic hormone, a chemical released from the posterior pituitary, can be used for the management of variceal bleeding because it promotes vasoconstriction. It is used to treat upper GI bleeding in patients who do not respond to other therapies and are poor candidates for surgery. It is administered systemically through a vein or intra-arterially at the local site of actual bleeding. Adverse effects of intravenously administered vasopressin include decreased myocardial contractility and decreased coronary blood flow. The patient undergoing vasopressin therapy must be closely monitored

for its myocardial, visceral, and peripheral ischemic adverse effects. Vasopressin should be used with caution in patients with a known history of vascular disease.

Efforts are made to reduce acid secretion because the acidic environment can alter platelet function and interfere with clot stabilization. H_2R blockers (e.g., ranitidine [Zantac]) or PPIs (e.g., pantoprazole [Pantoloc]) are administered intravenously to decrease acid secretion. Table 44-18 reviews the mechanism of action of H_2R blockers and PPIs. Although these drugs have no proven ability to control active bleeding, they have become part of standard treatment protocols.

TABLE 44-18

DRUG THERAPY
Gastro-Intestinal Bleeding

Drug	Source of Gastro-Intestinal Bleeding	Mechanism of Action
Antacids*	Duodenal ulcer, gastric ulcer, acute gastritis (corrosive, erosive, and hemorrhagic)	Neutralize acid and maintain gastric pH >5.5; elevated pH inhibits activation of pepsinogen
H_2-receptor blockers: cimetidine, famotidine (Pepcid), nizatidine (Axid), ranitidine (Zantac)	Duodenal ulcer, gastric ulcer, esophagitis, acute gastritis (especially hemorrhagic)	Inhibit action of histamine at H_2 receptors on parietal cells and decrease HCl secretion
Proton pump inhibitors: omeprazole (Losec), esomeprazole (Nexium), lansoprazole (Prevacid), pantoprazole (Pantoloc)	—	Inhibit the cellular pump, which is necessary for secretion of HCl
Vasopressin	Acute gastritis (corrosive, erosive, and hemorrhagic), esophageal varices	Causes vasoconstriction and increases smooth muscle activity of the GI tract; reduces pressure in the portal circulation and arrests bleeding
Octreotide (Sandostatin)	Upper gastro-intestinal bleeding, esophageal varices	Somatostatin analogue that decreases splanchnic blood flow; decreases HCl secretion via decrease in release of gastrin

*See Table 44-23.

GI, gastro-intestinal; *HCl*, hydrochloric acid.

In patients with upper GI bleeding, early administration of the somatostatin analogue octreotide (Sandostatin) may be used. The drug reduces splanchnic blood flow, as well as acid secretion. This

drug is given in IV boluses up to 5 to 6 days after the onset of bleeding.

Antacids have long been known to neutralize HCl and continue to be used as an adjunct therapy for PUD. Because antacids neutralize HCl and increase the pH of gastric contents to above 5, the conversion of pepsinogen to its active form, pepsin, is inhibited. The most frequently used antacid preparations are magnesium hydroxide, magnesium trisilicate, aluminum hydroxide, calcium carbonate, and sodium bicarbonate (see Table 44-23 later in this chapter). Aluminum hydroxide and magnesium trisilicate are the most useful because they are nonabsorbable. Calcium carbonate and sodium bicarbonate are absorbable, and prolonged use can lead to systemic alkalosis.

Sedatives to control agitation and restlessness should be administered cautiously. They make accurate assessment of the patient's condition more difficult. Anticholinergic drugs are contraindicated for use in acute upper GI bleeding episodes.

Nursing Management Upper Gastrointestinal Bleeding

Nursing Assessment

As the nurse begins care of a patient admitted with upper GI bleeding, a thorough and accurate nursing assessment is an essential first step. Subjective and objective data that should be obtained from the patient or significant others are listed in Table 44-19.

TABLE 44-19

NURSING ASSESSMENT
Upper Gastro-Intestinal Bleeding

Subjective Data
Important Health Information
Past health history: Precipitating events before bleeding episode, previous bleeding episodes and treatment, peptic ulcer disease, esophageal varices, esophagitis, acute and chronic gastritis, stress-related mucosal disease; family history of bleeding; history of smoking or heavy alcohol use *Medications:* Use of ASA (Aspirin), nonsteroidal anti-inflammatory drugs, corticosteroids, anticoagulants
Symptoms
• Nausea, vomiting, weight loss; thirst • Diarrhea; black, tarry stools; decreased urinary output; sweating • Weakness, dizziness, fainting • Epigastric pain, abdominal cramps
Objective Data
General
Fever
Integumentary
Clammy, cool, pale skin; pale mucous membranes, nail beds, and conjunctivae; spider angiomas; jaundice; peripheral edema
Respiratory
Rapid, shallow respirations
Cardiovascular
Tachycardia, weak pulse, orthostatic hypotension, slow capillary refill
Gastro-intestinal
Red or "coffee grounds" vomitus; tense, rigid abdomen, ascites; hypoactive or hyperactive bowel sounds; black, tarry stools
Urinary
Decreased urinary output, concentrated urine
Neurological
Agitation, restlessness; decreasing level of consciousness
Possible Findings
↓ Hematocrit and hemoglobin; hematuria; guaiac-positive stools, emesis, or gastric aspirate; ↓ levels of clotting factors; ↑ liver enzymes; abnormal results of upper GI studies or endoscopy

ASA, acetylsalicylic acid; *GI*, gastro-intestinal.

The patient experiencing upper GI bleeding may not be able to provide specific information about the cause of the bleeding until the immediate physical needs are met. An immediate nursing assessment is performed while the patient is being prepared for initial treatment. The assessment includes the patient's level of consciousness, vital signs, appearance of neck veins and skin colour, and capillary refill. The abdomen is checked for distension, guarding, and peristalsis. Immediate determination of vital signs indicates whether the patient is in shock from blood loss and also provides a baseline blood pressure and pulse by which to monitor

the progress of treatment. Signs and symptoms of hypovolemic shock include low blood pressure; rapid, weak pulse; increased thirst; cold, clammy skin; and restlessness. Vital signs are monitored every 15 to 30 minutes, and the health care provider should be informed of any significant changes.

Nursing Diagnoses

Nursing diagnoses for the patient with upper GI bleeding include, but are not limited to, the following:

- *Risk for decreased cardiac output* (related to loss of blood)
- *Deficient fluid volume* related to *insufficient fluid intake, excessive fluid loss through abnormal route* (acute loss of blood and gastric secretions)
- *Ineffective peripheral tissue perfusion* related to *insufficient knowledge of modifiable factors* (loss of circulatory volume)
- *Anxiety* related to *threat to current status, threat of death*

Planning

The overall goals are that the patient with upper GI bleeding will (a) have no further GI bleeding, (b) have the cause of the bleeding identified and treated, (c) experience a return to a normal hemodynamic state, (d) experience minimal or no symptoms of pain or anxiety, and (e) be able to verbalize causative and preventive measures.

Nursing Implementation

Health Promotion.

Although not all cases of upper GI bleeding can be anticipated and prevented, the nurse shares responsibility with the health care provider in trying to identify the patient who is at high risk. Patients with a history of chronic gastritis or PUD should always be considered in the high-risk category because of the increased incidence of bleeding associated with chronic irritation or chronic ulcers. Patients who have had one major bleeding episode are more likely than others to have another. Patients are instructed to avoid gastric irritants such as alcohol and smoking, to prevent or decrease stress-inducing situations at home or at work, and to take only prescribed medications. OTC drugs can be harmful because they may contain ingredients (e.g., ASA [Aspirin]) that have potentially irritating effects on the mucosa.

Patients who require regular administration of ulcerogenic drugs, such as ASA (Aspirin), corticosteroids, or NSAIDs, need instruction regarding the potential adverse effects that these drugs may have on the GI mucosa. These drugs are avoided if at all possible. However, if ASA (Aspirin) must be prescribed, enteric-coated tablets can be substituted for regular tablets. Taking the drugs with meals or snacks lessens the potential irritating effects. For patients who must take NSAIDs, a change to a preparation with less GI toxicity may be considered. COX-2 inhibitors (e.g., celecoxib [Celebrex]) have less of an effect on the production of tissue prostaglandins and are associated with fewer GI adverse effects, although cardiac risks are associated with COX-2 inhibitors. The coadministration of an NSAID with a PPI can reduce bleeding risk. For the patient at risk for gastric ulcers because of NSAID use, misoprostol may also be prescribed. This prostaglandin analogue inhibits acid secretion and reduces the incidence of upper GI bleeding episodes associated with NSAID use. However, the drug has several important adverse effects, including uterine cramping in women and diarrhea. Because of its effects on the uterus, its use is contraindicated in women of child-bearing age.

When the nurse is working with a patient who has a history of liver cirrhosis with esophageal varices, the instructions must be specific about the importance of avoiding known irritants, such as alcohol and smoking. The prompt treatment of an upper respiratory tract infection should be stressed. Severe coughing or sneezing can

create increased pressure on the already fragile varices and may result in massive hemorrhage.

Patients who are known to have blood dyscrasias (e.g., aplastic anemia) or liver dysfunction or who are taking cancer chemotherapeutic drugs have a potential for a bleeding problem because of altered hemostasis caused by a decrease in clotting factors and platelets. When such patients also have a history of ulcer disease, gastritis, varices, or drug and alcohol abuse, they should be carefully instructed regarding their disease process and drugs, and they should be closely observed for bleeding.

Acute Intervention.

Patients should be approached in a calm and assured manner to help decrease their level of anxiety. Caution should be used before sedatives are administered for restlessness because it is one of the warning signs of shock and may be masked by the drugs.

Once an infusion has been started, the IV line must be maintained for fluid or blood replacement. An accurate intake and output record is essential so that the patient's hydration status can be assessed. Urine output should be measured hourly. A rate of at least 0.5 mL/kg/hr indicates adequate renal perfusion. Lesser amounts may indicate renal insufficiency secondary to loss of blood volume. Specific gravity readings consistently greater than 1.030 (normal is 1.005–1.030) indicate that the urine is extremely concentrated and that the blood volume is probably low. The health care provider must be kept informed of these important parameters so that the IV solutions can be increased or decreased accordingly. If a patient has a central venous pressure line in place, readings should be recorded every 1 to 2 hours. Hemodynamic monitoring provides an accurate and quick assessment of blood flow and pressure within the cardiovascular system (see Chapter 68).

Older adult patients and patients with a history of cardiovascular problems should be observed closely for signs of fluid overload. However, the threat of volume overload and pulmonary edema must be a constant concern in all patients who are receiving large amounts of IV fluids within a short time. Therefore, auscultation of

breath sounds and close observation of respiratory effort are important. Electrocardiographic monitoring can also be used to evaluate cardiac function.

Foods such as beets or even swallowed mouthwash can give vomitus a bloody appearance. Unless the contents of the vomitus are checked for occult blood, recorded observations gleaned from appearance alone may be false. Swallowed blood from a nosebleed must also be accurately noted to avoid misdiagnosis of an upper GI bleeding episode. When an NG tube is inserted, the nurse must pay special attention to keeping it in proper position and observing the aspirate for blood.

The nurse caring for a patient with upper GI bleeding should be well informed as to what constitutes blood in the stools. Black, tarry stools are not usually associated with a brisk hemorrhage but are indicative of the presence of bleeding of prolonged duration. Bright red blood in the stool is usually from a source in the lower bowel. (Lower GI bleeding is discussed in Chapter 45.) Menses and bleeding hemorrhoids should be ruled out as possible sources of blood in the stools. When vomitus contains blood but the stool contains no gross or occult blood, the hemorrhage is considered to have been of short duration.

By monitoring results of the patient's laboratory studies, the nurse can estimate the effectiveness of therapy. The hemoglobin and hematocrit are usually evaluated about every 4 to 6 hours if the patient is actively bleeding. At first, the hematocrit level may not accurately reflect the amount of blood lost or the amount of blood replaced and will appear falsely high or low. The patient's BUN level is assessed. It is generally elevated with a significant hemorrhage because blood proteins are broken down by bacteria in the GI tract. However, renal disease may also result in an elevated BUN level. Many patients receive oxygen by mask or nasally to ensure that the circulating blood has an adequate oxygen content.

When oral nourishment is begun, the patient is observed for symptoms of nausea and vomiting and a recurrence of bleeding. Feedings initially consisting of clear fluids are given hourly until tolerance is determined. These feedings help neutralize the gastric secretions and assist in the mucosal repair. Foods are then

introduced gradually if the patient exhibits no signs of discomfort. Consultation with a dietitian ensures the introduction of appropriate foods and support for the patient's nutrition.

The patient in whom hemorrhage was the result of chronic alcohol abuse requires close observation for the beginning of delirium tremens as withdrawal from alcohol takes place. Symptoms indicating the beginning of delirium tremens are agitation, uncontrolled shaking, sweating, and vivid hallucinations. (Alcohol withdrawal is discussed in Chapter 11.)

Ambulatory and Home Care.

Patients and caregivers must be taught how to avoid future bleeding episodes. Ulcer disease, drug or alcohol abuse, and liver and respiratory diseases can all result in upper GI bleeding. Patients and caregivers must be made aware of the consequences of nonadherence to diet and drug therapy. It must be emphasized that no drugs (especially ASA [Aspirin] and NSAIDs) other than those prescribed by the health care provider should be taken. With the assistance of programs for smoking or alcohol cessation or rehabilitation, smoking and alcohol should be eliminated because they are sources of irritation and interfere with tissue repair. The need for long-term follow-up care may be necessary because of the possibility of another bleeding episode. The patient and the family should be instructed on what to do if an acute hemorrhage occurs in the future.

Evaluation

The following are expected outcomes for the patient with upper GI bleeding:

- The patient will have no upper GI bleeding.
- The patient will maintain normal fluid volume.
- The patient will experience a return to a normal hemodynamic state.

- The patient will experience absence of or tolerable levels of pain and will be comfortable.
- The patient will understand potential etiological factors and make appropriate lifestyle modifications.

Peptic Ulcer Disease

Peptic ulcer disease (PUD) is a condition characterized by erosion of the GI mucosa that results from the digestive action of HCl and pepsin. Any portion of the GI tract that comes into contact with gastric secretions is susceptible to ulcer development, including the lower esophagus, stomach, duodenum, and margin of gastro-jejunal anastomosis after surgical procedures.

Types

Peptic ulcers can be classified as acute or chronic, depending on the degree and duration of mucosal involvement (Figure 44-12), and as gastric or duodenal, according to the location. Acute ulcers (see Figure 44-12) are characterized by superficial erosion and minimal inflammation. They are of short duration and resolve quickly when the cause is identified and removed. Chronic ulcers (Figure 44-13) are of long duration, eroding through the muscular wall with the formation of fibrous tissue. They are present continuously for many months or intermittently throughout the lifetime. Chronic ulcers are at least four times as common as acute ulcers.

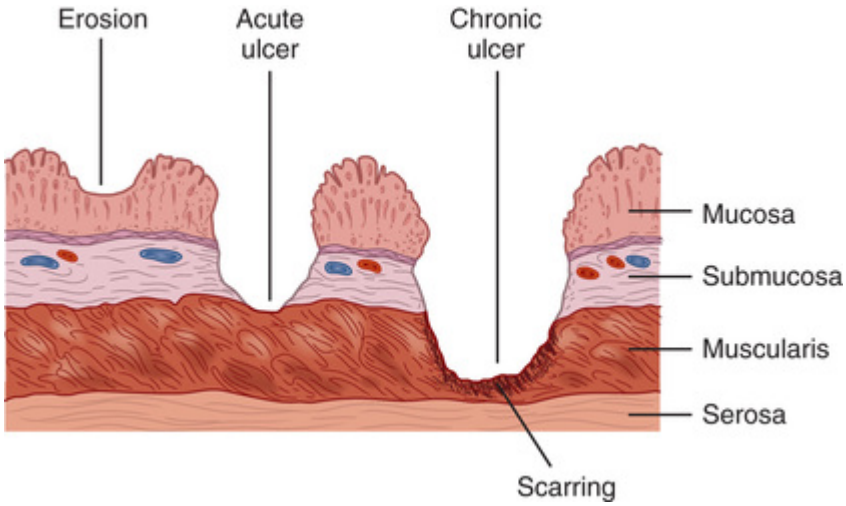

FIGURE 44-12 Peptic ulcers, including an erosion, an acute ulcer, and a chronic ulcer. Both the acute and the chronic ulcers may penetrate the entire wall of the stomach. Source: Modified from Price, S. A., & Wilson, L. M. (2003). *Pathophysiology: Clinical concepts of disease processes* (6th ed., p. 331). St. Louis: Mosby.

FIGURE 44-13 Peptic ulcer of the duodenum. Source: Kumar, V., Abbas, A. K., Fausto, N., et al. (2010). *Robbins and Cotran pathologic basis of disease* (8th ed.). Philadelphia: Saunders.

Gastric and duodenal ulcers, although defined as peptic ulcers, have different causes and incidences (Table 44-20). In general, treatment is similar for all types of ulcers.

TABLE 44-20
COMPARISON OF GASTRIC AND DUODENAL ULCERS

Characteristic	Gastric Ulcers	Duodenal Ulcers
Lesion	Superficial; smooth margins; round, oval, or cone shaped	Penetrating (associated with deformity of duodenal bulb from healing of recurrent ulcers)
Location of lesion	Predominantly in the antrum; also in body and fundus of stomach	First 1–2 cm of duodenum
Gastric secretion	Normal to decreased	Increased
Incidence	• Greater in women	• Greater in men, but increasing in women, especially postmenopausal
	• Peak age, 50–60 yr	• Peak age, 35–45 yr
	• Increased with smoking, drug, and alcohol use	• Increased with smoking, drug, and alcohol use
	• More common among persons of lower socioeconomic status and in unskilled labourers • Increased with incompetent pyloric sphincter and bile reflux • Increased with stress ulcers after severe burns, head trauma, and major surgery	• Associated with psychological stress • Associated with other diseases (e.g., chronic obstructive pulmonary disease, pancreatic disease, hyperparathyroidism, Zollinger–Ellison syndrome, chronic renal failure)
Clinical manifestations	• Burning or gaseous pressure in high left epigastrium and back and upper abdomen • Burning, cramping, pressure-like pain across midepigastrium and upper abdomen; back pain with posterior ulcers • Pain 1–2 hr after meals; if penetrating ulcer, aggravation of discomfort with food • Occasional nausea and vomiting, weight loss	• Pain 2–4 hr after meals and midmorning, midafternoon, middle of night; pain is periodic and episodic • Pain relief with antacids and food; occasional nausea and vomiting
Recurrence rate	High	High
Complications	Hemorrhage, perforation, outlet obstruction, intractability	Hemorrhage, perforation, obstruction

Etiology and Pathophysiology

Peptic ulcers develop only in the presence of an acidic environment. In typical cases, a person with a gastric ulcer has normal to less-than-normal gastric acidity in comparison with the person with a duodenal ulcer. However, some intraluminal acid does seem to be essential for a gastric ulcer to occur.

Pepsinogen, the precursor of pepsin, is activated to pepsin in the presence of HCl and a pH of 2 to 3. The HCl secreted by the parietal

cells has a pH of 0.8. After HCl mixes with the stomach contents, the pH reaches 2 to 3, a range of acidity highly favourable for pepsin activity. When the stomach acid level is neutralized by the presence of food or antacids, or acid secretion is blocked by drugs, the pH is increased to 3.5 or more. At a pH of 3.5 or more, pepsin has little or no proteolytic activity.

The stomach is normally protected from autodigestion by the gastric mucosal barrier. The GI tract has a high rate of cell turnover, and the surface mucosa of the stomach is renewed about every 3 days. As a result of this high turnover rate, the mucosa can continually repair itself except in extreme instances, when the cell breakdown rate surpasses the cell renewal rate. Normally, water, electrolytes, and water-soluble substances (e.g., glucose) can easily pass through the barrier. However, the mucosal barrier prevents the backwards diffusion of acid from the gastric lumen through the mucosal layers to the underlying tissue.

Under specific circumstances, the mucosal barrier can be impaired, and backwards diffusion of acid can occur (Figure 44-14). When the barrier is broken, HCl freely enters the mucosa and injury to the tissues occurs. This results in cellular destruction and inflammation. Histamine is released from the damaged mucosa, resulting in vasodilation and increased capillary permeability. The released histamine is then capable of stimulating further secretion of acid and pepsin.

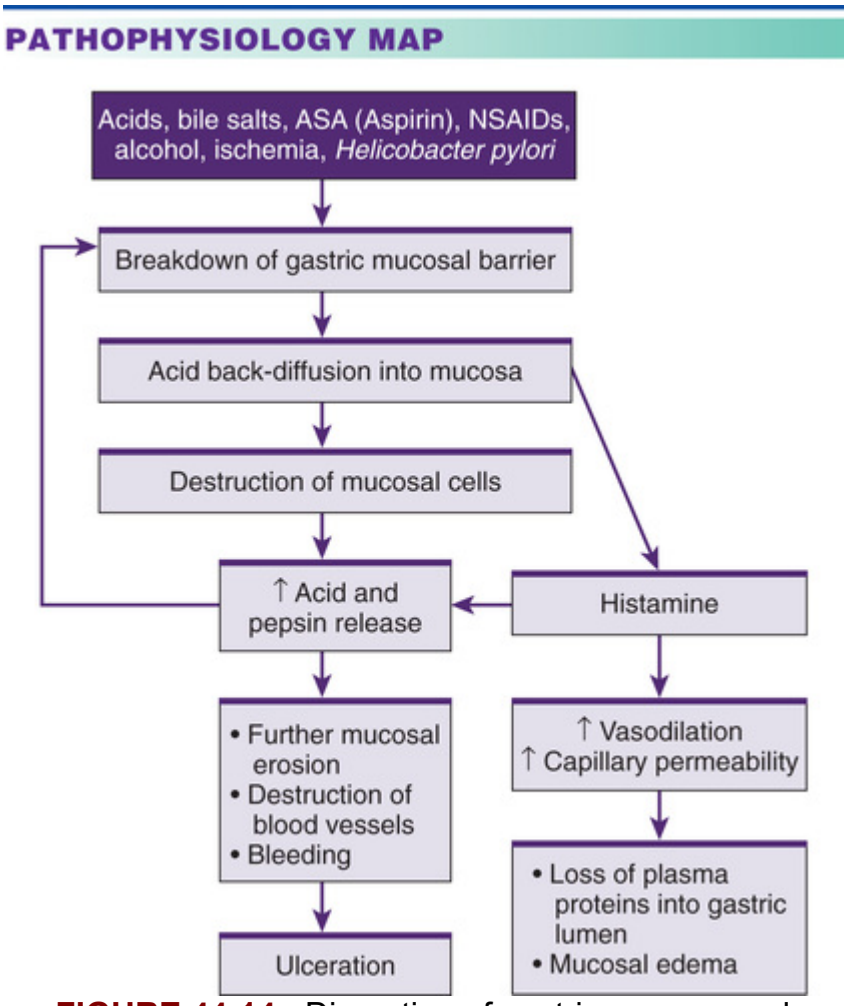

FIGURE 44-14 Disruption of gastric mucosa and pathophysiological consequences of backwards diffusion of acids. *ASA,* acetylsalicylic acid; *NSAIDs,* nonsteroidal anti-inflammatory drugs.

As described in the "Gastritis" section, a variety of agents are known to destroy the mucosal barrier. By generating ammonia in the mucous layer, *H. pylori* may create a condition of chronic inflammation, rendering the mucosa especially vulnerable to other noxious substances. Ulcerogenic drugs, such as ASA (Aspirin) and NSAIDs, inhibit synthesis of prostaglandins and cause abnormal permeability of the mucosal barrier. Corticosteroids have the ability to decrease the rate of mucosal cell renewal and thereby decrease its protective effects. Lipid-soluble cytotoxic drugs can pass through the barrier and destroy it.

When the mucosal barrier is disrupted, there is a compensatory increase in blood flow (Figure 44-15). This phenomenon can occur in several ways. Prostaglandin-like substances and histamine act as vasodilators, thus increasing capillary blood flow. As blood flow increases within the affected mucosa, H^+ are rapidly removed from the area, buffers are delivered to help neutralize the H^+ present, nutrients necessary for cell function arrive, and the rate of mucosal cell replication increases. When the increase is sufficient to dilute, buffer, and remove the excess H^+, tissue damage may be minimal or not occur at all. When blood flow is not sufficient to carry out these events, tissue injury results. Figure 44-15 shows a representation of the interrelationship between the mucosal blood flow and disruption of the gastric mucosal barrier.

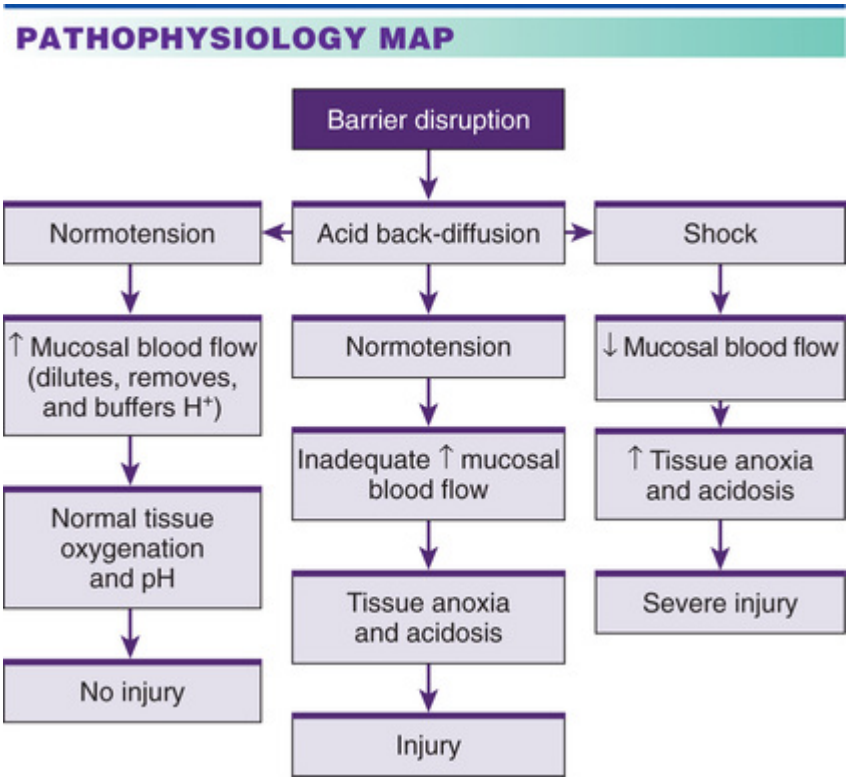

FIGURE 44-15 Relationship between mucosal blood flow and disruption of the gastric mucosal barrier.

Two mechanisms protect against damage. First, mucus is secreted by superficial mucous cells and forms a layer that can entrap or slow

the diffusion of H^+ across the mucosal barrier in the stomach. Second, bicarbonate is secreted by the gastric and duodenal mucosa, and this helps neutralize HCl in the lumen of the GI tract.

Increased vagal nerve stimulation from a variety of causes (e.g., emotions) results in hypersecretion of HCl. Increased concentrations of HCl can alter the mucosal barrier. Duodenal ulcers are associated with high acid content. It has been suggested that the continual response of the parietal cells to maximal stimulation results in hyperplasia of the cells.

Gastric Ulcers.

Although gastric ulcers can occur in any portion of the stomach, they are most commonly found on the lesser curvature close to the antral junction. Gastric ulcers are less common than duodenal ulcers. Gastric ulcers are more prevalent among women and in older adults. The rate of mortality from gastric ulcers is greater than that from duodenal ulcers because the incidence of gastric ulcers peaks in persons older than 50 years. Persons from the lower socioeconomic class and manual or unskilled workers are more prone to gastric ulcers.

Although gastric ulcers are characterized by normal to low secretion of gastric acid, the backwards diffusion of acid is greater with chronic gastric ulcers than with duodenal ulcers or in the healthy person. Therefore, the critical pathological process in gastric ulcer formation may not be the amount of acid that is secreted but the amount that is able to penetrate the mucosal barrier.

Gastric ulcers have also been attributed to various factors that can lead to acute episodes or to chronic involvement. The role of *H. pylori* in ulcer development is discussed in the following "Duodenal Ulcers" section. It is thought that destruction of the gastric mucosa by noxious agents such as drugs or smoking may be enhanced by the presence of *H. pylori,* which further promotes gastric mucosal destruction.

Drugs can cause acute gastric ulcers and, in some cases, can lead to the development of chronic ulcers. The drugs most often implicated include ASA (Aspirin), corticosteroids, NSAIDs (e.g., ibuprofen), and reserpine (Serpasil) (not commercially available in

Canada). It is estimated that 1% to 3% of patients taking NSAIDs for 1 year experience serious GI complications, including gastritis, gastric ulcer, upper GI hemorrhage, or ulcer perforation. Other known causes of gastric ulcer formation are chronic alcohol abuse, chronic gastritis, and bile reflux gastritis that results from an incompetent pyloric sphincter. Cigarette smoking is positively linked with gastric ulcers. Nicotine seems to enhance reflux of duodenal contents into the antrum of the stomach. The ingestion of hot, rough, or spicy foods has been suggested as a cause, but there is no evidence to substantiate this claim.

Duodenal Ulcers.

Duodenal ulcers account for about 80% of all peptic ulcers. Although duodenal ulcers still affect more men than women, the incidence of duodenal ulcers has followed a downward trend among men and steadily increased among women. The explanation for this change has not been clearly identified. Duodenal ulcers may occur at any age, but the incidence is especially high between the ages of 35 and 45 years. Duodenal ulcers can develop in anyone, regardless of occupation or socioeconomic group.

The development of duodenal ulcers is associated with high HCl secretion. Several diseases have been identified with a high risk of duodenal ulcer development, including chronic obstructive pulmonary disease, cirrhosis of the liver, chronic pancreatitis, hyperparathyroidism, chronic renal failure, and Zollinger–Ellison syndrome. (*Zollinger–Ellison syndrome* is a rare condition characterized by severe peptic ulceration, gastric acid hypersecretion, elevated serum gastrin levels, and gastrinoma of the pancreas or the duodenum.) The treatments used for these conditions may also promote ulcer development. Alcohol ingestion and heavy smoking habits are also associated with duodenal ulcer formation, inasmuch as both are known stimulants of acid secretion.

Although many factors are thought to contribute to the formation of duodenal ulcers, *H. pylori* has been identified as playing a key role. *H. pylori* is found in approximately 90% to 95% of patients with duodenal ulcers. However, a clear-cut direct causal relationship between *H. pylori* and duodenal ulcer formation has not yet been

proved. Not all individuals with evidence of *H. pylori* go on to develop ulcers, which suggests that additional factors are needed to produce these conditions. *H. pylori* survives in the human upper GI tract for a long time because of its ability to move in mucus and attach to mucosal cells. In addition, it secretes a substance called *urease,* which buffers the area around the bacterium and protects it from destruction in an acidic environment.

Infection with *H. pylori* is most common in underdeveloped countries and among persons of low socioeconomic status. Although the routes of transmission are largely unknown, it is thought that infection occurs during childhood via transmission from family members to the child, possibly through a fecal–oral route, an oral–oral route, or both. In Canada and the United States, persons born before 1940 have a significantly higher risk of carrying *H. pylori* than do younger persons. This enhanced prevalence in older persons has been attributed to the presence of crowded living conditions and poor sanitation practices, which were more common in the first half of the twentieth century.

Research into a genetic cause for ulcers has shown that some members of the same family are more prone than others to develop gastric or duodenal ulcers. Supporting a genetic etiology is the fact that persons with blood group O have an increased incidence of duodenal ulcers. Evidence is not complete, however, and the ulcer development could just as well be the result of sharing the same environment.

Stress-Related Mucosal Disease.

Stress-related mucosal disease (SRMD) is a condition of acute ulcers that develop after a major physiological insult such as trauma or surgery. A **physiological stress ulcer** is a form of erosive gastritis. It is believed that the gastric mucosa of the body of the stomach undergoes a period of transient ischemia in association with hypotension, severe injury, extensive burns, and complicated surgery. The ischemia is caused by decreased capillary blood flow or shunting of blood away from the GI tract so that blood flow bypasses the gastric mucosa. This occurs as a compensatory mechanism in hypotension or shock. The decrease in blood flow

produces an imbalance between the destructive properties of HCl and pepsin and the protective factors of the stomach's mucosal barrier, especially in the fundic portion, and this imbalance results in ulceration. Multiple superficial erosions result, and these may bleed. Risk factors for development of stress ulcer bleeding are respiratory failure and coagulopathy. Patients with those conditions should receive prophylaxis with antisecretory agents. Stress gastritis is diagnosed with endoscopy, and treatment is with aggressive reduction of gastric acid secretions by means of H_2R blockers or PPIs.

Clinical Manifestations

It is common for patients with gastric or duodenal ulcers to have no pain or other symptoms. The gastric and duodenal mucosae are not rich in sensory pain fibres, which may account for this phenomenon. When pain does occur with duodenal ulcer, it is described as "burning" or "cramplike," and it is most often located in the midepigastric region beneath the xiphoid process. In contrast, the pain associated with gastric ulcers is located high in the epigastrium; it occurs spontaneously about 1 to 2 hours after meals and is described as "burning" or "gaseous." The pain can occur when the stomach is empty or when food has been ingested. If the ulcer has eroded through the gastric mucosa, food tends to aggravate rather than alleviate the pain. Some persons do not experience any pain until the presence of the ulcer is demonstrated through a serious complication such as hemorrhage or perforation.

Ulcers located on the posterior aspect of the duodenum can be manifested by back pain. The pain usually occurs 2 to 4 hours after meals. It is relieved by antacids alone or in combination with an H_2R blocker or PPI and sometimes by foods that neutralize and dilute the HCl. A characteristic of duodenal ulcer is its tendency to occur continuously for a few weeks or months and then disappear for a time, only to recur some months later.

Complications

The three major complications of chronic PUD are hemorrhage, perforation, and gastric outlet obstruction. All are considered emergency situations and are initially treated conservatively. However, surgery may become necessary at any time during the course of the therapy.

Hemorrhage.

Hemorrhage is the most common complication of PUD. It develops as a result of erosion of the granulation tissue at the base of the ulcer during healing or erosion of the ulcer through a major blood vessel. Duodenal ulcers account for a greater percentage of upper GI bleeding episodes than do gastric ulcers.

Perforation.

Perforation of an ulcer is considered the most lethal complication of peptic ulcer. Perforation is common in large penetrating duodenal ulcers that have not healed and are located on the posterior mucosal wall (Figure 44-16). Perforated gastric ulcers are most often located on the lesser curvature of the stomach. Even though duodenal ulcers are more prevalent and perforate more frequently, mortality rates associated with perforation of gastric ulcers are higher.

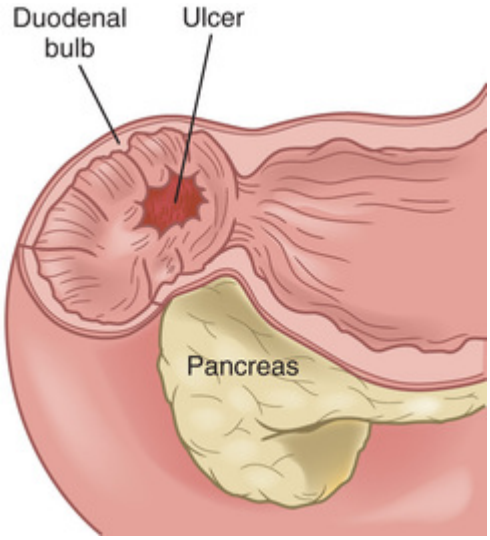

FIGURE 44-16 Duodenal ulcer of the posterior wall penetrating into the head of the pancreas, resulting in walled-off perforation.

Perforation of a peptic ulcer occurs when the ulcer penetrates the serosal surface, with spillage of either gastric or duodenal contents into the peritoneal cavity. The size of the perforation is directly proportional to the length of time the patient has had the ulcer: the larger the perforation, the longer the history of the ulcer. Small perforations seal themselves and result in a cessation of symptoms; larger perforations necessitate immediate surgical closure. Spontaneous sealing occurs as a result of large amounts of fibrin being produced in response to the perforation. This leads to fibrinous fusion of the duodenum or the gastric curvature to adjacent tissue, mainly the liver.

The clinical manifestations of perforation are characterized by their sudden and dramatic onset. The patient experiences sudden, severe upper abdominal pain that quickly spreads throughout the abdomen. The visceral and parietal layers of the peritoneum have an abundance of pain receptors, and this contributes to the abruptness and intensity of the pain experienced. There may be shoulder pain if the spillage causes irritation to the phrenic nerve. The abdominal muscles contract, appearing rigid and boardlike as they attempt to protect the abdomen from further injury. The patient's respirations become shallow and rapid. Bowel sounds are usually absent. Nausea and vomiting may occur but are generally absent. Many affected

patients report a history of ulcer disease or recent symptoms of indigestion.

The contents entering the peritoneal cavity from the stomach or the duodenum contain a variety of ingredients that include air, saliva, food particles, HCl, pepsin, bacteria, bile, and pancreatic fluid and enzymes. Bacterial peritonitis may occur within 6 to 12 hours. The intensity of the peritonitis is proportional to the amount and the duration of the spillage through the perforation. It is difficult to determine from the sudden onset of symptoms whether gastric or duodenal ulcer is the cause because the clinical characteristics of intestinal perforation are the same (see Chapter 45).

Gastric Outlet Obstruction.

Ulcers located in the antrum and the prepyloric and pyloric areas of the stomach and the duodenum can predispose to gastric outlet obstruction. In the early phase of obstruction (often referred to as the *compensated phase*), gastric emptying is normal to near normal. Over time, the increase in contractile force needed to empty the stomach results in hypertrophy of the stomach wall. After longstanding obstruction, the stomach enters the decompensated phase, which results in dilation and atony. The obstruction is not totally the result of fibrous scar tissue because active ulcer formation is associated with edema, inflammation, and pylorospasm, all of which contribute to the narrowing of the pylorus.

Patients with gastric outlet obstruction generally have a long history of ulcer pain. Ulcer-like pain of short duration or complete absence of pain is more indicative of a malignant obstruction. The pain progresses to a more generalized upper abdominal discomfort that becomes worse toward the end of the day as the stomach fills and dilates. Relief may be obtained by belching or by self-induced vomiting. Involuntary vomiting is common and often projectile. The vomitus contains food particles that were ingested many hours or even a day or two before the vomiting episode. There is often an offensive odour if the contents have been dormant in the stomach for a time. Affected patients who vomit frequently are anorexic, with evident weight loss, and report thirst and an unpleasant taste in the mouth.

Patients with gastric outlet obstruction may have a swelling in the upper abdomen that indicates dilation of the stomach. Peristalsis is loud, and visible peristaltic waves are often observed passing across the abdomen from left to right. If the stomach is grossly dilated, it is possible to palpate it as well.

Diagnostic Studies

The diagnostic measures used to determine the presence and location of a peptic ulcer are similar to those used for acute upper GI bleeding. Endoscopy is the procedure most often used because of the manoeuvrability of fibre-optic endoscopes for viewing the entire gastric and duodenal mucosa (Figure 44-17). This procedure can also be used to determine the degree of ulcer healing after treatment. During endoscopy, tissue specimens can be obtained for identification of *H. pylori* and to rule out gastric cancer.

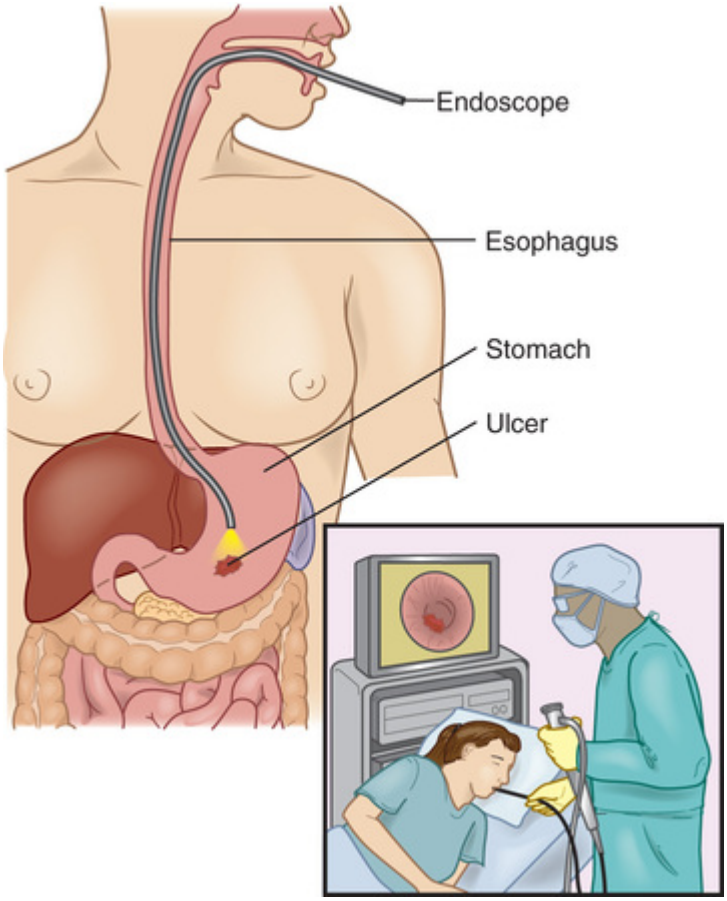

FIGURE 44-17 Esophago-gastro-duodenoscopy (EGD) enables the examiner to directly visualize the mucosal lining of the stomach with a flexible endoscope. Ulcers or tumours can be directly visualized and biopsy samples taken.

Currently, several diagnostic tests are available to confirm *H. pylori* infection. These are classified as noninvasive and invasive. *Noninvasive tests* include serum or whole blood antibody tests, particularly immunoglobulin G (IgG). However, because of the length of time that IgG levels remain elevated in the blood after the infection, the serological tests do not help distinguish active from recently treated disease. The urea breath test can determine the presence of active infection. Urea is a by-product of the metabolism of *H. pylori* bacteria. *Invasive tests* involve biopsy of the stomach and include the rapid urease test and tests of other histological markers of infection. These tests have greater sensitivity and specificity but involve an endoscopic procedure.

Barium studies are of benefit in the diagnosis of gastric outlet obstruction. Barium normally should pass from the stomach within 2 hours, but with gastric outlet obstruction, 50% of the barium remains on follow-up films up to 6 hours later.

Gastric analysis has questionable value in the diagnosis of PUD because, in many patients, gastric secretions are normal in amount and composition. However, it can provide important data for (a) identifying a possible gastrinoma (Zollinger–Ellison syndrome), (b) determining the degree of gastric hyperacidity, and (c) evaluating the results of therapy such as vagotomy and antisecretory drug therapy. Gastric analysis procedure is described in Chapter 41.

Laboratory analyses, including a CBC, urinalysis, liver enzyme studies, serum amylase determination, and stool examination, should be performed. A CBC may indicate the presence of anemia secondary to bleeding from the ulcer. Liver enzyme studies help determine any liver problems, such as cirrhosis, that may complicate the treatment of the ulcer. Urine and stool are routinely tested for the presence of blood. A serum amylase determination frequently provides information on pancreatic function in patients in whom posterior penetration of the pancreas is suspected.

Collaborative Care: Conservative Therapy

When the patient's clinical manifestations and health history suggest the diagnosis of PUD and diagnostic studies confirm it, a medical regimen is instituted (Table 44-21). The regimen consists of adequate rest, dietary modifications, drug therapy, elimination of smoking, and long-term follow-up care. The aim of the treatment program is to decrease the degree of gastric acidity, enhance mucosal defence mechanisms, and minimize the harmful effects on the mucosa.

TABLE 44-21

COLLABORATIVE CARE
Peptic Ulcer Disease

Diagnostic • History and physical examination • Complete blood cell count • *Helicobacter pylori* testing of breath, urine, blood, tissue • Liver enzyme measurements • Serum electrolyte measurements • Upper GI endoscopy with biopsy • Urinalysis **Collaborative Therapy** ***Conservative Therapy*** • Adequate rest • Bland diet (six small meals a day) • Cessation of smoking • Drug therapy • Antacids (see Table 44-23) • Antibiotics for *H. pylori* infection (see Table 44-14) • Anticholinergics • Cytoprotective drugs • H_2-receptor blockers (see Table 44-22) • Proton pump inhibitors (see Table 44-22) • Stress reduction	***Acute Exacerbation Without Complications*** • Adequate rest • Cessation of smoking • IV fluid replacement • NPO • Drug therapy • Antacids • Anticholinergics • H_2-receptor blockers • Proton pump inhibitors • Sedatives ***Acute Exacerbation With Complications (Hemorrhage, Perforation, Obstruction)*** • Bed rest • Blood transfusions • IV fluid replacement (lactated Ringer's solution) • NG suction • NPO • Stomach lavage (possible) ***Surgical Therapy*** • Billroth I and II procedures • Gastric outlet obstruction: pyloroplasty and vagotomy • Perforation: simple closure with omentum graft • Ulcers: removal or reduction • Vagotomy and pyloroplasty

GI, gastro-intestinal; *IV*, intravenous; *NG*, nasogastric; *NPO*, nothing by mouth.

Patients are generally treated in ambulatory care clinics. Pain disappears after 3 to 6 days, but ulcer healing is much slower. Complete healing may take 3 to 9 weeks, depending on ulcer size and the treatment regimen employed. Healing of the ulcer should be assessed by means of radiographic or endoscopic examination. Endoscopic examination is the only accurate method by which to monitor ulcer healing; follow-up examinations are performed 3 to 6 months after diagnosis and treatment.

Adequate rest, both physical and emotional, is important in the treatment process. A quiet, calm environment at home or on the job is not easy to achieve, and some modifications in the patient's daily routine may be needed. The elimination or reduction of stressors helps decrease the stimulus for overproduction of HCl. Moderation in daily activity is essential.

When ASA (Aspirin) or nonselective NSAIDs must be continued, enteric-coated preparations or coadministration with a PPI or misoprostol should be considered. Patients with *H. pylori* infection are treated as per established protocols.

As mentioned previously, smoking has an irritating effect on the mucosa, increases gastric motility, and delays mucosal healing. It should be eliminated completely or drastically reduced. The combination of adequate rest and abstinence from smoking accelerates ulcer healing.

Drug Therapy.

Drugs are a vital part of therapy. The patient must be well informed about each drug prescribed, why it is ordered, and the expected benefits. Strict adherence to the prescribed regimen of drugs is important. Drug therapy includes the use of antacids, H_2R blockers, PPIs, antibiotics, anticholinergics, and cytoprotective therapy (Tables 44-22 through 44-24).

TABLE 44-22
DRUG THERAPY
Peptic Ulcer Disease

Antisecretory	**Cytoprotective**
• H_2-receptor blockers	• Sucralfate bismuth subsalicylate (Pepto-Bismol)
• Famotidine (Pepcid)	**Neutralizing**
• Nizatidine (Axid)	• Antacids*
• Ranitidine (Zantac)	**Antibiotics for *Helicobacter pylori* Infection**
• Proton pump inhibitors	• Amoxicillin
• Dexlansoprazole (Dexilant)	• Clarithromycin (Biaxin)
• Esomeprazole (Nexium)	• Metronidazole (Flagyl)
• Lansoprazole (Prevacid)	• Tetracycline
• Omeprazole (Losec)	**Others**
• Pantoprazole (Pantoloc)	• Tricyclic antidepressants
• Anticholinergics	• Doxepin (Sinequan)
Antisecretory and Cytoprotective	• Imipramine
• Misoprostol	

*See Table 44-23.

TABLE 44-23

DRUG THERAPY
Antacid Preparations

Ingredient	Trade Name
Single substance	
• Aluminum carbonate	Basaljel
• Aluminum hydroxide gel tablets	Amphojel
• Aluminum phosphate	Phosphalugel
• Calcium carbonate	Alka-2, Tums
• Dihydroxyaluminum sodium carbonate	Rolaids
• Magaldrate	Riopan
• Magnesium hydroxide	Milk of magnesia
• Sodium bicarbonate	Alka-Seltzer
Mixtures of aluminum hydroxide and magnesium salts	Gaviscon, Maalox/Diovol

TABLE 44-24

DRUG THERAPY
Adverse Effects of Antacid Therapy

Antacid	Reactions
Aluminum hydroxide gels	Constipation, phosphorus depletion with chronic use
Calcium carbonate	Constipation or diarrhea, hypercalcemia, milk-alkali syndrome, renal calculi
Magnesium preparations	Diarrhea, hypermagnesemia
Sodium preparations	Milk–alkali syndrome if used with large amounts of calcium; used with caution in patients with sodium restrictions

Because recurrence of peptic ulcer is frequent, interruption or discontinuation of therapy can have detrimental results. The patient must be encouraged to comply with therapy and continue with follow-up care for at least 1 year. If changes in lifestyle are part of the prescribed therapy, they should be maintained. Antacids, H_2R blockers, and PPIs may be stopped after the ulcer has healed or may be prescribed in the form of low-dose maintenance therapy. No other drugs, unless prescribed by the health care provider, should be taken because they may have an ulcerogenic effect. Finally, the patient and the family should be told what to do in the event that pain and discomfort recur or blood is noted in the vomitus or stools.

Histamine-2 Receptor Blockers.

Histamine-2 (H_2)-receptor blockers, also called H_2R blockers, are frequently used in the management of PUD. These drugs block the action of histamine on the H_2Rs and thus reduce HCl secretion. This decreases the conversion of pepsinogen to pepsin and accelerates ulcer healing. (Antihistamine drugs used to treat allergies are H_1R blockers and have no effect on gastric acid secretion.)

H_2R blockers may be administered orally or intravenously; however, only ranitidine (Zantac) is available in an IV form. Depending on the specific drug, therapeutic effects last up to 12 hours. However, the onset of action (i.e., symptom relief) is longer than that of antacids. H_2R blockers have demonstrated capabilities in the healing of gastric and duodenal ulcers. OTC forms of H_2R blockers are currently available. H_2R blockers are used in combination with antibiotics to treat ulcers related to *H. pylori.*

Proton Pump Inhibitors.

PPIs block the adenosine triphosphatase enzyme that is important for the secretion of HCl. These agents are more effective than H_2R blockers in reducing gastric acid secretion and promoting ulcer healing. PPIs are also used in combination with antibiotics to treat ulcers caused by *H. pylori.*

Antibiotic Therapy.

Antibiotics are prescribed to eradicate *H. pylori* infection. The treatment of *H. pylori* is the most important element of treating ulcer disease in patients with *H. pylori* infection. When *H. pylori* is present, ulcer recurrence rates can be as high as 75% to 90% when H_2R blockers are taken alone, whereas with antibiotic treatment, the recurrence rate may be less than 10%. Antibiotic therapy for *H. pylori* is detailed in Table 44-14.

Once the presence of *H. pylori* has been determined, antibiotic treatment is instituted. The regimen of choice is based on the antibiotic susceptibility of the *H. pylori* organism, allergies, patient adherence, adverse effects, and costs. Most drug regimens involve

treatment for 7 to 14 days (Rx Files Academic Detailing Program, 2014).

Antacids.

Antacids are used as adjunct therapy for PUD. They increase gastric pH by neutralizing the acid. As a result, the acid content of chyme reaching the duodenum is reduced. In addition, some antacids, such as aluminum hydroxide, can bind to bile salts, thus decreasing the detrimental effects of bile on the gastric mucosa. Patients who are vulnerable to SRMD may be treated prophylactically with antacids along with an antisecretory agent.

Antacids consist of systemic and nonsystemic types. *Systemic antacids,* such as sodium bicarbonate, are extremely soluble and are absorbed into the circulation. Their long-term use can lead to systemic alkalosis; therefore, they are rarely used in ulcer treatment. The *nonsystemic antacids* are insoluble and poorly absorbed. The common commercial nonsystemic antacids consist of magnesium hydroxide or aluminum hydroxide as single preparations or in various combinations (see Table 44-23). The antacid preparation may be in liquid or tablet form. The neutralizing effects of antacids taken on an empty stomach last only 20 to 30 minutes because they are quickly evacuated. When antacids are taken after meals, the effects may last as long as 3 to 4 hours. With therapy regimens that call for frequent administration (e.g., hourly), adherence is often poor.

The type and dosage of the antacid prescribed depends on adverse effects (see Table 44-24), as well as potential drug interactions. Preparations with high sodium content should be administered with caution in older adults and in patients with liver cirrhosis, hypertension, heart failure, or renal disease. Magnesium preparations should not be prescribed for patients with renal failure because of the risk of magnesium toxicity. The most frequent adverse effect experienced with magnesium antacids is diarrhea. Aluminum hydroxide causes constipation. An antacid combination of aluminum and magnesium salts seems to lessen the adverse effects of both.

Antacids have the capacity to interact unfavourably with some drugs. They can enhance the absorption of drugs such as dicumarol

and amphetamines. The action of digitalis preparations can be potentiated when taken in combination with calcium or magnesium antacids. In some instances, antacids may decrease the absorption rates of prescribed drugs, such as tetracycline. Therefore, it is important to inform the health care provider of any drugs that the patient is taking before antacid therapy is begun.

Anticholinergic Drugs.

Anticholinergic drugs (e.g., scopolamine [hyoscine]) are only occasionally ordered in the treatment of PUD. These drugs decrease cholinergic (vagal) stimulation of HCl secretion. Opinion is divided with regard to their efficacy in preventing recurrences and their therapeutic effectiveness in alleviating symptoms and preventing complications. Because of their tendency to decrease gastric motility, they should not be used for gastric ulcers in which stasis of secretions increases the patient's pain and discomfort. Anticholinergics are associated with a number of adverse effects, such as dry mouth and skin, flushing, thirst, tachycardia, dilated pupils, blurred vision, and urine retention. Anticholinergics must be prescribed with caution in patients with narrow-angle glaucoma, benign prostatic hyperplasia, and gastric outlet obstruction.

Cytoprotective Drug Therapy.

Sucralfate is used for the short-term treatment of ulcers. It has proved to be cytoprotective of the esophagus, the stomach, and the duodenum. Its ability to accelerate ulcer healing is thought to be a result of the formation of an ulcer-adherent complex covering the ulcer and thereby protecting it from erosion caused by pepsin, acid, and bile salts. Sucralfate does not have acid-neutralizing capabilities. Its action is most effective at a low pH, and it should be given at least 30 minutes before or after an antacid. Adverse effects are minimal. However, it does bind with digoxin, warfarin (Coumadin), phenytoin (Dilantin), and tetracycline, which reduces the bioavailability of these drugs.

Misoprostol is a synthetic prostaglandin analogue. It has protective and some antisecretory effects on gastric mucosa. It is used for the prevention of gastric ulcers induced by NSAIDs and

ASA (Aspirin). A major advantage of misoprostol is that it does not interfere with the therapeutic effects of ASA (Aspirin) and NSAIDs. Persons who require ongoing NSAID therapy, such as those with osteoarthritis, may benefit from the use of misoprostol. All NSAIDs, even COX-2 inhibitors, impair ulcer healing.

Other Drugs.

Tricyclic antidepressants (e.g., imipramine, doxepin [Sinequan]) and serotonin reuptake inhibitors may be prescribed for patients with ulcer disease. Antidepressants may contribute to overall pain relief through their effects on pain transmission by afferent fibres. In addition, tricyclic antidepressants have, to varying degrees, some anticholinergic properties, which result in reduced acid secretion. Selective serotonin reuptake inhibitors are associated with a slight increase in risk of upper GI bleeding.

Nutritional Therapy.

Dietary modifications may be necessary so that foods and beverages irritating to the patient can be avoided or eliminated. Alcohol and caffeine-containing products should be eliminated because of their irritating effects.

Dietary instructions should include a sample diet with a list of foods that usually cause distress and should, therefore, be eliminated from the diet. Foods known to irritate the gastric mucosa include hot, spicy foods and pepper, alcohol, carbonated beverages, tea, coffee, and broth (meat extract). These foods also have limited buffering ability in addition to stimulating gastric acid secretion. Foods high in roughage, such as raw fruit, salads, and vegetables, may irritate an inflamed mucosa. If these foods are well chewed, this seems to be less of a problem.

Protein is considered the best neutralizing food, but it also stimulates gastric secretions. Carbohydrates and fats are the least stimulating to HCl secretion, but they do not neutralize acid well. The patient must determine a suitable combination of these essential nutrients that does not cause undue distress.

Milk can neutralize gastric acidity and contains prostaglandins and growth factors, both of which may protect the GI mucosa from

injury.

Therapy Related to Complications of Peptic Ulcer Disease

Acute Exacerbation.

An acute exacerbation of peptic ulcer can usually be treated with the same regimen used for conservative therapy. However, the situation is considered more serious because of the possible complications of perforation, hemorrhage, and gastric outlet obstruction.

Bleeding, increased pain and discomfort, and nausea and vomiting frequently accompany an acute exacerbation. If the patient experiences recurrent vomiting or gastric outlet obstruction, an NG tube may be placed into the stomach with intermittent suction for about 24 to 48 hours.

If the patient has a history of an incompetent pyloric sphincter that allows reflux of duodenal contents into the stomach, an NG tube is used to remove intestinal contents from the stomach. This period of stomach rest eliminates any causative factors that may have precipitated the acute exacerbation and enables the resolution of edema and inflammation of the mucosa. Fluids and electrolytes are replaced by IV infusion until the patient is able to tolerate oral feedings without distress.

Management is similar to that described for upper GI bleeding. Blood or blood products may be administered. Careful monitoring of the vital signs, intake and output, laboratory study results, and signs of impending shock is important during this acute episode.

Endoscopic evaluation is performed to reveal the degree of inflammation or bleeding, as well as the ulcer location. It is important to ascertain the presence of a prepyloric or pyloric ulcer that can cause gastric outlet obstruction. When endoscopic examination reveals no major problems and the patient's physical condition stabilizes, the plan of care for the patient should follow the same regimen of diet, activity, and drugs used in conservative therapy. A 5-year follow-up program is recommended after acute exacerbation. An increase in the healing rate is achieved after conservative treatment, but the treatment plan cannot prevent the scar formation that can result in gastric outlet obstruction.

Perforation.

The immediate focus of management of a patient with a perforation is to stop the spillage of gastric or duodenal contents into the peritoneal cavity and restore blood volume. An NG tube is inserted into the stomach to provide continuous aspiration and gastric decompression to halt spillage through the perforation. Although duodenal aspiration is not achieved as promptly, placement of the tube as near to the perforation site as possible facilitates decompression.

Circulating blood volume must be replaced with lactated Ringer's and albumin solutions. These solutions substitute for the fluids lost from the vascular and interstitial space as the peritonitis develops. Blood replacement in the form of packed RBCs may be necessary. A central venous pressure line and an indwelling urinary catheter, unless contraindicated, should be inserted and monitored hourly. Broad-spectrum antibiotic therapy should be started immediately to treat bacterial peritonitis. Administration of pain medications provides comfort.

The operative procedure involving the least risk to the patient is simple oversewing of the perforation and reinforcement of the area with a graft of omentum. The excess gastric contents are suctioned from the peritoneal cavity during the surgical procedure. There is controversy over whether more definitive surgical treatment of a perforated ulcer achieves better results than does simple closure. Other types of surgical procedures depend on the location of the peptic ulcer and the surgeon's preference. If cure of the ulcer is the ultimate goal, the surgical procedures may include gastric resection or vagotomy and pyloroplasty.

Gastric Outlet Obstruction.

The aim of therapy for obstruction is to decompress the stomach, correct any existing fluid and electrolyte imbalances, and improve the patient's general state of health. An NG tube is inserted into the stomach and attached to continuous suction to remove excess fluids and undigested food particles. With continuous decompression for several days, the stomach has the opportunity to regain its normal

muscle tone, the ulcer can begin healing, and the inflammation and edema will subside.

The tube is clamped after several days of suction, and gastric residue is measured periodically. The frequency and amount of time the tube remains clamped are proportional to the amount of aspirate obtained and the comfort level of the patient. A method commonly followed is to clamp the tube overnight for approximately 8 to 12 hours and to measure the gastric residue in the morning. When the aspirate falls below 200 mL, it is considered to be within a normal range, and the patient can begin oral intake of clear liquids. Initially, oral fluids are begun at 30 mL/hr and then gradually increased in amount. The patient must be watched carefully for signs of distress or vomiting. As the amount of gastric residue decreases, solid foods are added and the tube is removed.

IV fluids and electrolytes are administered according to the degree of dehydration, vomiting, and electrolyte imbalance indicated by laboratory studies. Pain relief results from the decompression measures, and analgesics are usually not necessary. Antacids and antisecretory drug therapy (i.e., H_2R blockers, PPIs) are an integral part of treatment if the obstruction has been determined on endoscopic examination to be the result of an active ulcer. Pyloric obstruction may be treated nonsurgically by balloon dilations performed through the endoscope. Surgical intervention may be necessary to remove scar tissue.

Nursing Management Peptic Ulcer Disease

Nursing Assessment

Subjective and objective data that should be obtained from a patient with PUD are presented in Table 44-25.

TABLE 44-25

NURSING ASSESSMENT
Peptic Ulcer Disease

Subjective Data
Important Health Information
Current health history: Chronic alcohol abuse, smoking, caffeine use *Past health history:* Chronic kidney disease, pancreatic disease, chronic obstructive pulmonary disease, serious illness or trauma, hyperparathyroidism, cirrhosis of the liver, Zollinger–Ellison syndrome; family history of peptic ulcer disease *Medications:* Use of acetylsalicylic acid (ASA: Aspirin), corticosteroids, nonsteroidal anti-inflammatory drugs *Surgery or other treatments:* Complicated or prolonged surgery
Symptoms
• Black, tarry stools • Common: burning midepigastric or back pain occurring 2–4 hrs after meals and relieved by food (duodenal ulcers), nocturnal pain; high epigastric pain occurring 1–2 hrs after meals (gastric ulcers); pain may be precipitated or aggravated by food • Weight loss, anorexia; nausea and vomiting, hematemesis; dyspepsia, heartburn, belching
Objective Data
General
Anxiety, irritability
Gastro-intestinal
Epigastric tenderness
Possible Findings
Anemia; guaiac-positive stools; positive blood, urine, breath, or stool tests for *Helicobacter pylori*; abnormalities revealed by upper gastro-intestinal endoscopic and barium studies

Nursing Diagnoses

Nursing diagnoses related to PUD may include, but are not limited to, the following.

- *Acute pain* related to *biological injury agent* (increased gastric secretions)
- *Ineffective health management* related to *insufficient knowledge of therapeutic regimen*
- *Nausea* related to *anxiety, fear, gastro-intestinal irritation*

Additional information on nursing diagnoses for the patient with PUD is presented in NCP 44-2, available on the Evolve website.

Planning

Overall goals are that the patient with PUD will (a) comply with the prescribed therapeutic regimen, (b) experience a reduction in or absence of discomfort related to PUD, (c) exhibit no signs of GI complications related to the ulcerative process, (d) have complete healing of the peptic ulcer, and (e) make appropriate lifestyle changes to prevent recurrence.

Nursing Implementation

Health Promotion.

Nurses must be involved in identifying patients at risk for ulcer development. Early detection and treatment of ulcers are important aspects of reducing morbidity associated with ulcers. Patients with PUD who are taking ulcerogenic drugs such as ASA (Aspirin) and NSAIDs are at risk for ulcer development. Patients need to be encouraged to take these drugs with food. Patients should be taught to report symptoms related to gastric irritation, including epigastric pain, to their health care provider.

Acute Intervention.

During the acute exacerbation of an ulcer, patients generally report increased pain and nausea and vomiting, and some may have

evidence of bleeding. Initially, many patients attempt to cope with the symptoms at home before seeking medical assistance.

During this acute phase, the patient may be maintained on NPO status for a few days, an NG tube is inserted and connected to intermittent suction, and fluids are replaced intravenously. The rationale for this therapy must be conveyed to the anxious patient and caregiver. They must understand that the advantages far outweigh any temporary discomfort imposed by the presence of the tube. Regular mouth care alleviates the dry mouth. Cleansing and lubrication of the nares facilitates breathing and decreases soreness. When the stomach is kept empty of gastric secretions, the ulcer pain diminishes and ulcer healing begins. Usually, this form of intervention is effective.

Because the patient is on NPO status, IV fluids are ordered. The type and amount administered are directly related to the fluid lost, the manifestations exhibited by the patient, and the results of the hemoglobin, hematocrit, and electrolyte determinations. The nurse should be aware of any other current health problem that could be adversely affected by the type of fluid used or the rate of the infusion. Repeated monitoring of these parameters provides information on the hydration status and the effectiveness of treatment. Vital signs are initially measured at least hourly so that shock can be detected and treated.

Physical and emotional rest are conducive to ulcer healing. The patient's immediate environment should be quiet and restful. The use of a mild sedative or tranquilizer has beneficial effects when the patient is anxious and apprehensive. The nurse must use good judgement before sedating a person who is becoming increasingly restless. There is danger that the drug will mask the signs of shock secondary to upper GI bleeding.

If the patient's condition improves without progression of symptoms (e.g., increased pain, vomiting, and hemorrhage), the regimen outlined for conservative therapy is followed. However, complications such as hemorrhage, perforation, and obstruction can occur.

Hemorrhage.

Changes in the vital signs and an increase in the amount and redness of the aspirate often signal massive upper GI bleeding. When there is an increased amount of blood in the gastric contents, the patient's pain is often decreased because the blood helps to neutralize the acidic gastric contents. It is important to maintain the patency of the NG tube so that blood clots do not obstruct the tube. If the tube becomes blocked, the patient can develop abdominal distension. Similar interventions are used to those described for upper GI bleeding in the section "Nursing Management: Upper Gastrointestinal Bleeding." The nurse must monitor the results of the hemoglobin and hematocrit determinations.

Perforation.

When there is sudden, severe abdominal pain unrelated in intensity and location to the pain that brought the patient to the hospital, the nurse must recognize the possibility of ulcer perforation. When any patient with an ulcer, particularly a chronic duodenal ulcer, demonstrates these manifestations, perforation should be suspected and the health care provider notified immediately.

Patients with perforation demonstrate a rigid, boardlike abdomen; have severe generalized abdominal and shoulder pain; draw up the knees; and have shallow, grunting respirations. The bowel sounds that may have been previously normal or hyperactive may diminish and disappear.

Vital signs are important parameters and should be promptly recorded every 15 to 30 minutes. The nurse should temporarily stop all oral or NG drugs and feedings until the health care provider can be notified and a definitive diagnosis made. If perforation has taken place, anything taken internally can add to the spillage into the peritoneal cavity and increase discomfort. If IV fluids are being administered at the time of the perforation, the rate should be maintained or increased to replace the depleted plasma volume.

When perforation is confirmed, antibiotic therapy is usually started, and careful observation for allergic reactions must be made. When the perforation fails to seal spontaneously, surgical closure is necessary and is performed as soon as possible. There is often little time to prepare the patient and caregiver thoroughly for the surgical

intervention, but some instructions can be conveyed while the immediate therapy is begun. If major reconstructive surgery is anticipated, the patient and caregiver may question the need when the problem is only a small hole.

Gastric Outlet Obstruction.

Gastric outlet obstruction can occur at any time and is most likely to occur in patients in whom the ulcer is located close to the pylorus. Because the onset of symptoms is usually gradual, the condition is not generally as serious an emergency as hemorrhage or perforation. Relief of symptoms may be achieved by constant NG aspiration of stomach contents. This allows edema and inflammation to subside and then enables normal flow of gastric contents through the pylorus.

Obstruction can also occur during the treatment of an acute episode of peptic ulcer exacerbation. If these symptoms are experienced while the patient is still on NPO status, the patency of the NG tube should be investigated. Regular irrigation of the tube with a saline solution facilitates proper functioning. It may be helpful to reposition the patient from side to side so that the tube tip is not constantly lying against the mucosal surface.

When oral feedings have been resumed and symptoms of obstruction are observed, the health care provider should be promptly informed. In general, all that is necessary to treat the problem is to resume gastric aspiration so that the edema and inflammation resulting from the acute episode have time to resolve. IV fluids with electrolyte replacement keep the patient hydrated during this period. The NG tube can be clamped, and gastric fluids can be aspirated to check for retention. It is important to maintain accurate intake and output records, especially of the gastric aspirate. The patient should be kept aware of why these symptoms are being experienced. In some instances in which treatment is not successful, surgery may be performed after the acute phase has passed.

Ambulatory and Home Care.

Patients in whom PUD has been diagnosed have specific needs that must be met to prevent and avoid recurrence or complications.

General instructions should cover aspects of the disease process itself, drugs, possible changes in lifestyle (including diet), and regular follow-up care. Table 44-26 provides a patient and caregiver teaching guide for patients with PUD.

TABLE 44-26

PATIENT & CAREGIVER TEACHING GUIDE
Peptic Ulcer Disease

The following guidelines should be included when teaching the patient and caregiver about peptic ulcer disease. The nurse should:
1. Describe dietary modifications, including avoidance of foods that cause epigastric distress. These foods may include black pepper, spicy foods, and acidic foods. Carbonated beverages and caffeine should also be avoided. 2. Explain the rationale for avoiding cigarettes. In addition to promoting ulcer development, smoking delays ulcer healing. 3. Emphasize the need to reduce or eliminate alcohol ingestion. 4. Explain the rationale for avoiding OTC drugs unless approved by the patient's health care provider. Many preparations contain ingredients, such as ASA (Aspirin), that should not be taken unless approved by the health care provider. The patient should check with the health care provider regarding the use of nonsteroidal anti-inflammatory drugs. 5. Explain the rationale for not interchanging brands of antacids and H_2-receptor blockers that can be purchased OTC without checking with the health care provider. Doing so can lead to harmful adverse effects. 6. Emphasize the need to take all medications as prescribed, including both antisecretory and antibiotic drugs. Failure to take medications as prescribed can result in relapse. 7. Explain the importance of reporting any of the following: • Bloody emesis or tarry stools • Increase in epigastric pain • Increased nausea or vomiting 8. Describe the relationship between symptoms and stress. Stress-reducing activities and relaxation strategies are encouraged. 9. Encourage patient and caregiver to share concerns about lifestyle changes and living with a chronic illness.

ASA, acetylsalicylic acid; *OTC*, over-the-counter.

Knowing the cause of the ulcer and understanding the disease process may motivate a patient to become more involved in care and to adhere to the therapy regimen. The patient must understand the dietary modifications and why they are important for recovery and health maintenance. The nurse and the dietitian should elicit a dietary history from the patient and plan for ways that dietary modifications can be easily incorporated into the patient's home and work setting. The patient who is following a diet prescribed for

another illness needs to know how to balance the two so that neither condition is harmed by dietary interventions.

Patients do not always give the health care provider accurate information regarding habitual use of alcohol or cigarettes. The nurse should provide useful information about the detrimental effects of alcohol and cigarettes on ulcer disease and ulcer healing and provide resources on cessation and rehabilitation programs.

The nurse should teach the patient about prescribed drugs, including their actions, adverse effects, and inherent dangers if omitted for any reason. The patient should know why OTC drugs (e.g., ASA [Aspirin]) should not be taken unless approved by the health care provider. Because antacids and some H_2R blockers may be bought without a prescription, the patient must be informed that interchanging brands without checking with the health care provider or nurse can lead to harmful adverse effects.

Efforts should be made to obtain more information about the patient's psychosocial status. Knowledge of lifestyle, occupation, and coping behaviours can be helpful to the plan of care. The patient may be reluctant to talk about personal subjects, the stress experienced at home or on the job, the usual methods of coping, or dependence on drugs or alcohol. Unfortunately, the patient often does not recognize the relationship between lifestyle or occupation and ulcer disease. It is important to listen for subtle clues from the patient's statements and to observe for behaviours that broaden the database of what is known about the patient.

The need for long-term follow-up care must be stressed. Because successful treatment is frequently followed by a recurrence of the ulcer disease, patients should be encouraged to seek immediate intervention if symptoms of the disease come back. Patients who have recurrence of ulcer disease after initial healing must learn to live with a disease that is chronic. They may be angry and frustrated, especially if the prescribed mode of therapy has been faithfully followed and yet has failed to prevent the recurrence or extension of the disease process.

Unfortunately, many patients do not comply with the plan of care originally designed, and they experience repeated exacerbations. Patients quickly learn that they often experience no discomfort when

they omit prescribed drugs or indulge in occasional dietary indiscretions. Consequently, they make no or little alteration in lifestyle. After an acute exacerbation, the patient is often more amenable to following the plan of care and open to suggestions for changes in lifestyle. Changes, such as smoking cessation and alcohol abstinence, are difficult for many people, and the idea of making them may be met with resistance. The patient may fare better from a reduction in his or her use of these substances rather than from total elimination. Although alcohol and smoking are known to interfere with ulcer healing, they frequently serve as coping mechanisms. From the patient's point of view, the distress caused by their total elimination may outweigh the benefits to be gained from abstention. The goal, however, should always be total cessation. A patient with chronic ulcers must be aware of the complications that may result from the disease, the clinical manifestations indicating their presence, and what to do about them until the health care provider can be seen.

Evaluation

Expected outcomes for the patient with PUD are addressed in NCP 44-2 on the Evolve website.

Collaborative Therapy: Surgical Therapy for Peptic Ulcer Disease

Because of the use of antisecretory and antibiotic agents, surgery for PUD is uncommon. Surgery is performed on patients with complications that are unresponsive to medical management or who have concerns about gastric cancer.

A variety of surgical procedures are used to treat ulcer disease. They usually involve a partial gastrectomy, vagotomy, or pyloroplasty. Partial gastrectomy with removal of the distal two-thirds of the stomach and anastomosis of the gastric stump to the duodenum is called a *gastro-duodenostomy,* or *Billroth I* operation (Figure 44-18). Partial gastrectomy with removal of the distal two-thirds of the stomach and anastomosis of the gastric stump to the

jejunum is called a *gastro-jejunostomy,* or *Billroth II* operation. In both procedures, the antrum and the pylorus are removed. Because the duodenum is bypassed, the Billroth II operation is the preferred surgical procedure to prevent recurrence of duodenal ulcers.

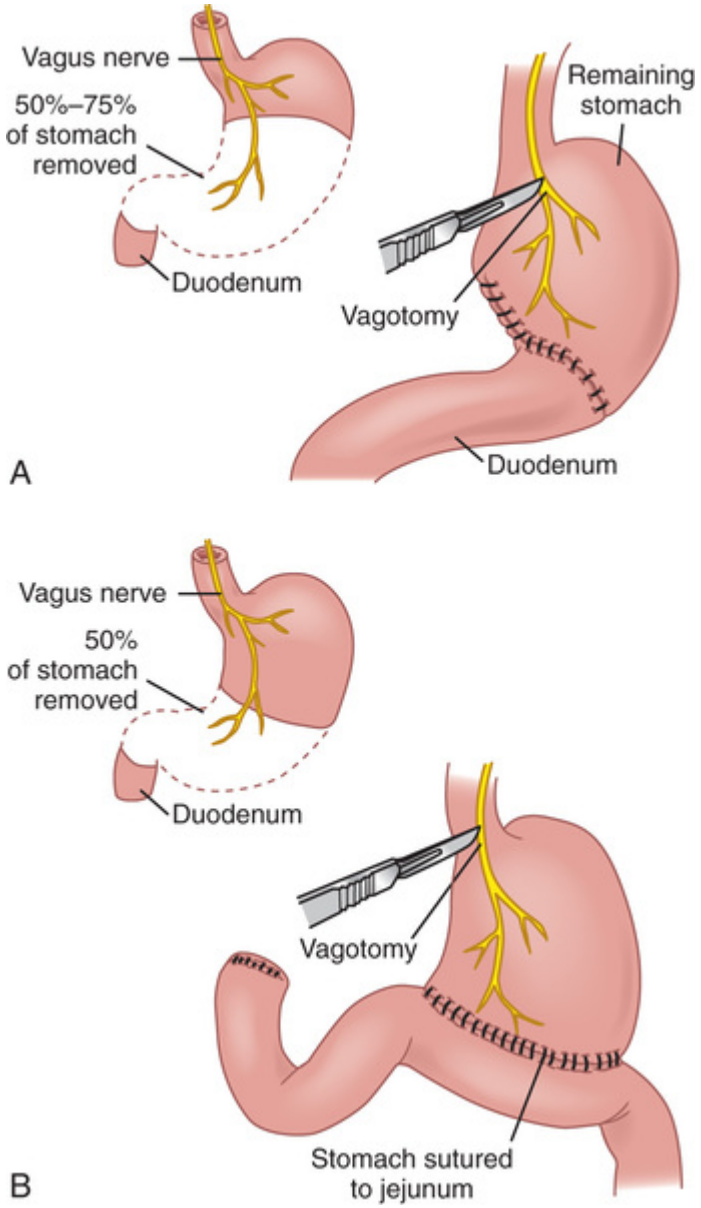

FIGURE 44-18 **A,** Billroth I procedure (subtotal gastric resection with gastro-duodenostomy anastomosis). **B,** Billroth II procedure (subtotal gastric resection with gastro-jejunostomy anastomosis).

Vagotomy is the severing of the vagus nerve, either totally (truncal) or selectively at some point in its innervation to the stomach. In a truncal vagotomy, both the anterior and the posterior trunks are severed. *Selective vagotomy* consists of cutting the nerve at a particular branch of the vagus nerve, resulting in denervation of only a portion of the stomach, such as the antrum or the parietal cell mass.

Pyloroplasty consists of surgical enlargement of the pyloric sphincter to facilitate the easy passage of contents from the stomach. It is most commonly done after vagotomy or to enlarge an opening that has been constricted from scar tissue. A vagotomy decreases gastric motility and, subsequently, gastric emptying. A pyloroplasty accompanying vagotomy increases gastric emptying.

Postoperative Complications.

The most common postoperative complications from peptic ulcer surgery are dumping syndrome, postprandial hypoglycemia, and bile reflux gastritis.

Dumping Syndrome.

Dumping syndrome, in which patients experience vagal symptoms after a meal, such as generalized weakness or dizziness, is the direct result of surgical removal of a large portion of the stomach and the pyloric sphincter. These changes drastically reduce the reservoir capacity of the stomach. Although dumping syndrome is more commonly experienced after a Billroth II procedure, it can occur after any gastric reconstruction and vagotomy.

Dumping syndrome is associated with meals having a hyperosmolar composition. Normally, gastric chyme enters the small intestine in small amounts, and shifts in fluid from the extracellular space are minimal. After surgery, however, the stomach no longer has control over the amount of gastric chyme entering the small intestine. Consequently, a large bolus of hypertonic fluid enters the intestine and results in fluid being drawn into the bowel lumen. This creates a decrease in plasma volume. A secondary consequence of this fluid shift is distension of the bowel lumen, which stimulates intestinal motility and the urge to defecate.

Approximately one-third to one-half of patients experience dumping syndrome after peptic ulcer surgery. The onset of symptoms occurs at the end of a meal or within 15 to 30 minutes after eating. The patient usually describes feelings of generalized weakness, sweating, palpitations, and dizziness. These symptoms are attributed to the sudden decrease in plasma volume. The patient reports abdominal cramps, borborygmi (audible abdominal sounds produced by hyperactive intestinal peristalsis), and the urge to defecate. These manifestations usually last for no longer than an hour after meals.

Postprandial Hypoglycemia.

Postprandial hypoglycemia is considered a variant of the dumping syndrome because it is the result of uncontrolled gastric emptying of a bolus of fluid high in carbohydrate into the small intestine. The bolus of concentrated carbohydrate results in hyperglycemia and the release of excessive amounts of insulin into the circulation. A secondary hypoglycemia then occurs, with symptoms appearing about 2 hours after meals. The symptoms experienced are the ones observed in any hypoglycemic reaction and include sweating, weakness, mental confusion, palpitations, tachycardia, and anxiety.

Bile Reflux Gastritis.

Gastric surgery that involves the pylorus, either reconstruction or removal, can result in reflux alkaline gastritis. Prolonged contact with bile, especially bile salts, causes damage to the gastric mucosa. Chronic gastritis of this form may result in the backwards diffusion of H^+ through the gastric mucosa. Paradoxically, peptic ulcer may recur after surgical treatment that was intended as a cure.

The symptoms associated with reflux alkaline gastritis are continuous epigastric distress that increases after meals. Vomiting relieves the distress but only temporarily. The administration of cholestyramine, either before or with meals, has met with success. Cholestyramine binds with the bile salts that are the source of irritation in this condition. Aluminum hydroxide antacids have also been used in the treatment of this condition.

Nutritional Therapy.

Discharge planning and instruction should be started as soon as the immediate postoperative period is successfully passed. Dietary instructions may be given by the dietitian and reinforced by the nursing staff. Because the stomach's reservoir has been greatly diminished after gastric resection, the meal size must be reduced accordingly. The patient should be advised to stop drinking fluids with meals. Dry foods with a low-carbohydrate content and moderate protein and fat content are better tolerated initially. These dietary changes, with the incorporation of a short rest period after each meal, reduce the likelihood of dumping syndrome. Reassurance that following these dietary measures will result in cessation of these symptoms within a few months is essential for long-term adherence to instructions.

Postprandial hypoglycemic reaction can be avoided if these dietary instructions are followed. The immediate ingestion of sugared fluids or candy relieves the hypoglycemic symptoms. The treatment of this type of hypoglycemia is similar to that of dumping syndrome. To avoid similar occurrences, the patient should be instructed to limit the amount of sugar consumed with each meal and to eat small, frequent meals with moderate amounts of protein and fat. Although only a small percentage of patients experience bile reflux gastritis, all patients must be cautioned to notify the health care provider of any continuous epigastric distress after meals that is similar to that felt before surgery.

With regard to dumping syndrome, the symptoms are self-limiting and often disappear within several months to a year after surgery. Interventions prescribed are diet instruction, rest, and reassurance. As mentioned previously, the diet should consist of small dry feedings daily that are low in carbohydrate, are restricted in refined sugars, and contain moderate amounts of protein and fat (Table 44-27). Fluids should be taken between meals but not with the meal, and the patient should plan rest periods of at least 30 minutes after each meal. The recumbent position is the most beneficial if the patient can arrange it. Reassuring the patient that the unpleasant symptoms are usually of short duration is helpful in gaining

cooperation. A small percentage of patients experience long-term problems and may require further reconstructive surgery.

TABLE 44-27

NUTRITIONAL THERAPY
Postgastrectomy Dumping Syndrome

Purpose
To slow the rapid passage of food into the intestine; to control symptoms of the dumping syndrome (dizziness, sense of fullness, diarrhea, tachycardia), which sometimes occur after a partial or total gastrectomy
Diet Principles
1. Meals are divided into six small feedings to avoid overloading intestines at mealtimes. 2. Fluids should not be taken with meals but at least 30–45 min before or after meals; this helps prevent distension or a feeling of fullness. 3. Concentrated sweets (e.g., honey, sugar, jelly, jam, candies, sweet pastries, sweetened fruit) are avoided because they sometimes cause dizziness, diarrhea, and a sense of fullness. 4. Protein and fats are increased to promote rebuilding of body tissues and to meet energy needs. Meat, cheese, eggs, and milk products are specific foods to increase in the diet. 5. The amount of time these restrictions should be followed varies. The health care provider decides the proper amount of time to remain on this prescribed diet according to the patient's clinical condition and progress.

Nursing Management Surgical Therapy for Peptic Ulcer Disease

Preoperative Care

When surgery is planned with the goal of curing the ulcer disease, the surgeon should provide necessary information about the procedure and the expected outcome so that the patient can make an informed decision. The nurse can help the patient and the family by clarifying and interpreting their questions. A discussion of the surgical procedure accompanied by a diagram or picture showing the anatomical changes that will result should be incorporated into the preoperative teaching plan. Instructions should be clear on what to expect after surgery, including comfort measures, pain relief, coughing and breathing exercises, use of an NG tube, and IV fluid administration (see Chapter 20).

Postoperative Care

Care of the patient after major abdominal surgery is similar to the postoperative care after abdominal laparotomy (see Chapter 45 and NCP 45-2). An NG tube is used to decompress the remaining portion of the stomach to decrease pressure on the suture line and to allow for resolution of edema and inflammation resulting from surgical trauma.

The gastric aspirate must be carefully observed for colour, amount, and odour during the immediate postoperative period. The colour of the aspirate is expected to be bright red at first, with a gradual darkening within the first 24 hours after surgery. Normally, the colour changes to yellow-green within 36 to 48 hours. If the tube becomes clogged during this period, the health care provider may order periodic gentle irrigations with normal saline solution. It is essential that the NG suction is working and that the tube remains patent so that accumulated gastric secretions do not put a strain on the anastomosis. This can lead to distension of the remaining portion of the stomach and result in (a) rupture of the sutures, (b) leakage of

gastric contents into the peritoneal cavity, (c) hemorrhage, and (d) possible abscess formation. If the tube must be replaced or repositioned, the health care provider must be called to perform this task because of the danger of perforating the gastric mucosa or disrupting the suture line.

The nurse observes the patient for signs of decreased peristalsis and lower abdominal discomfort that may indicate impending intestinal obstruction. Accurate intake and output records must be kept. Vital signs are monitored and recorded every 4 hours.

The patient is kept comfortable and free of pain by the administration of the prescribed drugs and by frequent changes in position. The incision is relatively high in the epigastrium and may interfere with deep-breathing and coughing measures. Splinting the area with a pillow while gently and persistently encouraging the patient to put forth the best efforts possible helps prevent pulmonary complications. Splinting also protects the abdominal suture line from rupturing during coughing. The dressing must be observed for signs of bleeding or odour and drainage indicative of an infection. Ambulation is encouraged and is increased daily.

While the NG tube is connected to suction equipment, IV therapy is maintained. Potassium and vitamin supplements are added to the infusion until oral feedings are resumed. Before the NG tube is removed, the patient starts oral feedings of clear liquids to determine the tolerance level. The stomach is aspirated within 1 or 2 hours to assess the amount remaining and its colour and consistency. When fluids are well tolerated, the tube is removed, and fluids are increased in frequency with a slow progression to regular foods. The regimen of six small meals a day is begun.

Pernicious anemia is a long-term complication of total gastrectomy and may occur after partial gastrectomy. Pernicious anemia is caused by the loss of intrinsic factor, which is produced by the parietal cells. Depending on the amount of parietal cell mass removed in surgery, the patient may eventually require regular administration of cobalamin (vitamin B_{12}). (Cobalamin deficiency and pernicious anemia are discussed in Chapter 33.)

PUD is a chronic problem, and ulcers can recur, especially at the site of the anastomosis. Adequate rest, nutrition, and avoidance of

known irritants and stressors are keys to complete recovery. Avoiding the use of drugs not prescribed by the health care provider is re-emphasized, along with restrictions on smoking and alcohol use. If the patient is willing to make these kinds of adjustments in lifestyle, rehabilitation is more likely to be successful.

Age-Related Considerations

Peptic Ulcer Disease

The incidence of peptic ulcers and, in particular, gastric ulcers in patients older than 60 years is increasing. This is related to the increased use of NSAIDs. In older adults, pain may not be the first symptom associated with an ulcer. For some patients, the first manifestation may be frank gastric bleeding (e.g., hematemesis, melena) or a decrease in hematocrit. The rates of morbidity and mortality associated with gastric ulcers are higher in older adults than in younger adults because of concomitant health problems (e.g., cardiovascular, pulmonary) and a decreased ability to withstand hypovolemia.

The treatment and management of ulcers in older adults are similar to that in younger adults. An emphasis is placed on prevention of both gastritis and peptic ulcers. This includes teaching patients to take NSAIDs and other gastric-irritating drugs with food, milk, or antacids. Patients may be treated with antisecretory agents (i.e., PPIs or H_2R blockers). They should be instructed to avoid irritating substances, such as alcohol and smoking, and to report abdominal pain or discomfort to the health care provider.

Case Study

Hiatal Hernia

Source: Blend Images/Shutterstock.com.

Patient Profile

Ishleen Chaudry, a 45-year-old elementary school teacher, has had a sliding hiatal hernia for 10 years. Mrs. Chaudry is admitted to the hospital for a hiatal hernia repair.

Subjective Data

- Reports increasing heartburn, especially at night
- Is currently on a bland diet and taking antacids
- Reports of substernal pain and heartburn
- Reports some problems with regurgitation

Objective Data

Physical Examination

- 157 cm tall and weighs 88 kg

Diagnostic Study

- Barium swallow study and an endoscopy revealed a large sliding hiatal hernia.

Collaborative Care

- Mrs. Chaudry underwent a Nissen fundoplication through a laparoscopic approach.

Discussion Questions

1. Explain the pathophysiology of a hiatal hernia. What is the difference between a sliding and a paraesophageal hiatal hernia?
2. What are the characteristic symptoms of a hiatal hernia? Which of these did Mrs. Chaudry have?
3. Describe a Nissen fundoplication procedure. What is the objective of this surgical procedure? Why was a laparoscopic approach used?
4. What are potential postoperative complications, and what nursing measures prevent them?
5. What should be included in a teaching plan for Mrs. Chaudry?
6. ***Priority decision:*** On the basis of the assessment data presented, what are the priority nursing diagnoses? Are there any collaborative problems?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. The daughter of a client calls to tell the nurse that her 85-year-old mother has been nauseated all day and has vomited twice. Before the nurse hangs up and telephones the health care provider to communicate the assessment data, what does the nurse instruct the client's daughter to do?
   a. Administer antispasmodic drugs and observe skin turgor.
   b. Give her mother sips of water and elevate the head of her bed to prevent aspiration.
   c. Offer her mother a high-protein liquid supplement to drink to maintain her nutritional needs.
   d. Offer her mother large quantities of Gatorade to drink because older adults are at risk for sodium depletion.
2. The nurse explains to a patient with Vincent's infection that treatment will include which of the following?
   a. Smallpox vaccinations
   b. Viscous lidocaine rinses
   c. Amphotericin B suspension
   d. Topical application of antibiotics
3. The nurse is involved in health promotion related to oral cancer. Which behaviours are included in the teaching of adolescents with regard to behaviours that put them at risk for oral cancer? *(Select all that apply)*
   a. Avoiding use of perfumed lip gloss
   b. Discouraging use of chewing gum
   c. Avoiding use of smokeless tobacco
   d. Discouraging drinking of carbonated beverages
   e. Avoiding excessive alcohol consumption

4. What information is included when the nurse is explaining gastro-esophageal reflux disease (GERD) to a client with GERD?
   a. Results in acid erosion and ulceration of the esophagus caused by frequent vomiting
   b. Will require surgical wrapping or repair of the pyloric sphincter to control the symptoms
   c. Is the protrusion of a portion of the stomach into the esophagus through an opening in the diaphragm
   d. Often involves relaxation of the lower esophageal sphincter, allowing stomach contents to back up into the esophagus
5. A client who has undergone an esophagectomy for esophageal cancer develops increasing pain, fever, and dyspnea when a full liquid diet is started postoperatively. What are these symptoms most indicative of?
   a. An intolerance to the feedings
   b. Extension of the tumour into the aorta
   c. Leakage of fluid or foods into the mediastinum
   d. Esophageal perforation with fistula formation into the lung
6. The pernicious anemia that may accompany gastritis is caused by which of the following?
   a. Chronic autoimmune destruction of cobalamin stores in the body
   b. Progressive gastric atrophy from chronic breakage in the mucosal barrier and blood loss
   c. A lack of intrinsic factor normally produced by acid-secreting cells of the gastric mucosa
   d. Hyperchlorhydria resulting from an increase in acid-secreting parietal cells and degradation of red blood cells
7. For the client being discharged after an acute episode of gastrointestinal (GI) bleeding, what information would the nurse's teaching plan include?
   a. Taking only drugs prescribed by the health care provider

b. Avoiding taking ASA (Aspirin) with acidic beverages such as orange juice

c. Taking all drugs 1 hour before mealtime to prevent further bleeding

d. Reading all over-the-counter (OTC) drug labels to avoid those containing stearic acid and calcium

8. The nurse is teaching the client and her family about possible causes of peptic ulcers. How does the nurse explain ulcer formation?

a. Caused by a stressful lifestyle and other acid-producing factors such as *Helicobacter pylori*

b. Inherited within families and reinforced by bacterial spread of *Staphylococcus aureus* in childhood

c. Promoted by factors that tend to cause oversecretion of acid, such as excess dietary fats, smoking, and *H. pylori*

d. Promoted by a combination of possible factors that may result in erosion of the gastric mucosa, including certain drugs and alcohol

9. What information should be included in an optimal teaching plan for an outpatient with gastric cancer who is receiving radiation therapy?

a. Cancer support groups, alopecia, and stomatitis

b. Avitaminosis, ostomy care, and community resources

c. Prosthetic devices, skin conductance, and grief counselling

d. Wound and skin care, nutrition, drugs, and community resources

10. Several clients are seen at an urgent care centre with symptoms of nausea, vomiting, and diarrhea that began 2 hours ago while they were attending a large family reunion potluck dinner. What kinds of foods that were ingested should the nurse question the patients specifically about? *(Select all that apply)*

a. Beef

b. Meat and milk

c. Poultry and eggs

d. Home-preserved vegetables

e. Potato salad

1. b; 2. d; 3. c, e; 4. d; 5. c; 6. c; 7. a; 8. d; 9. d; 10. b, e.

CHAPTER 45

Nursing Management

Lower Gastro-Intestinal Problems

Written by, Diana L. Gallagher, Mariann M. Harding

Adapted by, Françoise Verville

LEARNING OBJECTIVES

1. Explain the common etiologies, collaborative care, and nursing management of diarrhea, fecal incontinence, and constipation.
2. Describe the common causes of acute abdominal pain and nursing management of the patient following an exploratory laparotomy.
3. Describe the collaborative care and nursing management of acute appendicitis, peritonitis, and gastro-enteritis.
4. Compare and contrast ulcerative colitis and Crohn's disease, including pathophysiology, clinical manifestations, complications, collaborative care, and nursing management.
5. Differentiate among mechanical, neurogenic, and vascular bowel obstructions, including causes, collaborative care, and nursing management.
6. Describe the clinical manifestations and collaborative management of colorectal cancer.
7. Explain the anatomical and physiological changes and nursing management of the patient with an ileostomy and the patient with a colostomy.

8. Differentiate between diverticulosis and diverticulitis, including clinical manifestations, collaborative care, and nursing management.
9. Compare and contrast the types of hernias, including etiology and surgical and nursing management.
10. Describe the types of malabsorption syndrome and collaborative care.
11. Describe the types, clinical manifestations, collaborative care, and nursing management of anorectal conditions.

Diarrhea

Diarrhea—the frequent passage of loose, watery stools—is not a disease but a symptom. The term *diarrhea* may mean different things to different patients. It is commonly used to denote an increase in stool frequency or volume and an increase in the looseness of stool.

Etiology and Pathophysiology

Causes of diarrhea can be divided into general classifications of decreased fluid absorption, increased fluid secretion, motility disturbances, or a combination of these (Table 45-1). Causes of acute infectious diarrhea are listed in Table 45-2.

TABLE 45-1
CAUSES OF DIARRHEA

Decreased Fluid Absorption
• Oral intake of poorly absorbable solutes (e.g., laxatives) • Maldigestion and malabsorption • Mucosal damage: celiac disease, inflammatory bowel disease, radiation injury, ischemic bowel • Pancreatic insufficiency (e.g., cystic fibrosis) • Intestinal enzyme deficiencies (e.g., lactase) • Bile salt deficiency • Decreased surface area (e.g., intestinal resection, short gut syndrome)
Increased Fluid Secretion
• Infectious: bacterial endotoxins (e.g., cholera, *Escherichia coli, Shigella, Salmonella, Staphylococcus, Clostridium difficile,* viral agents [rotavirus], and parasitic agents [*Giardia lamblia*]) • Drugs: laxatives, antibiotics, suspensions, or elixirs containing sorbitol • Foods: candy, gum, and mints containing sorbitol • Hormonal: vasoactive intestinal polypeptide secretion from adenoma of the pancreas; gastrin secretion caused by Zollinger–Ellison syndrome; calcitonin secretion from carcinoma of the thyroid • Tumour: villous adenoma
Motility Disturbances
• Irritable bowel syndrome: ↑ visceral sensitivity and transit • Diabetic enteropathy: ↑ transit secondary to autonomic neuropathy • Gastrectomy: ↑ transit as a result of dumping syndrome

TABLE 45-2
CAUSES OF ACUTE INFECTIOUS DIARRHEA

	Onset	Duration	Symptoms and Signs
Viral			
Rotavirus	18–24 hr	3–8 days	Fever, vomiting, and profuse watery diarrhea
Norwalk virus	18–24 hr	24–48 hr	Nausea, vomiting, diarrhea, stomach cramping
Bacterial			
Escherichia coli	4–24 hr	3–4 days	Four or five loose stools per day, nausea, malaise, low-grade fever
Enterohemorrhagic E. coli (O157:H7)	4–24 hr	4–9 days	Bloody diarrhea, severe cramping, fever
Shigella	24 hr	7 days	Watery stools containing blood and mucus; tenesmus, urgency, severe cramping, fever
Salmonella	6–48 hr	2–5 days	Watery diarrhea, nausea, vomiting, abdominal cramps, fever
Campylobacter species	24 hr	<7 days	Profuse, watery diarrhea; malaise, nausea, abdominal cramps, low-grade fever
Clostridium perfringens	8–12 hr	24 hr	Watery diarrhea, abdominal cramps, vomiting
Clostridium difficile	4–9 days after start of antibiotics	24 hr	Associated with antibiotic treatment; symptoms range from mild, watery diarrhea to severe abdominal pain, fever, leukocytosis, leukocytes in stool
Parasitic			
Giardia lamblia	1–3 wk	Few days to 3 months	Sudden onset; malodorous, explosive, watery diarrhea; flatulence, epigastric pain and cramping, nausea
Entamoeba histolytica	4 days	Weeks to months	Frequent soft stools with blood and mucus (in severe cases, watery stools), flatulence, distension, abdominal cramps, fever, leukocytes in stool
Cryptosporidium	2–10 days	1–6 months	Watery diarrhea, nausea, vomiting, abdominal cramps, weight loss in AIDS

AIDS, acquired immune deficiency syndrome.

Ingestion of infectious organisms is the primary cause of acute diarrhea. Viruses cause most cases of infectious diarrhea. Although viral infections can be deadly, they are usually short lived (48 hours) and mild. Therefore most patients rarely seek treatment.

Infectious organisms attack the intestines in different ways. Some organisms (e.g., *Rotavirus A, Norovirus, G. lamblia*) alter secretion or absorption (or both) of the enterocytes of the small intestine without causing inflammation. Other organisms (e.g., *Clostridium difficile*) impair absorption by destroying cells, cause inflammation in the colon, and produce toxins that also cause damage.

Organisms enter the body in contaminated food (e.g., *Salmonella* organisms in undercooked eggs and chicken) or contaminated

drinking water (e.g., *G. lamblia* in contaminated lakes or pools). Travellers often get diarrhea, especially if they travel to countries with poorer sanitation than their own. An infection can also be transmitted from one individual to another via the fecal–oral route. For example, adult day care workers can transmit infection from one resident to another if they do not wash their hands thoroughly after changing soiled linen.

An individual's susceptibility to pathogenic organisms is influenced by age, gastric acidity, intestinal microflora, and immuno-competence. Older adults are most likely to suffer life-threatening diarrhea. Since stomach acid kills ingested pathogens, medications designed to decrease stomach acid (e.g., proton pump inhibitors and histamine [H_2]-receptor blockers) increase the likelihood that pathogens will survive (Blush & Matzo, 2012).

The healthy human colon contains short-chain fatty acids and bacteria such as *E. coli.* These organisms aid in fermentation and provide a microbial barrier against pathogenic bacteria. Antibiotics kill off the normal flora, making the individual more susceptible to pathogenic organisms. For example, patients receiving broad-spectrum antibiotics (e.g., clindamycin, cephalosporins, fluoroquinolones) are susceptible to pathogenic strains of *C. difficile. C. difficile* is the most serious antibiotic-associated diarrhea and is becoming more prevalent. Probiotics, in particular *Saccharomyces boulardii* and *Lactobacillus,* may be helpful in preventing antibiotic-induced diarrhea in some patients (Johnston, Ma, Goldenberg, et al., 2012).

People who are immuno-compromised because of disease (e.g., human immunodeficiency virus [HIV]) or immuno-suppressive medications are susceptible to gastro-intestinal (GI) tract infection.

Not all diarrhea is due to infection. For example, drugs and specific food intolerances can cause diarrhea. Also, large amounts of undigested carbohydrate in the bowel produce an osmotic diarrhea that promotes rapid transit and prevents absorption of fluid and electrolytes. Lactose intolerance and certain laxatives (e.g., lactulose, sodium phosphate, magnesium citrate) produce an osmotic diarrhea. Bile salts and undigested fats also lead to excessive fluid secretion in

the GI tract. The diarrhea from celiac disease and short bowel syndrome results from malabsorption in the small intestine.

Clinical Manifestations

Diarrhea may be acute or chronic. Acute diarrhea most commonly results from infection. Bacterial or viral infection of the intestine may result in explosive watery diarrhea, tenesmus (spasmodic contraction of the anal sphincter, with pain and persistent desire to defecate), and cramping abdominal pain. Perianal skin irritation may also develop. Systemic manifestations include fever, nausea, vomiting, and malaise. Leukocytes, blood, and mucus may be present in the stool, depending on the causative agent (see Table 45-2). Acute diarrhea is often self-limiting in the adult. Symptoms continue until the irritant or the causative agent is excreted. The mucous membrane lining of the GI tract is composed of epithelial cells, which regenerate following the inflammatory response.

Diarrhea is considered chronic when it persists for at least 2 weeks or when it subsides and returns more than 2 to 4 weeks after the initial episode. Severe diarrhea may be debilitating and life-threatening. A patient may have severe dehydration (water and sodium loss) and electrolyte disturbances (e.g., hypokalemia). Malabsorption and malnutrition are also sequelae of chronic diarrhea. Throughout the world, diarrhea is one of the major causes of death.

Diagnostic Studies

Accurate diagnosis and management of diarrhea require a thorough history, physical examination, and when indicated, laboratory tests. A thorough history, including history of travel, medication use, diet and food allergies, previous surgery and adjunctive therapies, interpersonal contacts, and family history should be obtained. Blood tests may identify anemia, elevated white blood cell (WBC) count, iron and folate deficiencies, elevated liver enzyme levels, and electrolyte disturbances. Stools may be examined for the presence of blood, mucus, WBCs, and ova and parasites. Stool cultures help to identify infectious organisms.

In a patient with chronic diarrhea, measurement of stool electrolytes, pH, and osmolality may help determine whether the diarrhea is related to decreased fluid absorption or increased fluid secretion (secretory diarrhea). Measurement of stool fat and undigested muscle fibre may indicate fat and protein malabsorption conditions, including pancreatic insufficiency. Elevated serum levels of GI hormones such as vasoactive intestinal polypeptide and gastrin may be present in some patients with secretory diarrhea. Endoscopy may be used to examine the mucosa and to obtain specimens via biopsy for examination. Upper and lower radiographic studies with barium contrast may be helpful in detecting mucosal disease as well as structural abnormalities.

Collaborative Care

The treatment of diarrhea is based on the cause and aimed at replacing fluid and electrolytes and decreasing the number, volume, and frequency of stools. Oral solutions containing glucose and electrolytes (e.g., Pedialyte) may be sufficient to replace losses from mild diarrhea. In situations of severe diarrhea, parenteral administration of fluids, electrolytes, vitamins, and nutrition is warranted.

Once the cause of the diarrhea has been determined, pharmaceutical agents may be given to coat and protect mucous membranes, absorb irritating substances, inhibit GI motility, decrease intestinal secretions, and decrease central nervous system stimulation of the GI tract (Table 45-3). Patients with infectious diarrhea are not given antidiarrheal agents because of the potential of prolonging exposure to the infectious agent. Regardless of the cause of diarrhea, antidiarrheal drugs should not be given for a prolonged time.

TABLE 45-3

DRUG THERAPY
Antidiarrheal Drugs

Type	Mechanism of Action	Examples
Demulcent	Soothes, coats, and protects mucous membranes	bismuth subsalicylate* (Pepto-Bismol); calcium polycarbophil
Anticholinergic (combination products)	Inhibits GI motility	diphenoxylate with atropine sulphate (Lomotil), loperamide (Imodium)†‡
Antisecretory	Decreases intestinal secretion	octreotide (Sandostatin), a synthetic analogue of somatostatin
Opioid	Decreases CNS stimulation of GI tract motility and secretion; directly inhibits GI motility	codeine
Probiotics	Alters balance of intestinal flora	*Saccharomyces, Lactobacillus*

*Also inhibits bacterial activity.

†Also absorbent, which contributes to the adhesiveness of the stool.

‡Has cholinergic and noncholinergic actions.

CNS, central nervous system; *GI*, gastro-intestinal.

Antibiotics are reserved for treating specific bacterial organisms. Antibiotics can cause diarrhea by altering the normal bowel flora. Patients receiving antibiotics (e.g., clindamycin) are susceptible to *Clostridium difficile (C. difficile)* infection.

C. difficile is a Gram-positive, spore-forming bacterium that causes diarrhea and serious intestinal problems such as pseudomembranous colitis (Goldberg, Bhalodia, Jacob, et al., 2015). *C. difficile* is the most common cause of infectious diarrhea in the developed world and one of the most common infections in both hospitals and long-term care facilities in Canada. Health care workers should follow infection control precautions to prevent transmission of *C. difficile* from patient to patient (Table 45-4). Symptoms of *C. difficile* include watery diarrhea with or without blood (at least three bowel movements per day for 2 or more days), fever, loss of appetite, nausea, and abdominal pain or tenderness.

TABLE 45-4

HANDWASHING TO PREVENT HEALTH CARE–ASSOCIATED INFECTIONS

The Four Moments for Hand Hygiene in Health Care
1. BEFORE initial patient–patient environment contact
2. BEFORE aseptic procedure
3. AFTER body fluid exposure risk
4. AFTER patient–patient environment contact

Source: Adapted from Public Health Ontario. (2016). Just clean your hands—your 4 moments for hand hygiene. Retrieved from *http://www.publichealthontario.ca/en/BrowseByTopic/InfectiousDiseases/JustCleanYourHands/Pages/Just-Clean-Your-Hands.aspx?_ga=1.252110089.1468344323.1452279958*.

This bacterium has been found to be present in normal bowel flora as well as in the genito-urinary tract, in abdominal wounds, and on the skin of hospital workers. Patients entering hospitals may already be colonized with *C. difficile,* although healthy people are not usually vulnerable to the organism. Prolonged antibiotic therapy, cytotoxic chemotherapy, and advanced age are risk factors that may affect the bowel's resistance to colonization or its ability to suppress competing organisms, thus enhancing the growth of *C. difficile.* Laboratory confirmation may be made on the basis of a single, unpreserved stool sample. Metronidazole (Flagyl) is the first-line therapy for this infection, followed by vancomycin. Fidaxomicin (Dificid) is also approved to treat *C. difficile*, but the cost precludes its use as a first line agent (Leong & Zelenitsky, 2013).

Nursing Management Acute Infectious Diarrhea

Nursing Assessment

Nursing assessment should begin with a thorough history and physical examination (Table 45-5). The patient should be asked to describe the stool pattern and associated symptoms. Questions should focus on duration of diarrhea and frequency, character, and consistency of stool. A medication history should include use of antibiotics, laxatives, and other drugs known to cause diarrhea. Recent travel, stress, and health and family illnesses should be discussed. Dietary history should include questions about eating habits, appetite, and food intolerances, especially milk and dairy products, as well as food preparation practices.

TABLE 45-5
NURSING ASSESSMENT
Diarrhea

Subjective Data
Important Health Information
Past health history: Recent travel, infections, stress; diverticulitis or malabsorption; metabolic disorders; inflammatory bowel disease; irritable bowel syndrome; chronic laxative abuse *Medications:* Use of laxatives, magnesium-containing antacids, sorbitol-containing suspensions or elixirs, antibiotics, methyldopa, digitalis, colchicine; OTC antidiarrheal medications *Surgery or other treatments:* Stomach or bowel surgery, radiation
Symptoms
• Malaise • Food intolerances; anorexia, nausea, vomiting; weight loss; thirst • Increased stool frequency, volume and looseness; change in colour and character of stools; steatorrhea, abdominal bloating; decreased urinary output • Abdominal tenderness, abdominal pain and cramping; tenesmus
Objective Data
General
Lethargy, sunken eyeballs, fever, malnutrition
Integumentary
Pallor, dry mucous membranes, poor skin turgor, perianal irritation
Gastro-Intestinal
Frequent soft to liquid stools that may alternate with constipation; altered stool colour; abdominal distension, hyperactive bowel sounds; presence of pus, blood, mucus, or fat in stools; fecal impaction
Urinary Tract
Decreased output, concentrated urine
Possible Findings
Abnormal serum electrolyte levels; anemia; leukocytosis; eosinophilia, hypoalbuminemia; positive stool cultures; presence of ova, parasites, leukocytes, blood, or fat in stool; abnormal sigmoidoscopic or colonoscopic findings; abnormal lower GI series (barium enema study)

GI, gastro-intestinal; *OTC*, over-the-counter.

Physical examination begins with obtaining vital signs, height, and weight. The patient's skin should be inspected for decreased turgor, dryness, and areas of breakdown. The abdomen should be inspected for distension, auscultated for bowel sounds, and palpated for tenderness.

Nursing Diagnoses

Nursing diagnoses for the patient with acute infectious diarrhea may include, but are not limited to, the following:

- *Diarrhea* related to *infection*

- *Deficient fluid volume* related to *insufficient fluid intake, excessive fluid loss through abnormal route*

For additional information on nursing diagnoses for diarrhea, see those presented in Nursing Care Plan (NCP) 45-1, available on the Evolve website.

Planning

The overall goals are that the patient with diarrhea will (1) not transmit the microorganism causing the infectious diarrhea, (2) cease having diarrhea and resume normal bowel patterns, (3) have normal fluid and electrolyte and acid–base balance, (4) have normal nutritional intake, and (5) have no perianal skin breakdown.

Nursing Implementation

Adherence to appropriate infection control practices and precautions (see Chapter 17, Table 17-8) is important, and all cases of acute diarrhea should be considered infectious until the cause is determined. The use of precautions is effective in reducing the spread of infectious diarrhea.

Handwashing is the most important measure in preventing the transfer of microorganisms. Hands should be washed before and after contact with each patient and when body fluids of any kind are handled. The patient should be taught the principles of hygiene, infection control practices and precautions, and the potential dangers of an illness that is infectious to themselves and others. Family and visitors should also be advised of precautions. Proper handling, cooking, and storage of food should be discussed with the patient suspected of having infectious diarrhea.

Best practice guidelines for the management of *C. difficile* (see the Resources at the end of this chapter) state that all patients suspected of having *C. difficile* should be placed in a single room with dedicated toileting facilities such as a private bathroom or individual commode chair. When the number of patients with *C. difficile* exceeds the institution's single-room capacity, those patients with

confirmed *C. difficile* may share a room. For patients in multi-bed rooms, the following precautions should be observed:

1. Signage indicating the precautions to be used should be visibly displayed.
2. A barrier supply cart should be easily accessible.
3. A laundry hamper should be placed as close to the patient's bed space as possible.
4. A commode chair should be dedicated for the patient's use.

Signage indicating that contact precautions are to be used should be posted on the door of any room of a patient with suspected or confirmed *C. difficile.* The nurse should ensure that appropriate environmental cleaning is taking place, including twice-daily cleaning with a hospital-grade disinfectant of all horizontal surfaces in the room and all items within reach of patients with suspected or confirmed *C. difficile.* Visitors should receive instruction from the nurse regarding the nature of *C. difficile* and the importance of hand hygiene and how to properly carry it out. Soap and warm water is recommended because alcohol-based hand sanitizers do not effectively destroy *C. difficile* spores. If a visitor is providing care for a patient or having significant contact with the patient's immediate environment, the visitor should wear gloves and gown. The visitor should also receive instruction from the nurse on the correct use of personal protective equipment and be instructed not to use the patient's toilet or go into other patients' rooms. Chapter 17 discusses contact precautions.

Fecal Incontinence

Etiology and Pathophysiology

Fecal incontinence, or the involuntary passage of stool, may result from multiple causes (Table 45-6). It is important to have an understanding of normal fecal continence to understand fecal incontinence. Normally, fecal contents pass from the sigmoid colon into the rectum, causing rectal distension. Sensory (stretch) receptors in the muscles surrounding the rectum provide the sensation of

rectal filling. This causes a reflex relaxation of the internal anal sphincter and contraction of the external anal sphincter. Sensory receptors in the epithelium of the anal canal can usually distinguish among solid, liquid, and gas. The combination of contraction of the abdominal muscles, relaxation of the pelvic muscles, squatting (which straightens the anorectal angle), and voluntary relaxation of the external anal sphincter allows for elimination of feces. Therefore, motor (contraction of muscles) or sensory (ability to perceive presence of stool or to experience the urge to defecate) problems or their combination can result in fecal incontinence. In addition, fecal incontinence can be secondary to **fecal impaction,** which is an accumulation of hardened feces in the rectum or the sigmoid colon that the individual is unable to move. Fecal incontinence caused by fecal impaction is a common problem in older adults.

TABLE 45-6
CAUSES OF FECAL INCONTINENCE

Traumatic	**Inflammatory**
• Anorectal surgery • Fistulectomy • Hemorrhoidectomy • Abdominal surgery (e.g., nerve injury) • Traumatic injuries (e.g., gunshot wounds, impalements, foreign body insertion) • Traumatic childbirth • Sexual abuse • Anal intercourse	• Infection • Radiation • Inflammatory bowel disease
	Other
	• Diarrhea • Fecal impaction • Loss of rectal elasticity
	Pelvic Floor Dysfunction • Medications • Rectal prolapse
Neurological	**Functional**
• Degenerative diseases • Dementia • Diabetes mellitus (secondary to neuropathic changes) • Multiple sclerosis • Spinal cord injuries • Spinal cord tumour • Stroke	• Physical or mobility impairments affecting toileting ability

Diagnostic Studies and Collaborative Care

The diagnosis and effective management of fecal incontinence require a thorough health history and physical examination, with appropriate diagnostic studies. In all cases, a rectal examination

should be performed, followed by examination with a flexible sigmoidoscope. Fecal impaction, internal prolapse, increased perineal descent, and rectocele may be identified by rectal examination. If the impaction is higher in the colon, an abdominal radiograph may be helpful. Flexible sigmoidoscopy may identify inflammation, tumours, fissures, and other sigmoid–rectal pathological conditions. Other studies may include barium enema, colonoscopy, endorectal ultrasound, and anorectal manometry.

Treatment of incontinence depends on the cause. If fecal incontinence is related to noninfectious diarrhea, dietary changes may be advised, and antidiarrheal agents may be prescribed. In contrast, the management of rectoceles (a defect of the recto-vaginal septum) may include teaching the patient exercises to strengthen the muscles of the pelvic floor (Kegel exercises), insertion of a vaginal pessary, and in some cases, surgery.

Fecal impaction usually resolves after manual disimpaction and use of lubricants and cleansing enemas. To prevent recurrence, a high-fibre diet (see Table 45-9, later in this chapter), along with increased fluid intake, should be given unless contraindicated. Dietary fibre supplements or bulk-forming laxatives (e.g., psyllium) can improve continence by increasing stool bulk, firming consistency, and promoting sensation of rectal filling. Protection of perianal skin and the use of appropriate fecal containment devices (e.g., perianal pouches or adult briefs) will help to protect skin and promote patient comfort and dignity.

Biofeedback therapy may be an option for the patient. This therapy is intended to (1) improve awareness of rectal sensation and coordination of the internal and external anal sphincters and (2) increase the strength of contraction of the external sphincter (Fargo & Latimer, 2012). Biofeedback training requires adequate mental status and motivation to learn. It is a safe, painless, and inexpensive treatment for fecal incontinence. (Biofeedback is discussed further in Chapter 12.)

Surgery (e.g., sphincter repair procedures, diverting ostomy) should be considered only when conservative treatment fails.

Nursing Management Fecal Incontinence

Nursing Assessment

Fecal incontinence is not only an embarrassment to the patient but also a potential hazard to the patient's normal skin integrity. An assessment of the patient's general condition is necessary to identify the best alternative for managing the patient with fecal incontinence. The health care provider should identify normal bowel habits and current symptoms, including stool frequency and consistency. Information about the passage of blood or mucus, pain during defecation, and a feeling of incomplete evacuation is sought. The health care provider determines whether the patient has defecation urgency and is aware of leaking stool. It should be determined whether there is coexisting urinary incontinence.

Assessment should also include history of multiple or traumatic childbirths, previous anorectal surgery, and injury. A neurological assessment that includes evaluation of mental status can be helpful in identifying the most effective treatment for the patient.

Nursing Diagnoses

Nursing diagnoses for the patient with fecal incontinence include, but are not limited to, the following:

- *Bowel incontinence* related to *generalized decline in muscle tone* (dysfunctional rectal sphincter)
- *Risk for falls* related to *diarrhea, incontinence*
- *Toileting self-care deficit* related to *impaired ability to transfer, impaired mobility*
- *Risk for situational low self-esteem* related to *decrease in control over environment* (inability to

control bowel movements, hospital isolation protocols)
- *Risk for impaired skin integrity* as evidenced by *excretions* (incontinence of stool)
- *Social isolation* related to *social behaviour incongruent with norms* (bowel incontinence)

Planning

The overall goals are that the patient with fecal incontinence will (1) have normal bowel control, (2) maintain perianal skin integrity, and (3) not suffer any self-esteem problems related to problems with bowel control.

Nursing Implementation

If appropriate, prevention and treatment of fecal incontinence may be managed by implementing a bowel training program. Bowel training is effective in many patients because, once the bowel is empty, the rectum does not fill until the next day. The lack of stool in the rectum reduces the likelihood of incontinence. The patient should be assisted to a commode or bathroom at a regular time daily to assist with re-establishment of bowel regularity. A good time to establish this pattern is within 30 minutes after breakfast. Most individuals experience an urge to defecate following the first meal of the day because of the gastrocolic reflex. If the usual bowel habits differ from this pattern, efforts should be made to adhere to the patient's individual timing. Patients are at risk for injury owing to falls related to their inability to control bowel evacuation and attempting to reach a bathroom in time. Safety measures should be implemented to prevent this. Best practice guidelines on the prevention of falls are available from the Registered Nurses' Association of Ontario (RNAO) (2011a).

If these techniques are ineffective in re-establishing bowel regularity, a bisacodyl (Dulcolax) or glycerin suppository or a small phosphate enema may be administered 15 to 30 minutes before the

usual evacuation time. These preparations stimulate the anorectal reflex and often can be discontinued when a regular pattern is re-established.

Maintenance of skin integrity is important, especially in patients who are bedridden or older-adult patients. Nursing management may necessitate the use of fecal containment devices, incontinence briefs, and meticulous skin care. Rectal tubes and catheters are usually not recommended because their use for an extended period may decrease responsiveness of the rectal sphincter and cause ulceration or perforation of the rectal mucosa. Use of incontinence briefs may be helpful in maintaining skin integrity if changed frequently. Meticulous cleaning after each stool is required. Gentle washing, rinsing, thorough drying, and application of a protective barrier cream with each bowel movement are essential to the maintenance of skin integrity. Monitor the skin for the development of yeast or fungal infections.

Perianal pouching is an alternative in the management of fecal incontinence. These are pouches similar in appearance to one-piece ostomy pouches that are designed to be applied over the anus, allowing for the collection of stool. Pouching provides skin protection, odour control, fecal containment, comfort, and dignity. Because odour is often a problem, deodorant sprays and room deodorizers may be used. For the patient who is ambulatory, a regular chair or special tilt commode wheelchair may be used. Regardless of the patient's mobility, the nurse must make sure the skin is clean and intact and the odour is controlled.

Constipation

Constipation is a decrease in frequency of bowel movements from what is “normal” for the individual; hard, difficult-to-pass stools; a decrease in stool volume; retention of feces in the rectum; or some combination of these problems. Because individuals vary, it is important to compare current symptoms with the patient's normal pattern of elimination. It is also important to remember that changes in bowel habits may indicate bowel obstruction produced by an underlying disease process, such as a tumour.

Etiology and Pathophysiology

Constipation may be caused by insufficient dietary fibre, inadequate fluid intake, medications, and lack of exercise. If proper preventive measures are subsequently taken, constipation should not recur. Constipation may also occur as a result of behaviours related to sociocultural beliefs, environmental constraints, ignoring the urge to defecate, chronic laxative abuse, and multiple organic causes. Changes in diet, mealtime, or daily routines are a few environmental factors that may cause constipation. Depression and stress can also result in constipation.

Some patients believe that they are constipated if they do not have a daily bowel movement. This can result in chronic laxative use and subsequent cathartic colon syndrome. In this condition, the colon becomes dilated and *atonic* (lacking muscle tone).

Ignoring the urge to defecate for a time causes the muscles and mucosa in the rectal area to become insensitive to the presence of feces. In addition, the prolonged retention of feces in the rectum results in drying of the stool because of the absorption of water. The harder and drier the feces, the more difficult they are to expel.

Clinical Manifestations

The clinical presentation of constipation may vary from a chronic discomfort to an acute event mimicking an "acute abdomen." Other clinical manifestations are presented in Table 45-7. Hemorrhoids, or dilated hemorrhoidal veins or varicosities, are the most common complication of chronic constipation. They result from venous engorgement caused by repeated executions of the Valsalva manoeuvre (straining) and venous compression from hard, impacted stool. (Hemorrhoids are further discussed later in this chapter, in the section on anorectal problems.)

TABLE 45-7
CLINICAL MANIFESTATIONS OF CONSTIPATION

• Abdominal distension or bloating • Abdominal pain • Anorexia • Decreased frequency of bowel movements • Hard, dry stool • Headache • Increased flatulence	• Increased rectal pressure • Nausea • Palpable mass • Stone- or rock-shaped stool (fecalith) • Stool with blood • Straining • Tenesmus

The Valsalva manoeuvre is a manoeuvre that involves contraction of the chest muscles on a closed glottis with simultaneous contraction of the abdominal muscles; it is used during straining to pass a hardened stool and may cause serious problems in patients with heart failure, cerebral edema, hypertension, and coronary artery disease. During straining, the patient takes a deep inspiration, the breath is held, and the glottis closes and traps the air. Simultaneously with the contraction of the chest muscles against the closed airway, the abdominal muscles contract and try to push against the colon. Increases in intra-abdominal pressure and intrathoracic pressure occur, reducing venous return to the heart. The heart slows (bradycardia) temporarily, cardiac output is decreased, and there is a transient drop in arterial pressure. When the patient relaxes, there is decreased thoracic pressure and a sudden flow of blood into the heart, causing distension and an increase in heart rate. Immediately, arterial pressure rises momentarily. These changes may be fatal for the patient who cannot compensate for sudden overload of blood flow returning to the heart.

Constipation may contribute to diverticulosis. Diverticula are thought to be caused by increased intraluminal pressure and decreased intestinal compliance. Diverticulosis and diverticulitis are described later in this chapter.

In the presence of *obstipation,* or fecal impaction secondary to constipation, colonic perforation may occur. Perforation, which is life-threatening, causes abdominal pain, nausea, vomiting, fever, and an elevated WBC count. An abdominal radiograph shows the presence of free air, which is diagnostic of perforation. Anal fissures

and rectal mucosal ulcers may also occur as a result of stool stasis or straining.

Diagnostic Studies and Collaborative Care

A thorough history and physical examination should be performed to determine the underlying cause of constipation and initiate treatment. Abdominal radiographs, barium enema, colonoscopy, sigmoidoscopy, and anorectal manometry may be helpful in the diagnosis. Many cases of constipation can be managed with diet therapy, including increased intake of fibre and fluids and an exercise program. Consult a dietitian to review dietary influences. Laxatives (Table 45-8) should be used cautiously because with chronic overuse, they may contribute to ongoing constipation. A stepwise approach for laxative use that progresses from bulk-forming fibre preparations to stimulants is recommended, depending on the acuteness of the constipation episode. Enemas are fast-acting and are beneficial in the immediate treatment of constipation, but their use for long-term treatment of constipation should be limited. Soapsuds enemas should be avoided because they may lead to inflammation of colonic mucosa. Excessive hypotonic enemas with tap water can cause water excess, and sodium phosphate enemas have been associated with electrolyte imbalances. Oil-retention enemas may be used to soften fecal impactions. Biofeedback therapy may benefit patients who are constipated as a result of *anismus* (uncoordinated contraction of the anal sphincter during straining). Methylnaltrexone (Relistor) is a peripheral μ-opiate receptor antagonist that decreases constipation caused by opioid use. The drug is administered subcutaneously. This agent does not block the analgesic effects (Rx Files Academic Detailing Program, 2014).

TABLE 45-8

DRUG THERAPY
Cathartic Agents

Category	Mechanisms of Action	Example	Onset of Action	Comments
Bulk-forming	Absorb water; increase bulk-stimulating peristalsis	Psyllium: Metamucil	Usually within 24 hr	Must be taken with adequate fluids; can increase gas; contraindicated in patients with possible obstruction or known strictures
Stool softeners and lubricants	Lubricate intestinal tract and soften feces, making hard stools easier to pass; do not affect peristalsis	Mineral oil, docusate calcium, docusate sodium (Colace)	Softeners up to 72 hr; lubricants up to 8 hr	Can block absorption of fat-soluble vitamins A, D, E, and K
Saline and osmotic solutions	Cause retention of fluid in intestinal lumen due to osmotic effect	Magnesium salts: magnesium citrate, magnesium hydroxide (milk of magnesia) Sodium phosphates: Fleet enema, Fleet Phospho-Soda oral solution Lactulose Polyethylene glycol saline solutions: PegLyte, GoLYTELY, Colyte	15 min–3 hr	Magnesium-containing products may cause hypermagnesemia in patients with renal insufficiency; sodium phosphate products may cause electrolyte imbalances in patients with renal insufficiency (increased sodium, increased phosphate, decreased calcium)
Stimulants	Increase peristalsis by irritating colon wall and stimulating enteric nerves	Anthraquinone drugs: cascara sagrada, senna (Senokot) bisacodyl (Dulcolax)	Usually within 12 hr	Can cause melanosis coli (brown or black pigmentation of colon); are most widely abused laxatives; should not be used in patients with impaction or obstipation
Selective chloride channel activator	Increases intestinal fluid secretion and motility	lubiprostone (Amitiza)	Usually within 24 hr	Used in the treatment of idiopathic constipation and irritable bowel syndrome with constipation (women only) Contraindicated in patients with history of mechanical GI obstruction

Category	Mechanisms of Action	Example	Onset of Action	Comments
Intestinal secretagogue	Increases fluid secretion and accelerates intestinal transit	linaclotide (Constella)	Usually within 24 hr	Used in the treatment of idiopathic constipation and irritable bowel syndrome with constipation (men and women)

Nurses must educate patients in whom the perception of constipation is related to beliefs and misinformation about bowel function. Appropriate information on normal bowel function must be given and discussed along with information on the adverse consequences of excessive use of laxatives and enemas.

A patient with severe constipation related to bowel motility or mechanical disorders may require more intensive treatment. Diagnostic studies such as anorectal manometry, GI tract transit studies, and sigmoidoscopic rectal biopsies should be performed before treatment.

Nutritional Therapy.

Diet is an important factor in the prevention of constipation. Many patients experience an improvement in their symptoms when they simply increase their intake of dietary fibre and fluids. Dietary fibre is found in two forms: insoluble and soluble in water. Both are contained in most foods, but some foods are higher in soluble fibre (Table 45-9).

TABLE 45-9

NUTRITIONAL THERAPY
High-Fibre Foods*

	Fibre per Serving (g)	Size of Serving	Calories of Serving

*Recommended for patients with diverticulosis, irritable bowel syndrome, constipation, hemorrhoids, atherosclerosis, dyslipidemia, and diabetes mellitus.

Insoluble fibre, which is found in higher concentrations in whole wheat and bran, remains essentially unchanged by the time it reaches the colon. Soluble fibres form gel-like substances that add viscosity to the digested contents, causing decreased gastric emptying and increased transit in the small intestine. When these fibres ferment and form gas, the gas increases stool bulk, promoting defecation and sequestering fluid, which softens stools. Soluble fibre is found in oat bran, fruits, vegetables, and psyllium. Patients should be told that fibre will increase gas production initially but that this effect decreases with time.

The diet should also include a fluid intake of at least 3 000 mL/day, unless contraindicated by cardiac or renal disease. Increasing fibre intake without increasing fluids may predispose the patient to worsening constipation, impaction, or obstruction. The nurse should consult a dietitian to help with patient food preferences and access. The patient's understanding of the diet and the importance of dietary fibre is important for ensuring compliance.

Nursing Management Constipation

Nursing Assessment

Subjective and objective data that should be obtained from a patient with constipation are presented in Table 45-10.

TABLE 45-10

NURSING ASSESSMENT
Constipation

Subjective Data
Important Health Information
Current health history: Chronic laxative or enema abuse; rigid beliefs regarding bowel routine; changes in diet or mealtime; inadequate fibre and fluid intake; immobility; change in daily activity routines; sedentary lifestyle *Past health history:* Colorectal disease, neurological dysfunction, bowel obstruction, environmental changes, cancer, irritable bowel syndrome; history of chronic laxative or enema abuse *Medications:* Use of aluminum and calcium antacids, anticholinergics, antidepressants, antihistamines, antipsychotics, diuretics, opioids, iron, laxatives, enemas
Symptoms
• Malaise • Anorexia, nausea • Hard, difficult-to-pass stool, decrease in frequency and amount of stools; flatus, abdominal distension; tenesmus, rectal pressure; fecal incontinence (if impacted) • Dizziness, headache, anorectal pain; abdominal pain on defecation
Objective Data
General
Lethargy
Integumentary
Anorectal fissures, hemorrhoids
Gastro-Intestinal
Abdominal distension; hypoactive or absent bowel sounds; palpable abdominal mass, usually in LLQ; fecal impaction; small, hard, dry stool; stool streaked with blood
Possible Findings
Positive FOB; abdominal radiograph demonstrating stool in lower colon

FOB, fecal occult blood test; *LLQ*, left lower quadrant.

Nursing Diagnoses

Nursing diagnoses for the patient with constipation can include, but are not limited to, the following:

- *Constipation* related to *decrease in gastrointestional motility, dehydration*

Planning

The overall goals are that the patient with constipation will (1) increase dietary intake of fibre and fluids; (2) have the passage of soft, formed stools; and (3) not have any complications, such as bleeding hemorrhoids.

Nursing Implementation

Nursing management should be based on the patient's symptoms (see Table 45-7) and the assessment of the patient (see Table 45-10). An important role of the nurse is teaching the patient the importance of dietary measures to prevent constipation. A patient and caregiver teaching guide for constipation is presented in Table 45-11. Additional constipation guidelines are readily available, including those developed by the Registered Nurses' Association of Ontario (2011b). Emphasis should be placed on maintenance of a high-fibre diet, increased fluid intake, and a regular exercise program. The patient should be taught to (1) establish a regular meal pattern, (2) maintain a regular time to defecate, and (3) avoid suppressing the urge to defecate. In many people, the urge to defecate occurs after breakfast because of the stimulation of the gastrocolic reflex. The patient should be discouraged from using laxatives and enemas to achieve and maintain fecal elimination.

TABLE 45-11

PATIENT & CAREGIVER TEACHING GUIDE
Constipation

The following guidelines should be included when teaching the patient and caregiver(s) about constipation.
1. Eat dietary fibre. Eat 20 to 30 g of fibre per day. Gradually, over 1 to 2 weeks, increase the amount of fibre eaten. Fibre softens hard stools and adds bulk to stool, promoting evacuation. • Foods high in fibre: raw vegetables and fruits, beans, breakfast cereals (All-Bran, oatmeal) • Fibre supplements: Metamucil, Citrucel, FiberCon 2. Drink fluids. Drink 3 L/day. Drink water or fruit juices; avoid large volumes of caffeinated coffee, tea, and cola. Fluids soften hard stools; caffeine promotes fluid loss through urination. 3. Exercise regularly. Walk, swim, or bike at least three times per week. Contract and relax abdominal muscles when standing or by doing sit-ups to strengthen muscles and prevent straining. Exercise stimulates bowel motility and moves stool through the intestine. 4. Establish a regular time to defecate. First thing in the morning or after the first meal of the day is a good time because people often have the urge to defecate at this time. 5. Do not delay defecation. Respond to the urge to have a bowel movement as soon as possible. Persistently delaying defecation results in hard stools and a decreased "urge" to defecate. More water is absorbed from stool by the intestine over time. The intestine becomes less sensitive to the presence of stool in the rectum. 6. Record your bowel elimination pattern. Record bowel movements on a calendar. Regular monitoring of bowel movement will assist in early identification of a problem. 7. Avoid laxatives and enemas. Do not overuse laxatives and enemas. They may actually promote constipation because the normal motility of the bowel is interrupted and bowel habituation cannot occur.

Proper position is important when defecating. For a patient in bed, the bedpan should be placed and the head of the bed should be elevated as high as the patient can tolerate. For the person who can sit on a toilet, a footstool may be placed in front of the toilet. Placing the feet on the footstool promotes flexion of the hips, which assists in defecation. For those requiring commodes, tilt commodes may provide proper positioning.

The patient with poor muscle tone should be assessed by a physiotherapist for abdominal muscle strength and taught to contract the abdominal muscles several times a day. Sit-ups and straight leg raises can also be used to improve abdominal muscle tone.

Acute Abdominal Pain

Etiology and Pathophysiology

The causes of an acute onset of abdominal pain ("acute abdomen") are varied and can include conditions related to inflammation, peritonitis, obstruction, and internal bleeding (Table 45-12).

TABLE 45-12
CAUSES OF ACUTE ABDOMINAL PAIN

• Abdominal penetrating trauma • Acute ischemic bowel injury • Appendicitis • Blunt abdominal trauma • Bowel obstruction with perforation or necrosis • Cholecystitis • Crohn's disease • Diverticulitis ± peritonitis • Foreign body perforation • Gastritis • Gastro-enteritis • Incarcerated or strangulated hernias	• Mesenteric adenitis • Pancreatitis • Pelvic inflammatory disease • Peptic ulcer • Perforated gastro-intestinal malignancy • Peritonitis • Postcolonoscopy bowel perforation • Ruptured abdominal aneurysm • Ruptured ectopic pregnancy • Ruptured ovarian cyst • Ulcerative colitis ± toxic megacolon • Uterine rupture • Volvulus

Clinical Manifestations

Pain is the presenting symptom of greatest relevance for acute abdominal pain. The patient may also complain of abdominal tenderness, nausea, vomiting, diarrhea, constipation, flatulence, fatigue, fever, and abdominal distension.

Diagnostic Studies and Collaborative Management

Many disorders must be ruled out before a diagnosis is confirmed. Diagnosis begins with a complete history and physical examination. Physical examination should include a rectal and pelvic examination. A complete blood cell count (CBC), urinalysis, an abdominal radiographic examination, and an electrocardiogram (ECG) are done initially. In women of child-bearing age who have acute abdominal pain, pregnancy tests should be performed to rule

out ectopic pregnancy. The findings of these studies may provide some information about the cause of the acute abdomen.

Emergency management of the patient with acute abdominal pain is presented in Table 45-13. The goal of management is to stabilize the patient's condition and to identify and treat the cause. When the patient is seen with an acute condition in the abdomen, the health care provider attempts to make a differential diagnosis because some causes of abdominal pain do not necessitate surgery (see Table 45-12). It was previously thought that pain medication should be withheld because analgesics might obscure progression of clinical manifestations and impede diagnosis. In fact, appropriate pain management that does not result in altered consciousness can decrease diffuse pain and abdominal rigidity and help localize the pain, leading to earlier diagnosis and treatment.

R&M, routine and microscopic.

In addition to being a therapeutic measure, surgery can also be diagnostic. Operative exploration is done, usually after a careful examination, a review of the patient status, and a review of diagnostic test results. Surgical exploration may be done laparoscopically or through an open midline abdominal wound (laparotomy). Direct examination may permit the cause to be identified and allow for completion of the definitive procedure.

Nursing Management Acute Abdominal Pain

Nursing Assessment

Vital signs, including blood pressure and pulse rate, should be taken immediately to determine hypovolemic changes. An elevated temperature may indicate an inflammatory or infectious process. The abdomen should be inspected for distension, masses, abnormal pulsation, rashes, scars, and pigmentation changes. Bowel sounds should be auscultated. Bowel sounds that are diminished, absent, or hyperactive in a quadrant may indicate a complete bowel obstruction, acute peritonitis, or paralytic ileus. Palpation should be gentle.

A thorough assessment of the patient's symptoms should be made to determine onset, location, intensity, duration, frequency, and character of pain. The nurse should determine whether the pain has spread or moved to new locations (quadrants) as well as what makes the pain worse or better. It should also be determined whether the pain is associated with other symptoms, such as nausea, vomiting, changes in bowel and bladder habits, or vaginal discharge in women. Assessment of vomiting should include amount, colour, consistency, and odour of the vomitus. Bowel patterns and habits should also be assessed carefully.

Nursing Diagnoses

Nursing diagnoses for the patient with acute abdominal pain include, but are not limited to, the following:

- *Acute pain* related to *biological injury agent* (inflammation of the peritoneum, abdominal distention)
- *Risk for deficient fluid volume* as evidenced by *insufficient fluid intake* (inflammation or infection)

- *Anxiety* related to *threat to current status, threat of death*

Planning

The overall goals are that the patient with acute abdominal pain will have (1) resolution of the underlying process, (2) relief of abdominal pain, (3) freedom from complications (especially hypovolemic shock), and (4) normal nutritional status.

Nursing Implementation

Nursing interventions are based on the diagnosis and medical or surgical management of the patient. General care for the patient involves management of fluid and electrolyte imbalances, pain, and anxiety.

Acute Intervention

Preoperative Care.

Emergency preparation of the patient with acute abdominal pain is usually limited to a CBC, typing and crossmatching of blood, and clotting studies. Catheterization, administration of medications (e.g., antibiotics), and the passage of a nasogastric (NG) tube may be done in the emergency department or operating room. (General care of the preoperative patient is discussed in Chapter 20.)

Postoperative Care.

Postoperative care depends on the type of surgical procedure performed. The increased use of laparoscopic procedures has reduced the risk for potential postoperative complications related to wound care and altered GI motility. These newer procedures generally result in shorter hospital stays. A general NCP for the postoperative patient is available on the Evolve website for Chapter 22. Nursing care for the patient following a laparotomy is presented in NCP 45-2, also on the Evolve website.

An NG tube may or may not be present in the patient returning from surgery. If present, the NG tube is connected to suction as ordered. The purpose of the NG tube is to empty the stomach of secretions and gas to prevent gastric distension. GI peristaltic activity is often impaired because of the manipulative procedures of the surgery and anaesthesia.

If the upper GI tract has been entered, drainage from the NG tube may be dark brown to dark red for the first 12 hours. Later, it should be light yellowish-brown, or it may have a greenish tinge because of the presence of bile. If a dark red colour continues or if bright red blood is observed, the health care provider should be notified at once of the possibility of hemorrhage. The "coffee grounds" appearance of the drainage is owing to the presence of small amounts of blood that have been chemically altered by gastric secretions.

The NG tube is checked regularly for patency. The tube may become obstructed with mucus, sediment, or blood clots. An order is usually written to irrigate the tube with 20 to 30 mL of tap or sterile water or normal saline solution if needed. An accurate record of intake and output, including emesis and gastric drainage, is essential. The nurse assesses serum electrolyte values and acid–base balance because prolonged gastric suctioning can result in loss of sodium, chloride, potassium, water, and hydrochloric acid.

The NG tube is removed when intestinal peristalsis returns, usually 24 to 72 hours after surgery. Motility of the stomach normally returns within 24 to 48 hours. Motility of the small intestine usually resumes within 12 to 24 hours, whereas return of large intestine motility may take as long as 3 to 5 days. Peristaltic activity can be assessed by auscultation for bowel sounds.

Mouth care and nasal care are essential. The patient tends to breathe through the mouth while the NG tube is in place. In addition, increased nasal secretions and crusting result from mechanical stimulation of the NG tube.

Parenteral fluids are administered to provide the patient with fluids and electrolytes until bowel sounds return. Ice chips may be ordered because they aid in the flow of saliva and prevent a dry mouth and sore throat. When bowel sounds return, fluids and food are increased gradually. Nausea and vomiting are not uncommon

after abdominal surgery and are often self-limiting. Observation is important in determining the cause. Antiemetics such as dimenhydrinate (Gravol), ondansetron (Zofran), or metoclopramide may be ordered.

Abdominal distension and gas pains are also common after surgery; these are owing to swallowed air and impaired peristalsis resulting from immobility, manipulation of abdominal contents during surgery, and adverse effects of anaesthesia. The health care provider should be informed of abdominal distension and rigidity and worsening abdominal pain. Gradually, as intestinal activity increases, distension and gas pains decrease.

Care of Nasogastric and Nasointestinal Tubes.

Nurses may be instructed to insert NG tubes. Insertion is easier if the patient relaxes, takes deep breaths, and swallows when instructed. Once the tube is in place, it is extremely important to (1) confirm placement of the tube (e.g., by aspiration of gastric contents), (2) ensure the tube is properly secured to prevent dislodgement, and (3) provide appropriate nasal and mouth care. When an NG tube is in place, the patient breathes through the mouth, drying the mouth and lips. The nurse should encourage and assist the patient to brush the teeth frequently. Mouthwash and water for the patient to use in rinsing the mouth and petroleum jelly (if the patient is not on oxygen) or water-soluble lubricant for the lips should be provided at the bedside.

The patient's nose should be checked for signs of irritation from the NG tube. This area should be cleaned and dried daily with application of a water-soluble lubricant and retaping of the tube. NG tubes should be checked every 4 hours for patency. Characteristics of the NG losses may differ depending upon the underlying reason for the tube placement. Pale yellow to dark green bile drainage is more likely after abdominal surgery, whereas odoriferous thick drainage with food particles may be seen with bowel obstructions. Hemolyzed sanguineous drainage (often called “coffee grounds” owing to its dark brown, granular appearance) or fresh sanguineous drainage should be reported immediately to the physician or

surgeon. The volume of NG losses should also be monitored. Excessive losses (>500–1 000 mL/24 hr) may have to be replaced with intravenous (IV) fluids and electrolytes to maintain adequate hydration. Generally, NG tubes can be removed once normal bowel function returns (passing of gas and stool) and the patient is no longer vomiting.

Ambulatory and Home Care.

Preparation for discharge begins when the patient returns from the operating room. Instructions to the patient and family should include any modifications in activity, care of the incision, diet, and drug therapy. Small, frequent meals high in calories should be taken initially, with a gradually increased intake of food as tolerated.

Normal activities should be resumed gradually. Some activity restrictions may be required for 6 to 8 weeks. The patient should be aware of possible complications after surgery and should notify the health care provider immediately if vomiting, fever, pain, weight loss, incisional drainage, or changes in bowel function occur.

Evaluation

The expected outcomes are that the patient with acute abdominal pain will have (1) resolution of the cause of the acute abdominal pain; (2) relief of abdominal pain and discomfort; (3) freedom from complications (especially hypovolemic shock and septicemia); and (4) normal fluid, electrolyte, and nutritional status.

Abdominal Trauma

Etiology and Pathophysiology

Injuries to the abdominal area occur most often as a result of blunt trauma (e.g., motor vehicle accident) or penetration injuries, primarily gunshot wounds or stab wounds to the abdomen. Blunt trauma is most common. Regardless of whether it is a blunt or penetration injury, the result is often the same: damage to or alteration of the internal organs.

Common injuries of the abdomen include lacerated liver, ruptured spleen, pancreatic trauma, mesenteric artery tears, diaphragmatic rupture, urinary bladder rupture, great vessel tears, renal injury, and stomach or intestinal rupture. These injuries may result in massive blood loss and hypovolemic shock. Surgery must be performed as early as possible to repair the damaged organs and to stop the bleeding. Common sequelae of intra-abdominal trauma are peritonitis and sepsis, particularly when the bowel is perforated.

Clinical Manifestations

Clinical manifestations of abdominal trauma are (1) guarding and splinting of the abdominal wall; (2) a hard, distended abdomen (may indicate intra-abdominal bleeding); (3) decreased or absent bowel sounds; (4) contusions, abrasions, or bruising over the flanks or the abdomen; (5) severe abdominal pain; (6) pain over the scapula caused by irritation of the phrenic nerve by free blood in the abdomen; (7) hematemesis or hematuria; and (8) signs of hypovolemic shock (Table 45-14). An ecchymotic discoloration around the umbilicus (Cullen's sign) can indicate intra-abdominal or retroperitoneal hemorrhage.

TABLE 45-14

EMERGENCY MANAGEMENT
Abdominal Trauma

Etiology	Assessment Findings	Interventions
Blunt • Falls • Motor vehicle collisions • Pedestrian accidents • Assault with blunt object • Crush injuries • Explosions **Penetrating** • Knife • Gunshot wounds • Other missiles	**Hypovolemic Shock** • ↓ Level of consciousness • Tachypnea • Tachycardia • ↓ Blood pressure • ↓ Pulse pressure **Surface Findings** • Abrasions or ecchymoses on abdominal wall, flank, or perineum • Open wounds: lacerations, eviscerations, puncture wounds, gunshot wounds • Impaled object • Healed incisions or old scars **Abdominal and Gastro-Intestinal Findings** • Nausea and vomiting • Bloody urine • Abdominal pain • Abdominal distension • Abdominal rigidity • Guarding • Rebound tenderness • Pain with radiation to shoulder and back	**Initial** • Ensure patent airway. • Administer O_2 via face mask. • Control external bleeding with direct pressure or sterile pressure dressing. • Establish IV access with two large-bore catheters, and infuse warm normal saline or lactated Ringer's solution. • Obtain blood for type and crossmatch and CBC. • Remove clothing. • Stabilize impaled objects with bulky dressing—do not remove. • Cover protruding organs or tissue with sterile, saline dressing. • Insert indwelling urinary catheter if there is no blood at the meatus, pelvic fracture, or boggy prostate. • Obtain urine for urinalysis. • Insert NG tube if no evidence of facial or neck trauma. • Anticipate diagnostic peritoneal lavage. **Ongoing Monitoring** • Monitor vital signs, level of consciousness, O_2 saturation, and urine output. • Maintain patient warmth using blankets, warm IV fluids (40–45°C), or warm humidified oxygen.

CBC, complete blood cell count; *IV*, intravenous; *NG*, nasogastric.

Intra-abdominal injuries can also be associated with low rib fractures, fractured femur, fractured pelvis, and thoracic injury. If any of these injuries are present, the patient should be observed for abdominal trauma.

Diagnostic Studies

Specific diagnostic procedures include CBC, urinalysis, radiographs of the abdomen and the chest, high-resolution computed tomographic (CT) scan, and abdominal ultrasound. With the availability of emergency department ultrasound and CT, peritoneal lavage is rarely performed as a diagnostic tool and is contraindicated in pregnant women or patients with pelvic fractures. If performed,

the fluid is observed for gross abnormalities—such as the presence of blood, bile, feces, or food fibres—and is sent to the laboratory for microscopic evaluation.

Nursing and Collaborative Management Abdominal Trauma

Emergency management of abdominal trauma focuses on establishing a patent airway and adequate breathing, fluid replacement, and prevention of hypovolemic shock (see Table 45-14). IV lines are inserted, and volume expanders or blood is given if the patient is hypotensive. An NG tube is inserted to decompress the stomach and prevent the aspiration of vomitus.

Regardless of the mechanism of injury, physical evidence of abdominal trauma in a patient who is hemodynamically unstable mandates immediate laparotomy. In other cases, the indications for laparotomy must be correlated with the mechanism of injury. For example, if an individual has a gunshot wound or impaled object, surgery is usually indicated. An impaled object should never be removed until skilled surgical care is available. Removal may cause further injury and bleeding. If surgery is performed, the postoperative nursing care is similar to the care of the patient after laparotomy (see NCP 45-2, available on the Evolve website).

Chronic Abdominal Pain

Chronic abdominal pain may originate from abdominal structures or may be referred from a site with the same or a similar nerve supply. Some common causes are irritable bowel syndrome (IBS), peptic ulcer disease, diverticulitis, chronic pancreatitis, hepatitis, cholecystitis, pelvic inflammatory disease, and vascular insufficiency.

Diagnosis of chronic abdominal pain presents a challenge. Assessment should begin with a thorough history and identification of the specific pain pattern. Character and severity of pain, location, duration, and onset should be determined. The assessment should also include the relationship of pain to meals, defecation, and activity and factors that increase or decrease the pain. Chronic abdominal pain can be described as dull, aching, or diffuse.

Endoscopy, CT scans, magnetic resonance imaging (MRI), laparoscopy, and radiological barium studies have decreased the need for exploratory laparotomy. Treatment for chronic abdominal pain is comprehensive and directed toward palliation of symptoms using appropriate medications, such as analgesics and antiemetics, as well as psychological or behavioural therapies (e.g., relaxation therapies).

Irritable Bowel Syndrome

Irritable bowel syndrome (IBS) is a chronic functional disorder characterized by intermittent and recurrent abdominal pain associated with an alteration in bowel function (diarrhea or constipation or both). Other symptoms commonly found include abdominal distension, excessive flatulence, bloating, urge to defecate, urgency, and sensation of incomplete evacuation. IBS is a common problem affecting approximately 5 million Canadians (Canadian Digestive Health Foundation, 2016). Neurological hypersensitivity within the GI (enteric) nerves, physical or emotional stress (or both), dietary issues such as food allergies or sensitivities, antibiotic use, GI infection, bile acid malabsorption, chronic alcohol

abuse, abnormalities in GI secretions or digestive muscle contractions (peristalsis) (or both), acute infection or inflammation of the intestine (enteritis) have been identified as factors that precipitate IBS symptoms (Thompson & Read, 2015). IBS is not a psychological disorder, even though stress, depression, panic, or anxiety may aggravate bowel symptoms.

The key to accurate diagnosis is a thorough history and physical examination. Emphasis should be on symptoms, past health history (including psychosocial aspects such as physical or sexual abuse), family history, and drug and dietary history. Diagnostic tests should be used to rule out more serious life-threatening disorders with symptoms similar to those of IBS, such as colorectal cancer (CRC), peptic ulcer disease, inflammatory bowel disease (IBD), and malabsorption disorders. Symptom-based criteria for IBS have been standardized and are referred to as the Rome III criteria. The Rome III criteria include abdominal discomfort or pain for at least 3 months, with onset at least 6 months before, that has at least two of the following characteristics: (1) relieved with defecation, (2) onset associated with a change in stool frequency, and (3) onset associated with a change in stool appearance (Ishihara, Yashima, & Kushiyama, et al., 2012).

The health care provider should encourage the patient to verbalize concerns and anxiety. A diet containing at least 20 g/day of dietary fibre should be initiated (see Table 45-9). This may also include the addition of psyllium-containing products (e.g., Metamucil).

The patient whose primary symptoms are abdominal distension and increased flatulence should be advised to eliminate common gas-producing foods such as broccoli and cabbage from the diet and to use lactose-free products if there is lactose intolerance. Various medications are available and choice will depend on whether the patient has diarrhea or constipation. Other therapies include relaxation and stress management techniques, antidepressants, acupuncture, and herbal therapy, although no single therapy has been found to be effective for all patients. Patients should be referred to a dietitian to review dietary practices. Maintaining a healthy diet according to Canada's Food Guide (see Chapter 42) should be encouraged.

Inflammatory Disorders

Appendicitis

Appendicitis is an inflammation of the appendix, a narrow blind tube that extends from the inferior part of the cecum. Appendicitis occurs in approximately 7% of the world's population. It can occur at any age but is most common in young adults (Pickhardt, Lawrence, Pooler, et al., 2011).

Etiology and Pathophysiology

The most common causes of appendicitis are occlusion of the appendiceal lumen by a *fecalith* (accumulated feces) (Figure 45-1) and intramural thickening caused by hypergrowth of lymphoid tissue. Obstruction results in edema, venous engorgement, and the invasion by bacteria, which can lead to gangrene and perforation.

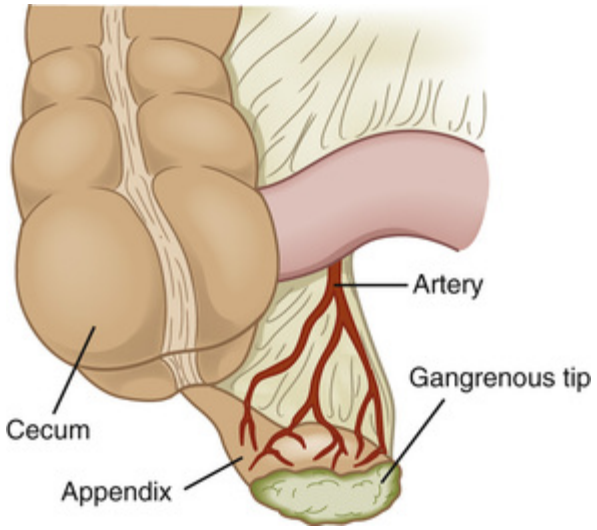

FIGURE 45-1 In appendicitis, the blood supply of the appendix is impaired by inflammation and bacterial infection in the wall of the appendix, which may result in gangrene.

Clinical Manifestations

Appendicitis typically begins with periumbilical pain, followed by anorexia, nausea, and vomiting. The pain is persistent and continuous, eventually shifting to the right lower quadrant and localizing at the McBurney point (located halfway between the umbilicus and the right iliac crest). The iliopsoas and obturator tests may further support a diagnosis of appendicitis. Further assessment of the patient reveals localized tenderness, rebound tenderness (Blumberg sign), and muscle guarding. The patient usually prefers to lie still, often with the right leg flexed. Low-grade fever may or may not be present, and coughing aggravates pain. Older adults may report less severe pain, slight fever, and discomfort in the right iliac fossa. The Rovsing sign may be elicited by palpation of the left lower quadrant, causing pain to be felt in the right lower quadrant. Complications of acute appendicitis are perforation, peritonitis, and abscesses.

Diagnostic Studies and Collaborative Care

Examination of the patient includes a complete history and physical examination (particularly palpation of the abdomen) and a differential WBC count. A urinalysis may be done to rule out genito-urinary conditions that mimic the manifestations of appendicitis. CT scan is the preferred diagnostic procedure, but ultrasound is also used.

The treatment of appendicitis may include surgical removal (appendectomy) if the inflammation is localized. If the appendix has ruptured and there is evidence of peritonitis or an abscess, conservative treatment, consisting of antibiotic therapy and parenteral fluids, may be used to prevent sepsis and dehydration for 6 to 8 hours before an appendectomy is performed.

Nursing Management Appendicitis

The patient with abdominal pain is encouraged to see a health care provider and to avoid self-treatment, particularly the use of laxatives and enemas. The increased peristalsis from these may cause perforation of the appendix. Until the patient is seen by a health care provider, nothing should be taken by mouth (NPO) to ensure that the stomach is empty in the event that surgery is needed. Local application of heat is never used because it may cause the appendix to rupture. In addition, the patient should be observed for evidence of peritonitis. Usually, surgery is performed as soon as a diagnosis is made.

Postoperative nursing management is similar to postoperative care of the patient after laparotomy (see NCP 45-2 on the Evolve website). Ambulation begins the day of surgery or the first postoperative day. The diet is advanced as tolerated. The patient is usually discharged on the first or second postoperative day, and normal activities are resumed 2 to 3 weeks after surgery.

Peritonitis

Etiology and Pathophysiology

Peritonitis results from a localized or generalized inflammatory process of the peritoneum. Causes of peritonitis are listed in Table 45-15. Peritonitis may appear in acute and chronic forms; trauma or rupture of an organ containing chemical irritants or bacteria (which are released into the peritoneal cavity) may cause it. Examples of a chemical peritonitis include peptic ulcer perforation and ruptured ectopic pregnancy. A chemical peritonitis is commonly followed by bacterial invasion. Bacterial peritonitis can be caused by a traumatic injury (e.g., gunshot wound, ruptured appendix), or it can be secondary to other diseases or conditions (e.g., pancreatitis, peritoneal dialysis).

TABLE 45-15
CAUSES OF PERITONITIS

Primary	• Diverticulitis with rupture • Ischemic bowel disorders • Obstruction in the gastro-intestinal tract • Pancreatitis • Perforated peptic ulcer • Peritoneal dialysis • Postoperative anastomotic leak
• Bloodborne organisms • Genital tract organisms • Cirrhosis with ascites • GI tract organisms	
Secondary	
• Appendicitis with rupture • Blunt or penetrating trauma to abdominal organs	

GI, gastro-intestinal.

The response of the peritoneum to the leakage of GI contents is to attempt to localize the offending agent by "walling it off" by exuding fibrin-containing fluids and swelling. Adhesions may form. These adhesions may reduce or disappear when the infection is eliminated. Normally, peritoneal injuries heal without formation of adhesions unless other factors—such as infection, ischemia, or foreign substances—are present.

Clinical Manifestations

Abdominal pain is the most common symptom of peritonitis. A universal sign of peritonitis is tenderness over the involved area. Rebound tenderness, muscular rigidity, and spasm are other major signs of irritation of the peritoneum. Abdominal distension or ascites, fever, tachycardia, tachypnea, nausea, vomiting, and altered bowel habits may also be present. These manifestations vary depending on severity and acuteness of the underlying cause. Complications of peritonitis include hypovolemic shock, septicemia, intra-abdominal abscess formation, paralytic ileus, and organ failure.

Diagnostic Studies

A CBC is done to determine elevations in WBC count and hemoconcentration (Table 45-16). Peritoneal aspiration may be performed and the fluid analyzed for blood, bile, pus, bacteria, fungus, and amylase content. A radiograph of the abdomen may show dilated loops of bowel consistent with paralytic ileus, free air if

perforation has occurred, or air–fluid levels if an obstruction is present. Ultrasound and CT scans may identify the presence of ascites and abscesses. *Peritoneoscopy* (an endoscope is placed through a stab wound in the abdomen to inspect the peritoneum) may be helpful in the patient without ascites. Direct examination of the peritoneum can be obtained along with biopsy specimens for diagnosis.

TABLE 45-16

COLLABORATIVE CARE
Peritonitis

Diagnostic	• NG suction • Analgesics • Preparation for surgery to include the above and nutritional support
• History and physical examination • CBC • Serum electrolytes • Abdominal radiographic examination • Abdominal paracentesis and culture of fluid • CT scan or ultrasound • Peritoneoscopy	***Postoperative***
Collaborative Therapy	• NPO status • NG tube to suction • Semi-Fowler's position • IV fluids with electrolyte replacement • Nutritional support as needed • Antibiotic therapy • Blood transfusions as needed • Sedatives and opioids
Preoperative or Nonoperative	
• NPO status • Oxygen support • Fluid replacement • Antibiotic therapy	

CBC, complete blood cell count; *CT,* computed tomographic (scan); *IV,* intravenous; *NG,* nasogastric; *NPO,* nothing by mouth.

Collaborative Care

The goals of the management of peritonitis are to identify and eliminate the cause, combat infection, and prevent complications. Patients with milder cases of peritonitis or those who are poor surgical risks may be managed nonsurgically. Treatment consists of antibiotics, NG suction, analgesics, and IV fluid administration. Patients who require surgery need preoperative preparation as previously described. Those patients may be placed on parenteral nutrition (PN) because of increased nutritional requirements. (PN,

formerly called *total parenteral nutrition* [TPN], is discussed in Chapter 42.)

Nursing Management Peritonitis

Nursing Assessment

Assessment of the patient's pain, including the location, is important and may help in determining the cause of peritonitis. The patient should be assessed for the presence and the quality of bowel sounds, increasing abdominal distension, abdominal guarding, nausea, fever, and manifestations of hypovolemic and septic shock.

Nursing Diagnoses

Nursing diagnoses for the patient with peritonitis include, but are not limited to, the following:

- *Acute pain* related to *biological injury agent* (inflammation of the peritoneum, abdominal distention)
- *Risk for deficient fluid volume* related to *insufficient fluid intake* (fluid shifts into the peritoneal cavity secondary to trauma, infection or ischemia)
- *Anxiety* related to *threat to current status, threat of death*

Planning

The overall goals for the patient with peritonitis are for (1) resolution of inflammation, (2) relief of abdominal pain, (3) freedom from complications, and (4) normal nutritional status.

Nursing Implementation

The patient with peritonitis is extremely ill and needs skilled supportive care. The patient is monitored for signs of sepsis, pain, and response to analgesic therapy. The patient may be positioned with knees flexed to increase comfort. The nurse should provide rest and a quiet environment. Sedatives may be given to allay anxiety.

Accurate monitoring of fluid intake and output and electrolyte status is necessary to determine replacement therapy. Vital signs are monitored frequently. Antiemetics may be administered to decrease nausea and vomiting and further fluid losses. The patient is on NPO status and may have an NG tube in place to decrease gastric distension.

If the patient has an open surgical procedure, drains are inserted to remove purulent drainage and excessive fluid. Postoperative care of the patient is similar to the care of the patient with an exploratory laparotomy (see NCP 45-2, on the Evolve website).

Gastro-enteritis

Gastro-enteritis is an inflammation of the mucosa of the stomach and the small intestine. Clinical manifestations include nausea, vomiting, diarrhea, abdominal cramping, and distension. Fever, increased WBC counts, and blood or mucus in the stool may be present. Causative agents are varied (see Table 45-2). Most cases are self-limiting and do not necessitate hospitalization. However, older-adult patients and patients who are chronically ill may be unable to consume sufficient fluids orally to compensate for fluid loss. Until vomiting has ceased, the patient should be on NPO status. If dehydration has occurred, IV replacement of fluids may be necessary. As soon as tolerated, oral fluids containing glucose and electrolytes should be given. If the causative agent is identified, appropriate pharmaceutical therapy is initiated.

Nursing Management Gastro-enteritis

Accurate monitoring of intake and output is important for successful replacement of lost fluid. Strict medical asepsis and infection control precautions should be instituted when indicated. The patient should be instructed in the importance of proper food handling and preparation of food to prevent infections such as salmonellosis and botulism (see Chapter 44, Table 44-3).

Symptomatic nursing care is given for nausea, vomiting, and diarrhea. The importance of rest and increased fluid intake should be stressed. The nurse should assess complaints of pain, vomiting, and diarrhea because, often, gastro-enteritis is confused with appendicitis. To allay the patient's apprehension, the nurse should explain that gastro-enteritis usually runs an acute course with no sequelae.

Inflammatory Bowel Disease

Inflammatory bowel disease (IBD) is an autoimmune disease that currently refers to two disorders of the GI tract (Crohn's disease and ulcerative colitis [UC]) characterized by idiopathic inflammation and ulceration. Multiple factors are likely involved in the etiology of IBD, including environmental factors, genetic predisposition, and alterations in the function of the immune system (Leone, Chang, & Devkota, 2013). Both UC and Crohn's disease commonly occur during the teenage years and early adulthood, but both have a second peak from ages 50 to 70. Both are more prevalent in industrialized regions of the world. Epidemiological studies show a higher incidence of IBD in White people (particularly those of Jewish descent) (see the "Determinants of Health" box) and in family members (especially monozygotic compared with dizygotic twins). For both conditions, the clinical manifestations are varied, with unpredictable periods of remission interspersed with episodes of acute inflammation (Figure 45-2). Both diseases can be debilitating. In Canada, about 10 000 new cases of IBD are diagnosed annually (Canadian Society of Intestinal Research, 2014).

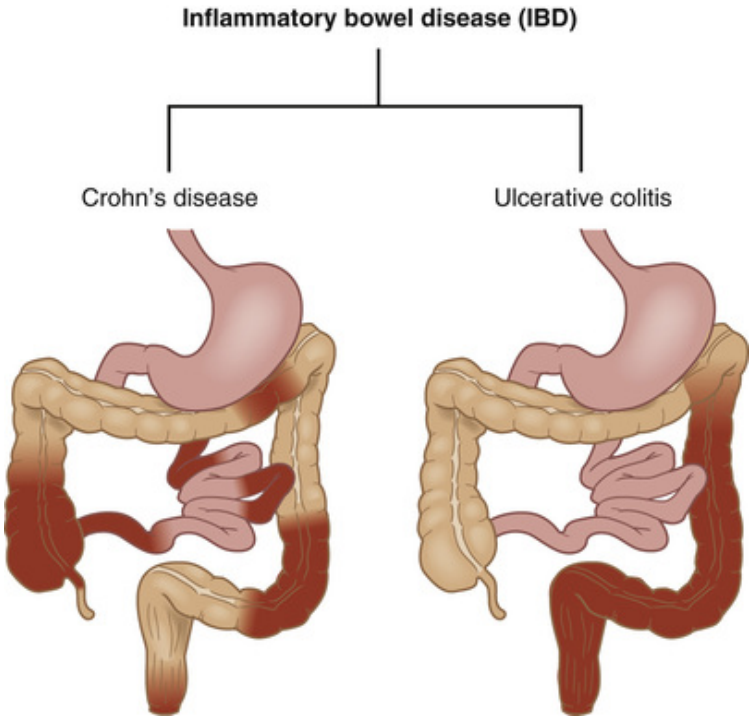

FIGURE 45-2 Comparison of distribution patterns of Crohn's disease and ulcerative colitis.

Determinants of Health

Colon Disorders

Physical Environment

- Inflammatory bowel disease (IBD) is more common in temperate regions of North America, South Africa, and Australia.*
- The prevalence of colorectal cancer is highest in Canada and the United States, northwestern Europe and Australia.†

Biology and Genetic Endowment: Culture

- Familial adenomatous polyposis (FAP) is a genetic condition that causes adenomatous polyps to develop on the inner lining, or mucosa, of the colon and rectum. If untreated, most people with FAP will develop colorectal cancer by age 30.

- IBD is more common among Ashkenazi Jewish people and those of Scandinavian descent.*

Gender

- Men are at greater risk of developing colorectal cancer. The risk for colorectal cancers also increases with age. Most people who are diagnosed are older than 50.

Ulcerative Colitis

Ulcerative colitis (UC) is a chronic IBD characterized by inflammation and ulceration of the rectum and the colon. It may occur at any age but peaks between the ages of 15 and 25 years. There is a second, smaller peak onset between 50 and 70 years of age. UC equally affects both sexes (Rocchi, Benchimol, Bernstein, et al., 2012).

Etiology and Pathophysiology

The inflammation of UC is diffuse and involves the mucosa and the submucosa, with alternate periods of exacerbations and remissions (see Table 45-24 later in the chapter). The disease begins in the rectum and spreads proximally along the colon in a continuous fashion.

The mucosa of the rectum and the colon is hyperemic and edematous in the affected area. Multiple abscesses develop in the crypts of Lieberkühn (intestinal glands). As the disease advances, the abscesses break through the crypts into the submucosa, leaving ulcerations. These ulcerations also destroy the mucosal epithelium, causing bleeding and diarrhea. Losses of fluid and electrolytes occur because of the decreased mucosal surface area for absorption. Breakdown of cells results in protein loss through the stool. Areas of inflamed mucosa can form pseudopolyps—tonguelike projections into the bowel lumen. Granulation tissue develops, and the mucosa musculature becomes thickened, shortening the colon.

Although the precipitating factors involved in UC are poorly understood, it is clear that the disease onset involves an inflammatory response. Specific proinflammatory cytokines such as tumour necrosis factor–alpha (TNF-α) have been implicated in promoting this inflammatory response.

Clinical Manifestations

UC may appear as an acute fulminating crisis or, more commonly, as a chronic disorder with mild to severe acute exacerbations that occur at unpredictable intervals over many years. The major symptoms of UC are bloody diarrhea and abdominal pain. Pain may vary from the mild lower abdominal cramping associated with diarrhea to the severe, constant abdominal pain that may be associated with toxic megacolon and acute perforations. With mild disease, diarrhea may consist of one or two semiformed stools, containing small amounts of blood, per day. The patient may have no other systemic manifestations. In moderate UC, there is increased stool output (four to five stools per day), increased bleeding, and systemic symptoms (e.g., fever, malaise, anorexia). In severe cases, diarrhea is bloody, contains mucus, and occurs 10 to 20 times a day. In addition, fever, weight loss greater than 10% of total body weight, anemia, tachycardia, and dehydration are present.

Complications

Complications of UC may be classified into those that are intestinal and those that are extraintestinal. Intestinal complications of UC include hemorrhage, perforation, toxic megacolon, and colonic dilation. Hemorrhage is a result of inflamed, ulcerated mucosa and is usually controlled with conservative medical therapy. Massive hemorrhage is unusual and requires emergency surgery. *Toxic megacolon* (extensive dilation and paralysis of the colon), bleeding, and fulminant colitis are the most common complications associated with UC. Colonic dilation, most often in the transverse colon, occurs as a result of severe acute inflammation of the entire colon wall. Perforation is most often associated with toxic megacolon but may occur alone. Most cases of perforation occur in the left side of the colon.

A patient who has had UC for more than 10 years is at greater risk for colorectal cancer. The risk for cancer depends on age at onset, duration, and extent of disease. The patient should be regularly screened with colonoscopy. Extraintestinal manifestations of the disease may be directly related to the colitis, or they may be nonspecific complications mediated by a disturbance in the immune system (Table 45-17). Colitis-related complications are associated with active inflammation and may respond to treatment of the underlying bowel disease. These manifestations can involve the joints, the skin, the mouth, and the eyes as well as disturbances of the hematological system, including anemia, leukocytosis, and

thrombocytosis. Skin lesions such as erythema nodosum and pyoderma gangrenosum are among the most frequently seen extraintestinal manifestations. Uveitis is the most common eye problem (Crohn's and Colitis Canada, 2016).

TABLE 45-17

EXTRAINTESTINAL MANIFESTATIONS OF INFLAMMATORY BOWEL DISEASE

Musculo-skeletal	**Metastatic Crohn's Disease**
• Peripheral arthritis (colitic) • Ankylosing spondylitis • Sacroiliitis • Osteoporosis • Finger clubbing	***Mouth***
Dermatological	• Aphthous ulcers (stomatitis)
• Erythema nodosum • Pyoderma gangrenosum	***Ophthalmological*** • Conjunctivitis • Uveitis • Episcleritis
Other	***Hepatobiliary***
• Thrombo-embolism • *Clostridium difficile*	• Gallstones • Primary sclerosing cholangitis • Portal vein thrombosis
	Genito-Urinary
	• Kidney stones

Diagnostic Studies

Several studies are appropriate for diagnosis of UC (Table 45-18). Blood studies should include a CBC, serum electrolyte levels, and serum protein levels. A CBC typically shows iron-deficiency anemia from blood loss. An elevated WBC count may indicate toxic megacolon or perforation. Elevated erythrocyte sedimentation rate and C-reactive protein reflect inflammation. Decreases in serum electrolytes, such as sodium, potassium, chloride, bicarbonate, and magnesium, are caused by fluid and electrolyte losses from diarrhea. Hypoalbuminemia is present with severe disease and results from protein loss from the bowel. The stool should be examined for blood, pus, and mucus. Stool cultures should be obtained to rule out infectious causes of inflammation.

TABLE 45-18

COLLABORATIVE CARE
Ulcerative Colitis

Diagnostic	*Severe (Fulminant) Disease*
• History and physical examination • Colonoscopy • Sigmoidoscopy • Barium enema • CBC, ESR, electrolytes, BUN,* creatinine, albumin • Culture and sensitivity testing of stool (including *Clostridium difficile*) • Stool for occult blood	• IV fluids with electrolytes • Blood transfusions • NPO status • Nutritional support (parenteral therapy) • Antimicrobial therapy† • Immuno-suppressants† • Immuno-modulators† • Corticosteroids† • Surgery if no improvement
Collaborative Therapy	
Mild and Moderate Disease	
• Nutritional support (low-residue diet and no dairy products) • Antimicrobial therapy† • 5-Aminosalicylates† • Corticosteroids† • Antidiarrheal agents†	

*Serum urea (nitrogen).

†See Table 45-19.

BUN, blood urea nitrogen; *CBC*, complete blood cell count; *IV*, intravenous; *NPO*, nothing by mouth; *ESR*, erythrocyte sedimentation rate.

Imaging studies include double-contrast barium enema, small bowel series (small bowel follow-through), transabdominal ultrasound, CT, and MRI. Examinations with a sigmoidoscope and a colonoscope allow direct examination of the mucosa of the lower GI tract. Using a sigmoidoscope, the health care provider can view the rectum, the sigmoid colon, and the distal descending colon. The colonoscope allows for examination of the entire large intestine. The extent of inflammation, ulcerations, pseudopolyps, strictures, and lesions may be identified. Biopsy specimens should be taken for definitive diagnosis. Scopes should not be used when the rectum and the colon are severely inflamed because of the risk for perforation.

Collaborative Care

The goals of treatment are to (1) rest the bowel, (2) control the inflammation, (3) manage fluids and nutrition, (4) manage patient stress, (5) provide education about the disease and treatment, and (6) provide symptomatic relief. The mainstays of drug therapy are sulphasalazine (Salazopyrin) and corticosteroids. Hospitalization is indicated if the patient fails to respond to corticosteroid therapy or if complications are suspected.

Drug Therapy.

Drug therapy is an extremely important aspect of treatment (Table 45-19) (Rx Files Academic Detailing Program, 2014). The principal drug used is sulphasalazine (Salazopyrin), a combination of sulphapyridine and 5-aminosalicylic acid (5-ASA). It is effective in the maintenance of clinical remission and in the treatment of mild to moderately severe disease episodes. After remission is obtained, therapy is continued with a gradual reduction over several months. The maintenance dose is usually continued for at least 1 year.

TABLE 45-19

DRUG THERAPY
Inflammatory Bowel Disease

Category	Action	Examples
Antimicrobial	Prevent or treat secondary infection	metronidazole (Flagyl), ciprofloxacin (Cipro)
5-Aminosalicylates (5-ASA)	Decrease GI inflammation*	*Systemic:* sulphasalazine (Salazopyrin), mesalazine (Asacol, Pentasa), olsalazine (Dipentum) *Rectal suppository:* mesalazine (Salofalk)
Corticosteroids	Decrease inflammation	*Systemic:* corticosteroids (cortisone, prednisone, budesonide) *Enemas:* hydrocortisone (Cortenema), budesonide (Entocort) *Rectal foam:* hydrocortisone (Cortifoam)
Antidiarrheal	Decrease GI motility†	diphenoxylate (Lomotil), loperamide (Imodium)
Immuno-suppressants	Suppress immune response	azathioprine (Imuran), cyclosporine (Neoral)
Immuno-modulators	Inhibit the cytokine tumour necrosis factor–alpha (TNF-α)	infliximab (Remicade), adalimumab (Humira)
Hematinics and vitamins	Correct iron deficiency anemia and promote healing	*Oral iron:* ferrous sulphate, ferrous gluconate *Iron injection:* iron dextran (DexIron), iron sucrose (Venofer)

*Mechanism of action unknown, possibly antimicrobial as well as anti-inflammatory.

†Used with caution during severe disease because of potential to produce toxic megacolon.

GI, gastro-intestinal.

Drug Alert

Sulphasalazine (Salazopyrin)

- May cause yellowish-orange discoloration of skin and urine.

- Avoid exposure to sunlight and ultraviolet light until photosensitivity is determined.

During active disease, 5-ASA (the active form of sulphasalazine) and corticosteroid enemas are effective in the treatment of left-sided UC and proctitis. Topical salicylate therapy is the treatment of choice in patients with localized disease. 5-ASA (mesalazine) can also be administered orally. The acrylic-coated tablets provide delivery of the drug more distally in the intestine.

Corticosteroids are of proven benefit in the management of active UC. Oral prednisone or prednisolone is effective in treatment of mild to moderate disease without systemic manifestations. If remission is not achieved, the patient requires hospitalization and IV corticosteroid therapy. The patient is placed on a regimen of bowel rest. Fluids and electrolytes are administered intravenously. For *proctitis* (inflammation of the rectum and the anus), hydrocortisone enemas, rectal foams, or suppositories can be effective in the treatment of inflammation. Rectal foams are usually administered in 5-mL volumes, and patients can generally administer this themselves. Enemas are the preferred choice if the disease spreads beyond the rectum. Retention enemas have been shown to deliver drugs into the descending colon and beyond in patients with active disease. Patients taking corticosteroids need to be monitored for common adverse effects such as Cushing's syndrome, hypertension, hirsutism, and mood swings.

Immuno-suppressive drugs (e.g., cyclosporin) have been used in severe cases of UC, when a patient has failed to respond to any of the usual drugs and before surgery is considered. Adverse effects of cyclosporin include renal dysfunction, hypertension, headache, and muscle cramps. Regular cyclosporin trough levels should be determined to ensure proper dosing of this medication. Therapeutic response to IV cyclosporin usually allows for conversion to an oral preparation for long-term therapy. Anti–TNF-α blocking agents (e.g., infliximab [Remicade]) were previously considered for use more with Crohn's disease; they are now also considered valuable in the management of moderate to severe refractory UC (Rx Files Academic Detailing Program, 2014).

Surgical Therapy.

Approximately 80% to 85% of patients with UC go into remission with conservative therapy and nursing management, but 15% to 20% require surgery. Surgery is indicated if (1) the patient fails to respond to treatment;

(2) exacerbations are frequent and debilitating; (3) massive bleeding, perforation, strictures, or obstruction occurs; (4) there are tissue changes that suggest that dysplasia is occurring; or (5) carcinoma develops.

Surgical procedures used to treat chronic UC include (1) total proctocolectomy with permanent ileostomy and (2) total proctocolectomy with ileoanal reservoir.

Total Proctocolectomy With Permanent Ileostomy.

Total proctocolectomy with a permanent ileostomy is a one-stage operation involving the removal of the colon, the rectum, and the anus, with closure of the anus. The end of the terminal ileum is brought out through the abdominal wall and forms a stoma, or ostomy. The stoma is usually placed in the right lower quadrant within the rectus muscle.

Total Proctocolectomy With Ileoanal Reservoir.

A more widely performed procedure involves total proctocolectomy with the formation of an ileal reservoir and anal anastomosis (Figure 45-3). The ileoanal reservoir surgical procedure is usually a staged approach, encompassing a combination of one to three procedures, performed approximately 12 weeks apart. The initial procedure generally includes a colectomy with temporary end ileostomy and a possible mucous fistula. The second surgery involves a takedown of the ileostomy and mucous fistula, resection of the rectal stump to just above the anal sphincters, and formation of the ileal reservoir and subsequent anastomosis to the anus, with a diverting temporary loop ileostomy (to protect the reservoir during healing). The final, third, surgery involves a takedown of the loop ileostomy, which functionalizes the reservoir. Depending upon the preoperative health of the patient, these staged surgeries may be combined into a two-stage procedure or a single operation. Adaptation to the reservoir occurs over the next 3 to 6 months, which usually results in a bowel movement frequency of four to eight pasty stools per day and good daytime continence.

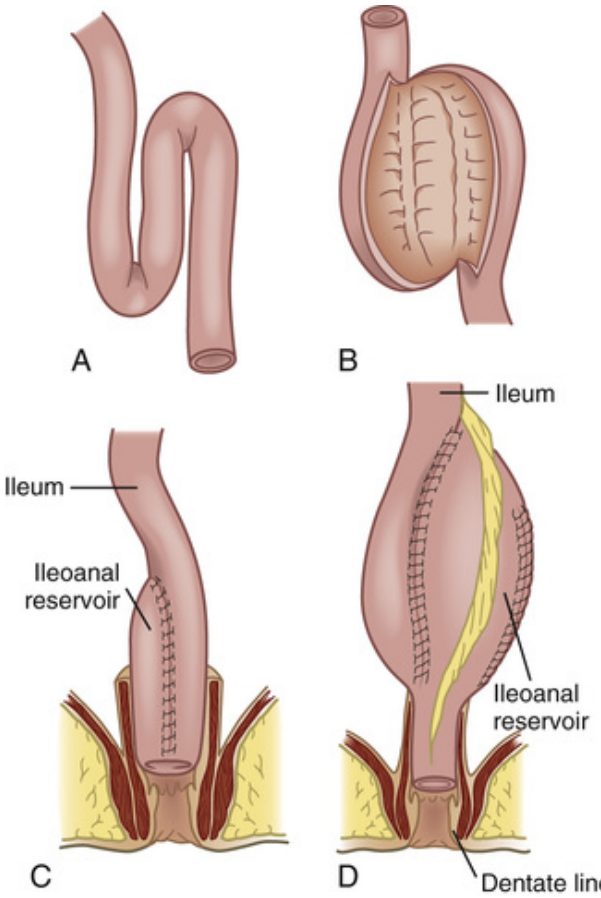

FIGURE 45-3 Ileoanal reservoir. **A,** Formation of a reservoir. **B,** Posterior suture lines completed. **C,** J-shaped configuration for an ileoanal reservoir. **D,** S-shaped configuration for an ileoanal reservoir.

Patient selection includes absence of colorectal cancer, small intestine free of disease (e.g., Crohn's disease), competent anorectal sphincter, and physical status adequate to permit lengthy surgery. In addition, the patient needs to be motivated and capable of understanding self-care instructions.

Postoperative Care.

Postoperative care following surgical procedures to treat UC includes routine observations for patients who have had abdominal surgery. Stoma viability, mucocutaneous border (the area where the mucous membrane of the bowel is sutured to the skin), and peristomal skin integrity must be monitored. Because a more proximal portion of the bowel is used to create the diverting loop ileostomy in the second stage, stomal output may be as high as 1 500 to 2 000 mL/24 hr. Intravenous fluid support is important, including replacements for excessive ileostomy losses (>1 200 mL/24 hr).

The patient must be observed for signs of hemorrhage, abdominal abscesses, small bowel obstruction, dehydration, and other related complications. If an NG tube is used, it will be removed when bowel function returns. Drainage of serosanguineous fluid from the abdominal drain site may vary from 100 to 150 mL/24 hr. The drain is usually removed within 3 to 4 days of surgery. The urinary catheter is removed 2 to 4 days after surgery. Systemic antibiotics are discontinued within 24 hours of the operation, and corticosteroids, if used, are tapered.

Transient incontinence of mucus from the reservoir is a result of intraoperative manipulation of the anal canal and the effects of some medications (opioids, sedatives). The patient should be reassured before and after the operation regarding this potential but transient problem. Kegel exercises may be recommended several weeks postoperatively to strengthen the pelvic floor and the sphincter muscles. They are not recommended in the immediate postoperative period. Perianal skin care must be implemented with the first bowel movement to protect the epidermis from frequent pericare and stool irritation. The patient should be instructed to gently rinse the skin with water or a spray cleanser with a surfactant and dry thoroughly. A barrier cream should be used, and a perineal pad may be required.

The most frequent type of ileostomy that is constructed is a loop. This can present as a pouching challenge because the os (opening) may tilt down and drain inferiorly such that stool causes irritation to the surrounding skin. An enterostomal therapy (ET) nurse will help with these challenging problems. Self-care instructions should be taught and reviewed, and written information with discharge supplies should be provided before discharge. Stoma care is presented later in this chapter (see Nursing Management: Ostomy Surgery).

Nutritional Therapy.

An important component in the treatment of UC is diet. The dietitian is an important member of the team and should be consulted regarding dietary recommendations. The goals of diet management are to provide adequate nutrition without exacerbating symptoms, to correct and prevent malnutrition, to replace fluid and electrolyte losses, and to prevent weight loss. The diet for each patient must be individualized.

Traditionally, during the acute phase, the patient may be on NPO status. When food is permitted, a high-calorie, high-protein, low-residue diet with vitamin and iron supplements is frequently prescribed. (A low-residue diet is presented in Table 45-20.) Special dietary restrictions are not usually

necessary. Some health care providers allow the patient to eat anything that does not cause symptoms. Cold foods, high-residue foods (e.g., whole wheat bread, cereal with bran, nuts, raw fruit), and smoking increase GI motility and should be avoided. Fish oil preparations have been evaluated for their ability to reduce inflammation in active UC. However, their palatability is low.

TABLE 45-20

NUTRITIONAL THERAPY
Low-Residue Diet

Purpose		
Low-residue diet provides foods low in fibre, which will result in a reduced amount of fecal material in the lower intestinal tract.		
General Principles		
1. This diet eliminates foods that are indigestible or stimulating to the intestinal tract to reduce the amount of residue in the colon. Foods should be included or excluded according to the following list. 2. Hot and cold foods should be eaten slowly. 3. Milk products are limited to 2 cups daily. For a more restricted-residue diet, milk should be eliminated.		
Food	**Foods Included**	**Foods Excluded**
Beverages	Carbonated drinks, coffee, tea, cocoa, strained fruit juices	Alcohol, fruit juices with pulp
Bread	White bread, rolls, rusks, melba toast, crackers	Bread and crackers containing whole grain flour or bran; any hot breads such as biscuits, muffins, waffles, or pancakes
Cereals	Cooked, refined, or strained cereals: cream of wheat, cream of rice, farina, grits, dry cereals without bran; noodles; spaghetti; macaroni	Whole grain cereals; cereals containing bran, nuts, and raisins; Shredded Wheat
Meat	Lean, tender ground beef, lamb, pork, veal or fish, broiled, stewed, or baked; canned tuna or salmon; shellfish; crisp bacon, chicken or turkey without skin, liver; creamy peanut butter	Fried, smoked, pickled, or cured meats; highly seasoned ham; fried fish; luncheon meats
Egg	All but fried	Fried or uncooked eggs
Cheese	Milk, cheese (aged cheddar), cottage cheese	All other cheeses
Milk	Limit to 1–2 cups (if tolerated), including that used in cooking; plain yogourt	Fruit yogourt
Fats	Butter, margarine, cream, oil, crisp bacon, mayonnaise, plain gravy	Any other; rich or spiced gravies
Soup	Cream and vegetable soups made from foods allowed and with quantity of milk allowed, bouillon, broth; strained vegetable juices	Cream and vegetable soups from foods not allowed (peas and dried beans)
Vegetables	Cooked or canned vegetables; strained vegetables; potatoes without skins; vegetable juices	Raw vegetables, all vegetables not strained, dried beans, peas, and legumes
Fruits	Strained fruit juices, cooked or canned fruits; ripe bananas, applesauce, pears, peaches, peeled apricots, Napoleon cherries, baked apple (no skin)	Raw fruits, fruits with skins, seeds
Desserts	Plain desserts (custards and puddings, plain ice cream for milk allowance), sherbet, plain gelatin desserts, angel food cake, sponge cake, plain butter cake, plain cookies	Nuts, coconut, raisins, rich desserts (pies, rich cakes, cobblers)
Condiments	Allspice, cinnamon, mace, paprika, salt, ground thyme, sugar, vinegar, lemon juice	All others

Often, enteral supplements and parenteral nutrition are necessary. Patients with systemic manifestations, significant fluid and electrolyte losses, or malabsorption may need parenteral nutrition or enteral feedings, such as elemental diets. Elemental diets are high in calories and nutrients, lactose free, and absorbed in the proximal small intestine.

Parenteral nutrition allows for a positive nitrogen balance. Vitamins, minerals, electrolytes, and other important nutrients (e.g., glucose, amino acids) can be administered to promote healing and correct nutritional deficiencies. (PN is discussed in Chapter 42.)

Supplemental iron (ferrous sulphate or ferrous gluconate) may be necessary to prevent or treat iron-deficiency anemia resulting from chronic blood loss. Parenteral iron may be needed for patients who cannot tolerate oral iron. Iron dextran (DexIron) administered intramuscularly by Z-track or intravenously may be necessary if anemia is severe. In patients receiving long-term sulphasalazine therapy, folic acid deficiency may develop, and supplementation may be necessary. Potassium supplements may be necessary if corticosteroid therapy is used because retention of sodium and loss of potassium can result in hypokalemia and subsequent toxic megacolon. Zinc deficiency can result from severe or chronic diarrhea, and supplementation may be necessary.

Nursing Management Ulcerative Colitis

Nursing Assessment

Subjective and objective data that should be obtained from a patient with UC are presented in Table 45-21.

TABLE 45-21

NURSING ASSESSMENT
Ulcerative Colitis

Subjective Data
Important Health Information
Past health history: Infection; autoimmune disorders; family history of inflammatory bowel disease *Medications:* Use of antidiarrheal medications, steroids, other immuno-suppressives; herbal, homeopathic, or naturopathic remedies
Symptoms
• Fatigue, malaise • Nausea, vomiting, anorexia; weight loss; dietary intolerances • Frequent bloody stools containing mucus and pus • Lower abdominal pain (worse before defecating), cramping, tenesmus
Objective Data
General
Intermittent fever; emaciated appearance
Integumentary
Pale skin with poor turgor, dry mucous membranes; rash, nodules (on lower legs), or blisters; anorectal irritation
Gastro-Intestinal
Abdominal distension, hyperactive bowel sounds, abdominal cramps
Cardiovascular
Tachycardia, hypotension (including postural)
Possible Findings
Anemia; leukocytosis; electrolyte imbalance; hypoalbuminemia; vitamin and trace metal deficiencies; abnormal sigmoidoscopic, colonoscopic, and barium enema findings

Nursing Diagnoses

Nursing diagnoses for the patient with UC include, but are not limited to, the following:

- *Diarrhea* related to *increase in stress level* (bowel inflammation and intestinal hyperactivity)
- *Imbalanced nutrition: less than body requirements* related to *insufficient dietary intake* (decreased absorption, increased nutrient loss through diarrhea)

- *Ineffective coping* related to *insufficient sense of control, inadequate confidence in ability to deal with situation*

For additional information on nursing diagnoses on IBD, see NCP 45-3, available on the Evolve website.

Planning

The overall goals are that the patient with UC will (1) respond to medical management, (2) maintain normal fluid and electrolyte balance, (3) be free from pain or discomfort, (4) participate in medical and surgical management, and (5) maintain nutritional balance.

Nursing Implementation

During the acute phase, attention is focused on hemodynamic stability, pain control, fluid and electrolyte balance, and nutritional support. Accurate intake and output records must be maintained. The number and characteristics of stools are monitored. Nursing care of the patient with UC is directed toward an intensive therapeutic and supportive program (see NCP 45-3). It is important for the nurse to establish a good working relationship and encourage the patient to talk about himself or herself and daily activities. An explanation of all procedures and treatment is necessary and may allay some apprehension.

Psychosocial support may be indicated if the patient is experiencing emotional problems, but the nurse must recognize that the patient's behaviour may result from factors other than emotional ones. Any person who has 10 to 20 bowel movements a day and has rectal discomfort may be anxious, frustrated, discouraged, and depressed. Along with other team members, the nurse can assist the patient to accept the chronic condition and to have an optimistic view with the possibility of cure after surgery. The nurse may find that inadequate coping mechanisms in the patient with UC are owing to early onset of the disease (often at 10–15 years of age), which may have interfered with usual growth, development, and maturation.

Restricted physical activity and possibly bedrest may be ordered if the patient has a severe exacerbation. Nursing interventions to prevent complications of immobility should be instituted. Teaching related to treatment, drugs, diet, diagnostic tests, and the disease and its management is important.

Rest is important in the management of UC. Patients may lose much sleep because of frequent episodes of diarrhea and abdominal pain. Nutritional deficiencies and anemia leave the patient feeling weak and listless. Activities should be scheduled around rest periods. Nurses can provide physical and emotional support to the patient during acute exacerbations.

Until diarrhea is controlled, the patient must be kept clean, dry, and free of odour. Facilitating management of bowel movements, including close proximity to a bathroom or a bedside commode, is helpful. A deodorizer should be placed in the room. Antidiarrheal agents should be administered as ordered. If the patient has continuous diarrhea, the ET nurse may give helpful suggestions. Meticulous perianal skin care using plain water or a skin cleanser (no harsh soap) is necessary to treat and prevent skin breakdown. Use of skin barrier creams may help to protect perianal skin.

Evaluation

The expected outcomes for the patient with UC are presented in NCP 45-3, available on the Evolve website.

Crohn's Disease

Crohn's disease is a chronic IBD of unknown origin that can affect any part of the GI tract from the mouth to the anus. Crohn's disease occurs most often between the ages of 15 and 30 years. When it occurs in older adults, the morbidity and mortality rates are higher because of other chronic problems that may be present. Both sexes are affected, with a slightly higher incidence in women. Similar to UC, it occurs more often in Jewish and upper–middle-class urban populations. Canada may have one of the highest incidence rates of both Crohn's disease and UC in the world.

Etiology and Pathophysiology

Crohn's is a systemic autoimmune disorder with significant abnormal inflammation of the GI tract (Mazal, 2014). Recently, the first gene associated with Crohn's disease, the *NOD2* gene, was identified. Research is ongoing to understand how defects in the *NOD2* gene lead to Crohn's disease and into finding the other genes that cause IBD. It can affect any part of the GI tract but is most often seen in the terminal ileum and the colon. Approximately 5% of patients with Crohn's disease have

ileojejunitis. Involvement of the esophagus, the stomach, or the duodenum is uncommon. The inflammation involves all layers of the bowel wall (i.e., it is transmural). Areas of involvement are usually discontinuous *skip lesions*, with segments of normal bowel occurring between diseased portions (see Table 45-24). Typically, ulcerations are deep and longitudinal and penetrate between islands of inflamed edematous mucosa, causing the classic cobblestone appearance. Thickening of the bowel wall occurs as well as narrowing of the lumen with stricture development. Abscesses or fistula tracts that communicate with other loops of bowel, the skin, the bladder, the rectum, or the vagina may develop. Histologically, granulomas (chronic inflammatory lesions) are present in 50% of patients and may be located in any layer of the bowel wall.

TABLE 45-24
COMPARISON OF ULCERATIVE COLITIS AND CROHN'S DISEASE

Characteristic	Ulcerative Colitis	Crohn's Disease
Clinical		
Usual age at onset	Teens to mid-30s	Teens to mid-30s
Diarrhea	Common	Common
Abdominal cramping pain	Common	Common
Fever (intermittent)	During acute episodes	Common
Weight loss	Rare	Severe
Rectal bleeding	Common	Fairly common
Tenesmus	Severe	Infrequent
Malabsorption and nutritional deficiencies	Minimal incidence	Common
Pathological		
Location	Starts distally in the rectum and spreads proximally in a continuous fashion up the colon	Can occur anywhere along GI tract from mouth to anus, with characteristic skip lesions; most frequent site is terminal ileum
Distribution	Continuous	Segmental (skip lesions)
Depth of involvement	Mucosa and submucosa	Entire thickness of bowel wall (transmural)
Granulomas	Occasional	Common
Cobblestoning of mucosa	Rare	Common
Pseudopolyps	Common	Rare
Small bowel involvement	Minimal (backwash ileitis)	Common
Complications		
Fistulas	Rare	Common
Strictures	Occasional	Common
Anal abscesses	Rare	Common
Perforation	Common	Common
Toxic megacolon	Common	Rare
Carcinoma	Increased incidence after 10 yrs of disease	Slightly greater than general population
Recurrence after surgery	Cure with proctocolectomy	40–60% or more recurrence after segmental resections of small or large intestine

GI, gastro-intestinal.

Clinical Manifestations

The manifestations of Crohn's disease depend largely on the anatomical site of involvement, the extent of the disease process, and the presence or absence of complications. The onset of Crohn's disease is usually insidious, with nonspecific complaints such as diarrhea, fatigue, abdominal pain, weight loss, and fever. Early diagnosis may be more difficult than for UC. The principal manifestations of Crohn's disease are diarrhea and abdominal pain. Diarrhea is usually nonbloody and is a result of the

inflammatory process or malabsorption. Pain may be severe and intermittent or constant, depending on the cause. Other manifestations include abdominal cramping and tenderness, abdominal distension, fever, and fatigue. Similar to UC, extraintestinal complications may be directly related to the GI inflammation and small intestinal pathological conditions (malabsorption), or they may be nonspecific complications mediated by a disturbance in the immune system. Extraintestinal manifestations, such as arthritis and finger clubbing, may precede the onset of bowel disease. As the disease progresses, there is weight loss, malnutrition, dehydration, electrolyte imbalances, anemia, increased peristalsis, pain around the umbilicus and right lower quadrant, and possible perianal disease.

Crohn's disease is a chronic disorder with unpredictable periods of recurrence and remission. Attacks are intermittent, usually recurring over a period of several weeks to months.

Complications

Complications, both GI and extraintestinal, are common in Crohn's disease. Scar tissue from the inflammation and ulceration narrows the lumen of the intestine and may cause strictures and obstruction, a frequent complication. Fistulas are a cardinal feature and may develop between segments of bowel. Cutaneous fistulas, common in the perianal area, and recto-vaginal fistulas also occur. Fistulas communicating with the urinary tract may cause urinary tract infections. Inflammation of the intestines may involve all layers, predisposing the patient to perforation and the formation of intra-abdominal abscesses and peritonitis (Mazal, 2014).

Impaired absorption causing various nutritional abnormalities may occur as a result of damage to areas of the intestinal mucosa. Fat malabsorption causes a deficiency in the fat-soluble vitamins (A, D, E, and K). The patient may have an intolerance to gluten (a protein found in barley, rye, and wheat).

Systemic complications are similar to those of UC and include arthritis, liver disease, cholelithiasis (especially with ileal involvement), ankylosing spondylitis, pyoderma gangrenosum, erythema nodosum, and uveitis. Renal disorders are common, especially nephrolithiasis (kidney stones) secondary to increased oxalate absorption.

Diagnostic Studies

Diagnosis of Crohn's disease can be made by means of a thorough history and physical examination, to establish clinical signs and symptoms;

barium studies; and endoscopy with biopsy (Table 45-22). Laboratory studies may determine electrolyte disturbances and the presence of anemia. Barium studies are useful in determining location and extent of the disease and may reveal classic findings, such as stricture formations in the ileum (string sign), cobblestoning of the mucosa, fistulas, and areas of abnormal and normal mucosa. Endoscopic studies, such as colonoscopy and sigmoidoscopy, are useful in detecting such early mucosal changes as patchy inflammation, small ulcerations, and skip areas that may not be seen radiologically. Biopsies may be performed to determine the presence of granulomas. Barium studies are performed to determine the degree of ileal involvement. Upper GI barium studies are done to diagnose upper gastro-duodenal disease. Because an endoscope can enter only the distal ileum, capsule endoscopy may be used in the diagnosis of small intestine disease. Capsule endoscopy is a useful diagnostic test, but the high cost of the procedure limits its use (Mazal, 2014).

TABLE 45-22

COLLABORATIVE CARE
Crohn's Disease

Diagnostic	Collaborative Therapy
• History and physical examination • CBC, ESR • Serum chemistries • Testing of stool for occult blood • Radiological studies with barium contrast • Sigmoidoscopy and colonoscopy with biopsy	• High-calorie, high-vitamin, high-protein, low-residue, dairy-free diet • Antimicrobial agents* • Corticosteroid drugs* • Immuno-suppressants* • Immuno-modulators* • Supplementary PN • Elemental diet • Physical and emotional rest • Surgery†

*See Table 45-19.

†See Table 45-23.

CBC, complete blood cell count; *ESR*, erythrocyte sedimentation rate; *PN*, parenteral nutrition.

Collaborative Care

The goal of collaborative care is to control the inflammatory process, relieve symptoms, correct metabolic and nutritional problems, and promote healing. Drug therapy and nutritional support are the mainstays of treatment.

Drug Therapy.

Drug therapy for Crohn's disease is presented in Table 45-19. Sulphasalazine (Salazopyrin) is effective when the disease involves the large intestine but is much less effective when only the small intestine is involved. Corticosteroid therapy is effective in reducing inflammation and suppressing disease. The dosage and the route of administration depend on severity of the illness and the area involved. Once clinical symptoms subside, the dosage should be tapered. Immuno-suppressive agents (azathioprine) may be tried if repeated trials with corticosteroids fail. Patients require close monitoring because of the serious adverse effects of these drugs. Metronidazole (Flagyl) is useful in treating Crohn's disease of the perianal area. Marked exacerbations have been reported when the drug is stopped. In patients with Crohn's disease in remission, fish oil preparations have been evaluated for their ability to prevent recurrence of inflammation; however, their palatability is low.

Biological drug therapies of Crohn's disease include monoclonal antibodies to TNF-α (infliximab [Remicade]), adalimumab [Humira]), and to a leukocyte adhesion molecule (natalizumab [Tysabri]). Infliximab has been shown to reduce the degree of inflammation in patients who are refractory to other drug therapies. However, not all patients with Crohn's disease respond to infliximab.

Nutritional Therapy.

Elemental diets and parenteral nutrition may be used in patients with Crohn's disease (see Chapter 42). Parenteral nutrition may be given to patients with severe disease, small bowel fistulas, or short bowel syndrome (described later in this chapter). It is given before and after surgery to promote wound healing, reduce complications, and hasten recovery. The elemental diet provides a high-calorie, high-nitrogen, fat-free, no-residue substrate that is absorbed in the proximal small bowel. This diet can be given to most patients with Crohn's disease, even during acute exacerbations.

The diet should otherwise be low in residue, roughage, and fat but high in calories and protein. It may be difficult to maintain adequate absorption during periods of disease exacerbation and even during periods of remission. Milk and milk products may have to be excluded from the diet. Lactose, the primary disaccharide found in milk, may not be adequately digested because of the inability of the damaged intestinal mucosa to produce sufficient amounts of lactase. High-fat diets are poorly tolerated

because of the loss of absorbing mucosa and altered bile salt metabolism and absorption.

Vitamin deficiencies may develop as a result of malabsorption. Cobalamin (vitamin B_{12}) injections every month may be needed because of the inability of the terminal ileum (if affected) to absorb this vitamin.

Surgical Therapy.

Surgery is used in patients with severe symptoms that are unresponsive to therapy and in those with life-threatening complications. The majority of patients with Crohn's disease eventually require surgery at least once in the course of their disease. Indications for surgery are outlined in Table 45-23. Unlike UC, Crohn's disease is not cured by surgery. The recurrence rate after surgery is high. The surgical procedure depends on the affected area and the condition of the patient. Conservative intestinal resection with anastomosis of healthy bowel is the procedure of choice.

TABLE 45-23

INDICATIONS FOR SURGICAL THERAPY FOR CROHN'S DISEASE

• Drainage of abdominal abscess • Failure to respond to conservative therapy • Fistulas • Inability to decrease corticosteroids • Intestinal obstruction	• Massive hemorrhage • Perforation • Secondary hydronephrosis • Severe anorectal disease • Suspicion of carcinoma

Nursing Management Crohn's Disease

Care of patients with Crohn's disease is similar to that of patients with UC (see NCP 45-3, available on the Evolve website). As the patient's condition improves, the nurse should allow for more self-care, provide frequent rest periods, and advise the patient of the importance of rest and avoidance or control of emotional stress. This may be difficult for the patient when told the nature of the disease and the limitations of the treatment. Patients who have perianal fistulas or abscesses may need special skin care. Postoperative care should be the same as for laparotomy.

In the majority of patients with Crohn's disease, the course is chronic and intermittent. The patient and significant others may need help in setting realistic short- and long-term goals. Teaching is important and should include (1) the importance of rest and diet management, (2) perianal care, (3) action and adverse effects of drugs, (4) symptoms of recurrence of disease, (5) when to seek medical care, and (6) use of stress management techniques.

Age-Related Considerations

Inflammatory Bowel Disease

Although IBDs (i.e., UC and Crohn's disease) are considered diseases of young adults, a second peak in the distribution of these inflammatory conditions occurs around the ages of 50 to 70 years. The pathogenesis, natural history, and clinical course of UC and Crohn's disease in older adults are similar to those observed in younger patients. However, the distribution of the inflammation appears to be somewhat different. In older-adult patients with UC, the distal colon is usually involved (proctitis). In older adults with Crohn's disease, the colon rather than the small intestine tends to be involved. There is less recurrence of Crohn's disease in older adults treated with surgical resection. The degree of inflammation associated with both conditions tends to be less in older-adult patients than in younger patients.

Collaborative care of older-adult patients with one of these conditions is similar to care of younger patients. However, because of increased risk for cardiovascular and pulmonary complications, older adults tend to have increased morbidity associated with surgical procedures.

In addition to Crohn's disease and UC, older adults are also vulnerable to inflammation of the colon (colitis) from medication use and systemic vascular disease. Drugs such as nonsteroidal anti-inflammatory drugs (NSAIDs), digitalis, vasopressin, estrogen, and allopurinol (Zyloprim) have been associated with colitis development in older-adult patients. Colitis may also be secondary to ischemic bowel disease related to atherosclerosis and heart failure.

Inflammation of the colon as a result of Crohn's disease or UC results in diarrhea, which may be bloody. The loss of fluid and electrolytes and possibly blood may leave older adults more vulnerable to problems related to volume depletion and dehydration. This may be particularly problematic in patients with diminished renal and cardiovascular function. Thus, nursing management is focused on careful assessment of fluid and electrolyte status and evaluation of the replacement therapies.

Malabsorption Syndrome

Malabsorption results from impaired absorption of fats, carbohydrates, proteins, minerals, and vitamins. The stomach, small intestine, liver, and pancreas regulate normal digestion and absorption. Digestive enzymes ordinarily break down nutrients so that absorption can take place through the intestinal mucosa and nutrients can get into the bloodstream. If there is an interruption in this process at any point, malabsorption may occur. Several problems can cause malabsorption (Table 45-25). They can be classified into malabsorption caused by (1) biochemical or enzyme deficiencies, (2) bacterial proliferation, (3) disruption of small intestine mucosa, (4) disturbed lymphatic and vascular circulation, or (5) surface area loss. Lactose intolerance is the most common malabsorption disorder, followed by IBD, celiac disease, tropical sprue, and cystic fibrosis.

TABLE 45-25
COMMON CAUSES OF MALABSORPTION

Biochemical or Enzyme Deficiencies	Disturbed Lymphatic and Vascular Circulation
• Lactase deficiency • Biliary tract obstruction • Pancreatic insufficiency • Cystic fibrosis • Chronic pancreatitis • Zollinger–Ellison syndrome	• Lymphoma • Ischemia • Lymphangiectasia • Heart failure
Bacterial Proliferation	**Surface Area Loss**
• Tropical sprue • Parasitic infection	• Billroth II gastrectomy • Gastro-jejunal bypass surgery for obesity • Short bowel syndrome • Distal ileal resection, disease, or bypass
Small Intestinal Mucosal Disruption	
• Celiac disease • Whipple's disease • Crohn's disease	

The most common clinical manifestation of malabsorption is steatorrhea, which is the passage of large amounts of fat as bulky, fatty, frothy, foul-smelling, yellow-grey, greasy stools with putty-like consistency that float in water and are difficult to flush (Table 45-26).

TABLE 45-26
CLINICAL MANIFESTATIONS OF MALABSORPTION

Clinical Manifestations	Pathophysiology
Gastro-Intestinal	
Weight loss	Malabsorption of fat, carbohydrates, and protein leading to loss of calories; marked reduction in caloric intake or increased use of calories
Diarrhea	Impaired absorption of water, sodium, fatty acids, bile, or carbohydrates
Flatulence	Bacterial fermentation of unabsorbed carbohydrates
Steatorrhea	Undigested and unabsorbed fat
Glossitis, cheilosis, stomatitis	Deficiency of iron, riboflavin, cobalamin, folic acid, and other vitamins
Hematological	
Anemia	Impaired absorption of iron, cobalamin, and folic acid
Hemorrhagic tendency	Vitamin C deficiency Vitamin K deficiency inhibiting production of clotting Factors II, VII, IX, and X
Musculo-Skeletal	
Bone pain	Osteoporosis from impaired calcium absorption Osteomalacia secondary to hypocalcemia, hypophosphatemia, inadequate vitamin D
Tetany	Hypocalcemia, hypomagnesemia
Weakness, muscle cramps	Anemia, electrolyte depletion (especially potassium)
Muscle wasting	Protein malabsorption
Neurological	
Altered mental status	Dehydration
Paresthesias	Cobalamin deficiency
Peripheral neuropathy	Cobalamin deficiency
Night blindness	Thiamine deficiency, vitamin A deficiency
Integumentary	
Bruising	Vitamin K deficiency
Dermatitis	Fatty acid deficiency, zinc deficiency, niacin and other vitamin deficiencies
Brittle nails	Iron deficiency
Hair thinning and loss	Protein deficiency
Cardiovascular	
Hypotension	Dehydration
Tachycardia	Hypovolemia, anemia
Peripheral edema	Protein malabsorption, protein loss in diarrhea

Tests used to determine the cause of malabsorption include qualitative examination of stool for fat (e.g., Sudan III stain), a 72-hour stool collection for quantitative measurement of fecal fat, serological testing for celiac disease, and fecal elastase testing to determine if there is pancreatic insufficiency. Other diagnostic studies include a CT scan and endoscopy to obtain a small bowel biopsy specimen for diagnosis. A small bowel barium enema is performed to identify abnormal mucosal patterns. Capsule endoscopy can be used to assess the small intestine for alterations in mucosal integrity and inflammation.

Tests for carbohydrate malabsorption include the D-xylose test and the lactose tolerance test. Laboratory studies that are frequently ordered include a CBC, measurement of prothrombin time (to see if vitamin K absorption is adequate), serum vitamin A and carotene levels, serum electrolytes, cholesterol, and calcium.

Celiac Disease

Celiac disease is an autoimmune disease characterized by damage to the small intestinal mucosa from the ingestion of wheat, barley, and rye in genetically susceptible individuals (Lowth, 2014). It was previously considered a rare intestinal disease that began in childhood, accompanied by symptoms of diarrhea, malabsorption, and malnutrition. We now know that it is relatively common, occurs at all ages, and has a wide variety of symptoms. *Celiac sprue* and *gluten-sensitive enteropathy* are other names for celiac disease. Celiac disease is not the same disease as *tropical sprue,* a chronic disorder acquired in tropical areas that is characterized by progressive disruption of jejunal and ileal tissue resulting in nutritional difficulties. Tropical sprue is treated with folic acid and tetracycline. Celiac disease is most common in people of European ancestry, and it is estimated that approximately 1 in every 133 people in Canada is affected by celiac disease (Canadian Celiac Association, 2014).

Etiology and Pathophysiology

Three factors necessary for developing celiac disease are genetic predisposition, gluten ingestion, and an immune-mediated response. As with other autoimmune diseases, the tissue destruction that occurs with celiac disease is the result of chronic inflammation. Inflammation is activated by the ingestion of gluten found in wheat, rye, and barley. Gluten contains specific peptides called *prolamines.* In genetically susceptible individuals, partial digestion of gluten releases prolamine peptides, which are absorbed into the lamina propria in the intestinal submucosa.

Once in the lamina propria, peptides bind to human leukocyte antigen (HLA)-DQ2 and HLA-DQ8 (or both) antigens and activate an inflammatory response. Inflammation damages the microvilli and brush border of the small intestine, decreasing the amount of surface area available for nutrient absorption (Mavrinac, Ohannessian, Dowling, et al., 2014). Damage is most severe in the duodenum, probably related to the

greater exposure to gluten. The intestinal damage decreases distal to the duodenum. The inflammation continues until gluten ingestion ceases.

Clinical Manifestations

Classic signs of celiac disease include foul-smelling diarrhea, steatorrhea, flatulence, abdominal distension, and symptoms of malnutrition. Some people have no obvious GI symptoms, and may have atypical symptoms such as decreased bone density and osteoporosis, dental enamel hypoplasia, iron and folate deficiencies, peripheral neuropathy, and reproductive problems (Mavrinac et al., 2014). A pruritic, vesicular skin lesion, called *dermatitis herpetiformis*, is sometimes present and occurs as a rash on the buttocks, scalp, face, elbows, and knees. Celiac disease is also associated with autoimmune diseases, particularly rheumatoid arthritis, type 1 diabetes mellitus, and thyroid disease. Protein, fat, and carbohydrate absorption is affected, leading to poor growth, weight loss, muscle wasting, and other signs of malnutrition. Abnormal folate, iron, and cobalamin levels can occur. Iron-deficiency anemia is one of the most common manifestations of celiac disease. Patients may exhibit lactose intolerance and should eliminate lactose-containing products until the disease is under control. Inadequate calcium intake and vitamin D absorption can lead to decreased bone density and osteoporosis. Poor nutrition leads to reproductive problems.

Diagnostic Studies and Collaborative Care

Celiac disease is confirmed when (1) there is histological evidence of the disease following biopsy from the small intestine and (2) the symptoms and histological evidence disappear when the person eats a gluten-free diet (Mavrinac et al., 2014). Diagnostic testing must be done before the person is placed on a gluten-free diet because the diet will alter the results. Biopsies show flattened mucosa and noticeable losses of villi. Celiac disease should be ruled out during a diagnostic workup of IBS because the symptoms are similar. Many people spend years seeking treatment for nonspecific complaints before celiac disease is diagnosed (thus the large number of people who are diagnosed in adulthood). Treatment with a gluten-free diet halts the process. Most patients recover completely within 3 to 6 months of treatment, but they need to maintain a gluten-free diet for life. Wheat, barley, oats, and rye products must be avoided. Although pure oats do not contain gluten, oat products can become contaminated with wheat, rye, and barley during the milling process. Gluten is also found in

some medications and in many food additives, preservatives, and stabilizers. A combination of corticosteroids and a gluten-free diet is used to treat individuals who do not respond to the gluten-free diet alone. If the disease is untreated, chronic inflammation and hyperplasia continue. Individuals with celiac disease have an increased risk for non-Hodgkin's lymphoma and GI cancers.

Lactase Deficiency

Lactase deficiency is a condition in which the lactase enzyme is deficient or absent. *Lactase* is the enzyme that breaks down lactose into two simple sugars—glucose and galactose. Although primary lactase deficiency seems to be hereditary, milk intolerance may not become clinically evident until late adolescence or early adulthood. About 5% of the adult population has primary lactase deficiency. The highest incidence in Canada is found in people who are Black, Indigenous, Latin American, Asian, and of Jewish descent. Often, acquired lactase deficiency is seen in conjunction with other GI diseases in which the mucosa has been damaged, including UC, Crohn's disease, gastro-enteritis, and celiac disease.

Clinical Manifestations

The symptoms of lactose intolerance include bloating, flatulence, crampy abdominal pain, and diarrhea. They may occur within a half hour to several hours after drinking a glass of milk or ingesting a milk product. The diarrhea of lactose intolerance results from fluid secretion into the small intestine, a response to the osmotic action of undigested lactose.

Nursing and Collaborative Management Lactase Deficiency

Many people who are lactose-intolerant are aware of their milk intolerance and avoid milk. A lactose intolerance test can be performed to rule out milk allergies. The patient is given 50 g of lactose orally. Blood samples are drawn before the consumption of lactose and at 15-, 30-, 60-, and 90-minute intervals. Failure of the blood glucose level to increase more than 20 mg/dL is suggestive of lactase deficiency. Results of the hydrogen breath test after ingestion of lactose are abnormal.

Treatment consists of eliminating lactose from the diet by avoiding milk and milk products. A lactose-free diet is given initially and is gradually advanced to a low-lactose diet, as tolerated by the patient. Many people who are lactose-intolerant may not exhibit symptoms if lactose is taken in small amounts. In some people, lactose may be tolerated better if taken with meals.

The patient needs to be aware that milk, ice cream, cottage cheese, and cheese have a high lactose content. If the milk has been fermented (e.g., cultured buttermilk, yogourt, sour cream), the patient with low lactase levels may tolerate it better.

Lactase enzyme (Lactaid) is available commercially as an over-the-counter (OTC) product. It is mixed with milk and breaks down the lactose before the milk is ingested. Lactase tablets can also be taken with the ingestion of other dairy products. Since avoidance of milk and milk products can lead to calcium deficiency, supplements may be necessary to prevent osteoporosis.

Short-Bowel Syndrome

Short bowel syndrome (SBS) results from extensive resection of the small intestine. Rapid intestinal transit, impaired digestive and absorption processes, and fluid and electrolyte losses characterize the syndrome. In adults, extensive resection of the small intestine may be necessary for bowel infarction because of vascular thrombosis or insufficiency, abdominal trauma, cancer, radiation enteritis, or Crohn's disease.

The length and the portions of small bowel resected are associated with the number and severity of symptoms. Resections of up to 50% of the small intestine cause little disturbance of bowel function, especially if the

terminal ileum and the ileocecal valve remain intact. After large resections, the remaining intestine undergoes adaptive changes that are more pronounced in the ileum. The villi and the crypts increase in size, and absorptive capacity of the remaining intestine increases. Intestinal adaptation is enhanced by the presence of food, fibre, bile, and pancreatic secretions in the lumen and continues for up to 2 years. Resection of the ileum, the ileocecal valve, or the colon results in a rapid intestinal transit, decreasing absorption time. Ileal resection causes malabsorption of cobalamin, bile salts, and fat, resulting in steatorrhea.

Clinical Manifestations

The predominant manifestations of SBS are diarrhea, steatorrhea, and weight loss. There may be signs of malnutrition and multiple vitamin and mineral deficiencies (e.g., cobalamin and zinc deficiency, hypocalcemia). The patient may develop lactase deficiency and bacterial overgrowth. Oxalate kidney stones may form from increased colonic absorption of oxalate.

Collaborative Care

The overall goals are that the patient with SBS will have fluid and electrolyte balance, normal nutritional status, and control of diarrhea. In the period immediately following massive bowel resection, patients receive PN to replace fluid, electrolyte, and nutrient losses. Hypersecretion of gastric acid, for which the cause is unknown, is reduced by proton pump inhibitors (e.g., omeprazole [Losec]).

A high-carbohydrate, low-fat diet supplemented with soluble fibre and pectin may slow transit time and improve nutrient absorption, decrease stool output, and enable patients to wean off parenteral nutrition. The patient with SBS is encouraged to eat at least six to eight meals per day to increase the overall time food is present in and in contact with the intestine. Oral intake can be supplemented with elemental nutrient formulas and tube feeding during the night. For patients with severe malabsorption, PN may be reinstituted. Oral supplements of calcium, zinc, and multivitamins are typically recommended.

Opioid antidiarrheal drugs are the most effective in decreasing intestinal motility (see Table 45-3). For patients with limited ileal resections (<100 cm), cholestyramine reduces diarrhea resulting from unabsorbed bile acids and increases their excretion in feces. Bile acids stimulate intestinal fluid secretion and reduce colonic fluid absorption.

Intestinal transplantation is a procedure performed at a few specialized transplant centres. Candidates for this procedure are patients with SBS, dependence on parenteral nutrition, and chronic liver disease. It is often considered a last-resort treatment option for patients with intestinal failure who develop life-threatening complications from parenteral nutrition. Transplantation may include the intestine alone, liver and intestine, or multivisceral combinations (stomach, duodenum, jejunum, ileum, colon, and pancreas).

Intestinal Obstruction

Intestinal obstruction occurs when a partial or complete obstruction of the intestine prevents intestinal contents from passing through the GI tract; it requires prompt treatment. The causes of intestinal obstruction can be classified as mechanical or nonmechanical.

Types of Intestinal Obstruction

Mechanical.

Mechanical obstruction may be caused by an occlusion of the lumen of the intestinal tract (Figure 45-4). Most intestinal obstructions occur in the small intestine and are usually due to adhesions. Adhesions can develop after abdominal surgery. Obstruction can occur within days of surgery or years later. Carcinoma is the most common cause of large bowel obstruction, followed by volvulus and diverticular disease.

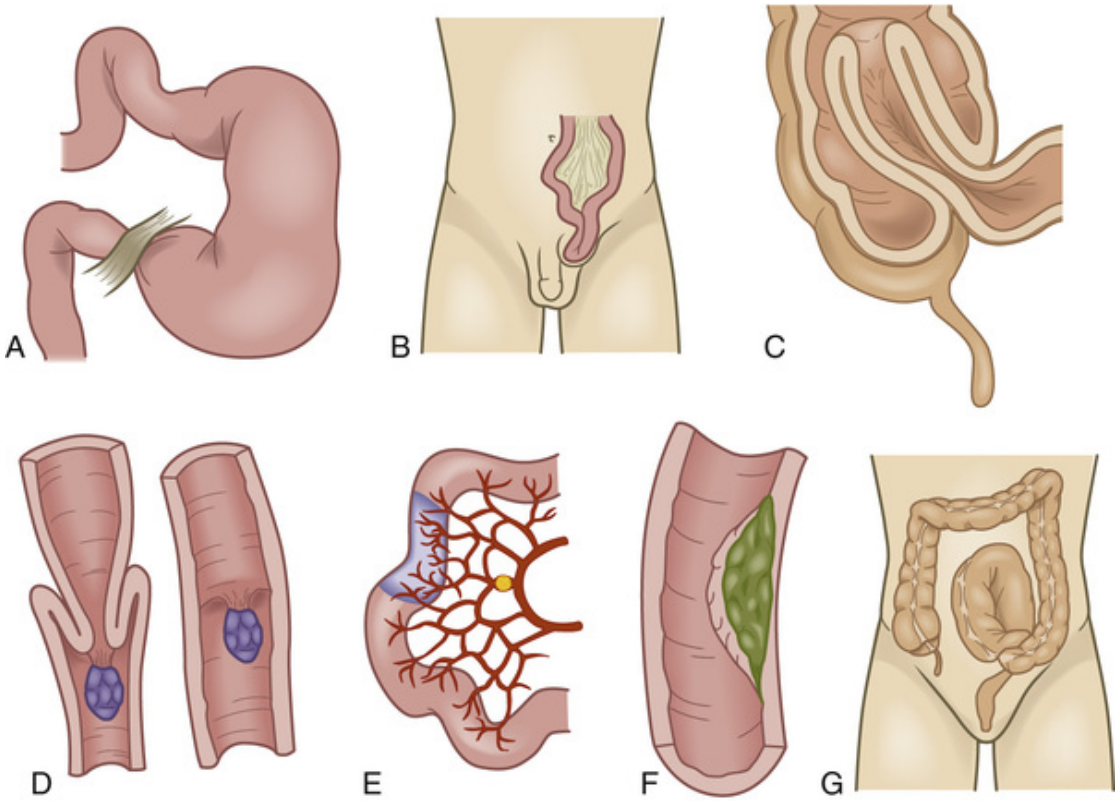

FIGURE 45-4 Bowel obstructions. **A,** Adhesions. **B,** Strangulated inguinal hernia. **C,** Ileocecal intussusception. **D,** Intussusception from polyps. **E,** Mesenteric occlusion. **F,** Neoplasm. **G,** Volvulus of the sigmoid colon.

Nonmechanical.

A *nonmechanical obstruction* may result from a neuro-muscular or vascular disorder. Paralytic (adynamic) ileus is an impairment of intestinal motility (ileus that persists for more than 2 to 3 days), and is the most common form of nonmechanical obstruction. It can occur after any abdominal surgery. Other causes of paralytic ileus include peritonitis, inflammatory responses (e.g., acute pancreatitis, acute appendicitis), electrolyte abnormalities, and thoracic or lumbar spinal fractures.

Pseudo-obstruction is an apparent mechanical obstruction of the intestine without demonstration of obstruction by radiological methods. Collagen vascular diseases and neurological and endocrine disorders may cause pseudo-obstruction, but mostly, it is found to be idiopathic.

Vascular obstructions are rare and are due to an interference with the blood supply to a portion of the intestines. The most common causes are emboli and atherosclerosis of the mesenteric arteries. The celiac, inferior, and superior mesenteric arteries supply blood to the bowel. Emboli may

originate from thrombi in patients with chronic atrial fibrillation, diseased heart valves, and prosthetic valves. Venous thrombosis may be seen in low–blood flow states, such as heart failure and shock.

Etiology and Pathophysiology

Normally, 6 to 8 L of fluid enters the small bowel daily. Most of the fluid is absorbed before it reaches the colon. Approximately 75% of intestinal gas is swallowed air. Bacterial metabolism produces methane and hydrogen gases. Fluid, gas, and intestinal contents accumulate proximal to the intestinal obstruction. This causes distension, and the distal bowel may collapse. The distension reduces the absorption of fluids and stimulates intestinal secretions. As the fluid increases, so does the pressure in the lumen of the bowel. The increased pressure leads to an increase in capillary permeability and extravasation of fluids and electrolytes into the peritoneal cavity. Edema, congestion, and necrosis from impaired blood supply as well as possible rupture of the bowel may occur. The retention of fluid in the intestine and the peritoneal cavity can lead to a severe reduction in circulating blood volume and result in hypotension and hypovolemic shock.

The electrolyte-rich fluids, which are normally absorbed in the bowel, are retained in the bowel and subsequently lost into the peritoneal cavity. The location of the obstruction determines the extent of fluid, electrolyte, and acid–base imbalances. If the obstruction is high, as in an obstruction in the pylorus, metabolic alkalosis may result from the loss of hydrochloric acid from the stomach through vomiting or NG intubation.

When the obstruction is located in the small bowel, dehydration occurs rapidly. Dehydration and electrolyte imbalances do not occur early in large bowel obstruction. If the obstruction is below the proximal colon, most GI fluids have been absorbed before reaching the point of the obstruction. Solid fecal material accumulates until symptoms of discomfort appear. Reverse peristalsis may cause vomiting of fecal material very late in the bowel obstruction.

Simple obstructions of the intestine involve blockage of the lumen in one spot. A closed-loop obstruction occurs when the lumen is blocked in two different spots (e.g., volvulus). This results in an isolated segment of bowel and obstruction proximal to that segment. Strangulation and gangrene are likely to develop if treatment is not immediate. A strangulated obstruction occurs when the circulation to the obstructed intestine is impaired. This is the most dangerous form of obstruction because it may lead to necrosis of

the intestine (incarcerated). Volvulus, hernias, or adhesions are the most common causes.

Clinical Manifestations

The clinical manifestations of intestinal obstruction vary, depending on the location of the obstruction, and include nausea, vomiting, abdominal pain, distension, inability to pass flatus, and obstipation (Table 45-27). Obstruction located high in the small intestine produces rapid-onset, sometimes projectile vomiting with bile-containing vomitus. Vomiting from more distal obstructions of the small intestine is more gradual in onset. The vomitus may be orange-brown and foul smelling because of bacterial overgrowth. Vomiting may be entirely absent in large bowel obstruction if the ileocecal valve is competent; otherwise, the patient may eventually vomit fecal material.

TABLE 45-27

CLINICAL MANIFESTATIONS OF SMALL AND LARGE INTESTINAL OBSTRUCTIONS

Clinical Manifestations	Small Intestine	Large Intestine
Onset	Rapid	Gradual
Vomiting	Frequent and copious	Late manifestation
Pain	Colicky, cramplike, intermittent	Low-grade, cramping abdominal pain
Bowel movement	Feces for a short time	Absolute constipation
Abdominal distension	Dependent upon location of obstruction, minimal to greatly increased	Greatly increased

Vomiting usually relieves abdominal pain in high intestinal obstructions. Persistent, colicky abdominal pain is seen with lower intestinal obstruction. A characteristic sign of mechanical obstruction is pain that comes and goes in waves. This is caused by intestinal peristalsis working to move bowel contents past the obstructed area. In contrast, paralytic ileus produces a more constant generalized discomfort. Strangulation causes severe, constant pain that is rapid in onset. Abdominal distension is a common manifestation of intestinal obstructions. It is usually absent or minimally noticeable in proximal obstructions of the small intestine and greatly increased in lower intestinal obstructions. Abdominal tenderness and rigidity are usually absent unless strangulation or peritonitis has occurred.

Auscultation of bowel sounds reveals high-pitched sounds above the area of obstruction. The patient often notes borborygmi (audible

abdominal sounds produced by hyperactive intestinal motility). The patient's temperature rarely rises above 37.8°C unless strangulation or peritonitis has occurred.

Diagnostic Studies

A thorough history and physical examination should be performed for patients with intestinal obstruction. CT scan and abdominal radiographic studies are the most useful diagnostic aids. Upright and lateral abdominal radiographs show the presence of gas and fluid in the intestines (air–fluid levels). The presence of intraperitoneal air indicates perforation. Sigmoidoscopy or colonoscopy may provide direct visualization of an obstruction in the colon.

Laboratory tests are important and provide essential information. A CBC and serum electrolyte, amylase, and blood urea nitrogen (BUN) determinations should be performed. An elevated WBC count may indicate strangulation or perforation; elevated hematocrit values may reflect hemoconcentration. Decreased hemoglobin and hematocrit values may indicate bleeding from a neoplasm or strangulation with necrosis. Serum electrolytes should be monitored to assess the patient's fluid and electrolyte balance. Serum sodium, potassium, and chloride concentrations are decreased in small-bowel obstruction. The BUN value may be increased because of dehydration. The stool should be checked for occult blood.

Collaborative Care

Treatment for intestinal obstruction is directed toward decompression of the intestine by removal of gas and fluid, correction and maintenance of fluid and electrolyte balance, and relief or removal of the obstruction. NG tubes may be used to decompress the bowel. NG tubes may be inserted before surgery to empty the stomach and relieve distension. NG or venting percutaneous tubes are effective in the treatment of patients with neurogenic obstruction who do not require surgery.

Sigmoidoscopy may successfully reduce a sigmoid volvulus. Colon-decompression catheters may be passed through partially obstructed areas via a colonoscope to decompress the bowel before surgery.

Intravenous infusions that contain normal saline solution and potassium should be given to maintain fluid and electrolyte balance. PN may be necessary in some cases to correct nutritional deficiencies, improve the

patient's nutritional status before surgery, and promote postoperative healing.

Most mechanical obstructions are treated surgically. Surgery may involve resecting the obstructed segment of bowel and anastomosing the remaining healthy bowel. Partial or total colectomy, colostomy, or ileostomy may be required when extensive obstruction or necrosis is present. Occasionally, obstructions can be removed nonsurgically. A colonoscope can be used to remove polyps, dilate strictures, and remove and destroy tumours with a laser.

Nursing Management Intestinal Obstruction

Nursing Assessment

Intestinal obstruction is a potentially life-threatening condition. Nursing assessment must begin with a detailed patient history and physical examination. The type and the location of obstruction usually cause characteristic symptoms. The nurse should determine location, duration, intensity, and frequency of abdominal pain and whether abdominal tenderness or rigidity is present. For vomiting, the onset, frequency, colour, odour, and amount of vomitus should be recorded. Bowel function, including passage of flatus, should be determined. The nurse auscultates for bowel sounds and documents the character and the location; inspects the abdomen for scars, palpable masses, and distension; and observes for muscle guarding and tenderness.

Nursing Diagnoses

Nursing diagnoses for patients with intestinal obstructions include, but are not limited to, the following:

- *Acute pain* related to *biological injury agent* (abdominal distention and increased peristalsis)
- *Deficient fluid volume* related to *insufficient fluid intake* (decrease in intestinal fluid absorption, third space fluid shifts, NG suction)

Planning

The overall goals are that the patient with an intestinal obstruction will have (1) relief of the obstruction and return to normal bowel function, (2) minimal to no discomfort, (3) normal fluid and electrolyte status, and (4) maintenance of adequate nutrition.

Nursing Implementation

The patient should be monitored closely for signs of dehydration and electrolyte imbalance. A strict intake and output record should be maintained. Intravenous fluids should be administered as ordered. Serum electrolyte levels should be monitored. A patient with a high obstruction is more likely to have metabolic alkalosis; a patient with a low obstruction is at greater risk for metabolic acidosis. The patient is often restless and constantly changes position to relieve the pain. The nurse should provide comfort measures, promote a restful environment, and keep distractions and visitors to a minimum. Nursing care of the patient after surgery for an intestinal obstruction is similar to care of the patient after a laparotomy (see NCP 45-2, available on the Evolve website).

Polyps of the Large Intestine

Colonic polyps arise from the mucosal surface of the colon and project into the lumen. They may be *sessile* (flat, broad based, and attached directly to the intestinal wall) or *pedunculated* (attached to the intestinal wall by a stalk). Polyps tend to be sessile when small and become pedunculated as they enlarge, especially if they are in the left or descending colon (Figure 45-5). They may be found anywhere in the large intestine but are most commonly found in the rectosigmoid area. Although most polyps are asymptomatic, rectal bleeding or occult blood in the stool are the most common manifestations.

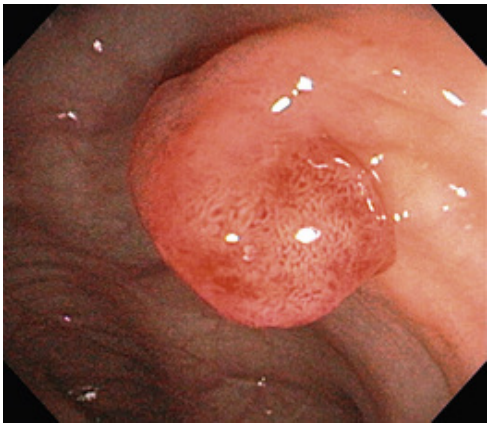

FIGURE 45-5 Endoscopic image of a pedunculated polyp in the descending colon. Source: David Musher/Science Source.

Types of Polyps

The most common types of polyp are hyperplastic and adenomatous. *Hyperplastic polyps* originate from the epithelium and are non-neoplastic growths. They rarely grow larger than 5 mm and never cause clinical symptoms. Other benign (non-neoplastic) polyps include inflammatory polyps, lipomas, and juvenile polyps (Table 45-28).

TABLE 45-28
TYPES OF POLYPS OF THE LARGE INTESTINE

Neoplastic	Non-Neoplastic
• Epithelial polyps (adenomatous) • Tubular adenoma • Tubular villous adenoma • Villous adenoma • Hereditary polyposis syndromes (adenomatous polyposis syndrome) • Familial adenomatous polyposis (FAP)	• Epithelial polyps (hyperplastic) • Hereditary polyposis syndromes • Familial juvenile polyposis • Inflammatory polyps • Pseudopolyps • Benign lymphoid polyps • Submucosal • Lipomas • Leiomyomas • Fibromas

Adenomatous polyps are characterized by neoplastic changes in the epithelium. They are closely linked to colorectal adenocarcinoma. Structurally, there are three types, with tubular adenomas being the most prevalent. The risk for cancer in the polyp increases with polyp size and villous structure. Villous adenomas have a higher risk of turning cancerous than tubular adenomas. Removing adenomatous polyps decreases the occurrence of colorectal cancer.

Although there are several polyposis syndromes, they are relatively rare. Of these, *familial adenomatous polyposis* (FAP) is the most common (see the "Genetics in Clinical Practice" box). This disorder is characterized by multiple polyps that at times number in the thousands and that are located in the large intestine and sometimes in other areas of the GI tract. Patients with a history of FAP have a lifetime risk of developing colorectal cancer that approaches 100%. They also develop cancer at an earlier age (i.e., <40 years of age) than patients with non-FAP colorectal cancer. For children of patients with FAP, screening must be initiated at puberty and then conducted annually. These children have a 50% risk of developing FAP. When there is indication of disease, total colectomy with ileostomy is the treatment of choice. Patients with FAP are also at risk for cancers of the thyroid, small bowel, liver, and brain, so lifetime cancer surveillance is essential (Suhaimi, Nazri, Latar, et al., 2015).

Genetics in Clinical Practice

Familial Adenomatous Polyposis (FAP)

Genetic Basis

- Autosomal dominant disorder
- Mutation in *APC* gene located on chromosome 5

Incidence

- 1 in 5 000–7 500 people
- Men and women affected equally

Genetic Testing

- DNA testing available to detect *APC* gene mutation

Clinical Implications

- FAP is characterized by the presence of colorectal polyps (usually >1 000).
- Polyps are not present at birth but appear during adolescence and early adulthood.
- FAP accounts for at least 1% of all colorectal cancers.
- If untreated, FAP almost always results in the development of colon cancer before the age of 40.
- With FAP, there is also increased incidence of gastric and small intestinal polyps.
- Many deaths related to FAP could be prevented with early and aggressive monitoring and treatment, including frequent colonoscopies and total colectomy.
- Individuals with a family history of FAP could benefit from genetic counselling and teaching.

APC, adenomatous polyposis coli; *FAP*, familial adenomatous polyposis.

Diagnostic Studies and Collaborative Care

Barium enema, sigmoidoscopy, colonoscopy and CT/MRI colonography (virtual colonoscopy) are used to diagnose polyps. All polyps are considered abnormal and should be removed. In patients whose polyps are identified through barium enema, removal (polypectomy) should be done through a colonoscope or a sigmoidoscope. If the polyp is not removable, a biopsy specimen should be taken for tissue examination. Surgery is not indicated unless carcinoma is present or certain cases of polyposis syndromes warrant it. The patient should be observed for rectal bleeding, fever, severe abdominal pain, and abdominal distension, which may indicate hemorrhage or perforation.

Colorectal Cancer

Colorectal cancer (a malignant disease of the colon, the rectum, or both) is the second-most common cause of cancer death in Canada. In 2015, it was estimated that there would be 25 100 new cases of colorectal cancer diagnosed in Canada, and that 9 300 people would die from it (Colorectal Cancer Association of Canada, 2016a).

The incidence of colorectal cancer at specific sites varies (Figure 45-6). In both sexes, the incidence of right colon cancers has increased, and cancers in the rectum have decreased. The highest percentages of colorectal cancers in Canada are currently located in the rectum, the ascending colon, and the sigmoid colon. Approximately 20% of colorectal cancers are within reach of the examining finger, and 50% are within reach of the sigmoidoscope.

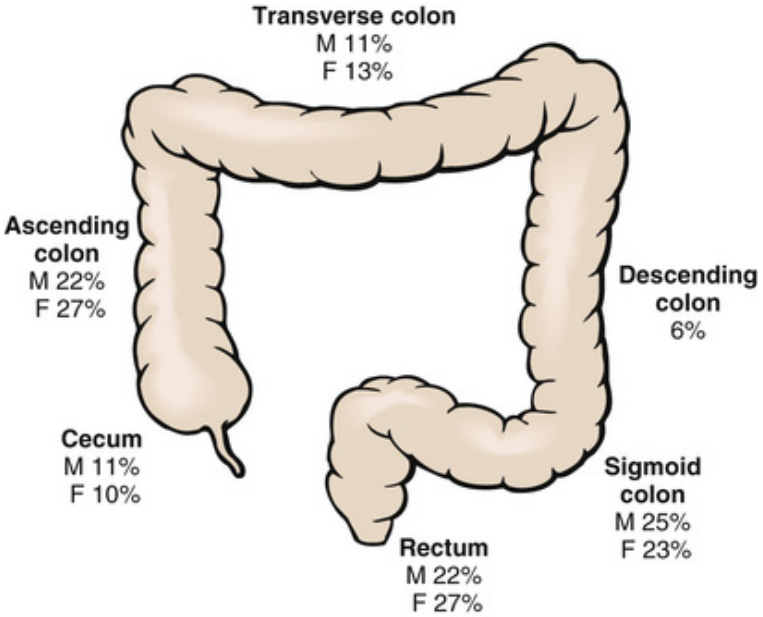

FIGURE 45-6 Incidence of colorectal cancer. Approximately one-half of all colon cancers occur in the rectosigmoid area. Percentages are listed for males *(M)* and females *(F)*.

Etiology and Pathophysiology

Risk factors for CRC include a diet high in red or processed meat, obesity, physical inactivity, alcohol, long-term smoking, and low intake of fruits and vegetables. Groups at high risk for colorectal cancer have been identified (Table 45-29), and genetic conditions such as FAP and a personal history of IBD place an individual at risk for CRC. About one-third of cases of CRC occur in patients with a family history of CRC. (See the two "Genetics in Clinical Practice" boxes in this chapter.) Age is a risk factor in both men and women. The risk for development in the general population increases slightly after the age of 50 years and then rises rapidly in the following decades.

TABLE 45-29
RISK FACTORS FOR COLORECTAL CANCER

• Age >50 years • Alcohol (over 4 drinks per week) • Chronic inflammatory bowel disease • Cigarette smoking • Colorectal polyps • Familial adenomatous polyposis (FAP) • Family history of colorectal cancer or adenomas • History of ovarian, endometrial, or breast cancer (women) • Increased consumption of red meat • Obesity • Previous history of colorectal cancer

Genetics in Clinical Practice

Hereditary Nonpolyposis Colorectal Cancer

Genetic Basis

- Autosomal dominant disorder
- Mutations in *MSH2, MLH1, MSH6, PMS2* genes
- Mutations in genes that error-check DNA (repair genes)

Incidence

- 1 in 500–2 000 people

Genetic Testing

- DNA testing available

Clinical Implications

- HNPCC accounts for 5% of all colorectal cancers.
- Individuals with gene mutation have 80%–90% lifetime risk of developing colorectal cancer.
- Average age of diagnosis is in the mid-40s.

- Cancer arises from single colorectal lesion in absence of polyposis.
- Cancers tend to occur on right side of colon.
- HNPCC is less aggressive and is associated with longer survival rates than colon cancers that develop without known risk factors.
- People with gene mutation are at high risk of developing other cancers, including uterine, ovarian, ureter, pancreas, stomach, and small intestinal cancer.
- Individuals with known gene mutations should be monitored with colonoscopy every year.
- Examination by pelvic ultrasound and endometrial biopsy should also be considered for women.

HNPCC, hereditary nonpolyposis colorectal cancer.

Adenocarcinoma is the most common type of colorectal cancer. Most colorectal cancers begin as adenomatous polyps that arise from the mucosa lining the lumen of the colon and the rectum. As it grows, the cancer progresses down from the tip of the polyp through the body and stalk. It becomes invasive and penetrates the muscularis mucosae. Once through the muscularis mucosae, tumour cells gain access to the regional lymph nodes and the vascular system and can spread to distant sites. The most common sites of metastasis are the regional lymph nodes, liver, lungs, and peritoneum. Because venous blood leaving the colon and rectum flows through the portal vein and inferior rectal vein, the liver and lung are common sites of metastasis. The cancer spreads from the liver to other sites, including the lungs, bones, and brain. The cancer can also spread directly into adjacent structures. The growing tumour can obstruct the bowel. Other complications include bleeding, perforation, peritonitis, and fistula formation.

Clinical Manifestations

Clinical manifestations of colorectal cancer are usually nonspecific or do not appear until the disease is advanced. Rectal bleeding is the most common symptom of colorectal cancer but it may not be visible to the naked eye Other commonly seen manifestations include alternating constipation and diarrhea, abdominal cramps, gas or bloating, change in stool calibre (narrow, ribbon-like), loss of appetite, early satiety, weight

loss, lethargy and sensation of incomplete evacuation (Figure 45-7) (Colorectal Cancer Association of Canada, 2016b).

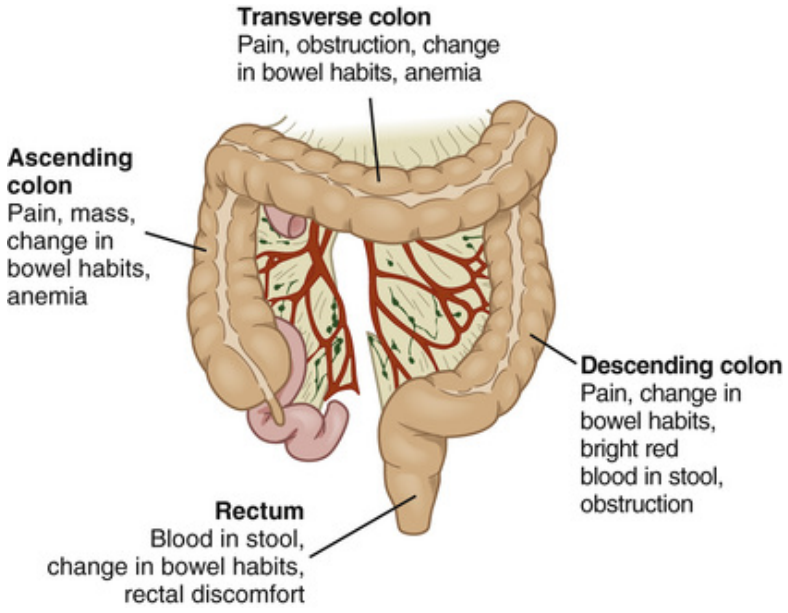

FIGURE 45-7 Signs and symptoms of colorectal cancer by location of primary lesion. Source: Modified from McCance, K. L., & Huether, S. E. (2010). *Pathophysiology: The biologic basis for disease in adults and children* (6th ed., p. 1502). St. Louis: Mosby.

Iron-deficiency anemia and occult bleeding dictate further investigation. Due to increased emphasis on screening practices, colon cancer is now often detected during screening procedures.

Diagnostic Studies

A thorough history, with close attention to family history, should be obtained, and a physical examination should be performed (Table 45-30). The digital rectal examination is the most important aspect of the physical examination because many rectal cancers are within reach of the finger. In the asymptomatic person who is 50 years or older with no risk factors (other than age), a *fecal occult blood test* (FOBT) or *fecal immunochemical test* (FIT) once a year and flexible sigmoidoscopy every 5 years beginning at age 50 are important aspects of the examination. Fecal occult blood tests have been used for more than 30 years to screen for colorectal cancer and continue to be widely used in North America. Patients need to be taught to abstain from red meat, acetylsalicylic acid (ASA; Aspirin) and NSAIDs (if

medically safe) before testing, to avoid false positives. The FIT uses antibodies to detect human hemoglobin protein in stool. It is performed in much the same way as the FOBT, but there are no drug or dietary restrictions. The Septin9 blood test is another screening tool for CRC. It detects the presence of methylated Septin9 DNA, which is correlated with an increased risk for CRC (Colorectal Cancer Association of Canada, 2016c).

TABLE 45-30

COLLABORATIVE CARE
Colorectal Cancer

Diagnostic	Collaborative Therapy

• History and physical examination
• Digital rectal examination
• Sigmoidoscopy
• Colonoscopy
• Barium enema
• CBC
• Liver function tests
• Testing of stool for occult blood
• Carcinoembryonic antigen (CEA) test
• CT scan of abdomen
• Ultrasound (including endorectal)
• MRI
	• Surgery
	  • Right hemicolectomy
	  • Left hemicolectomy
	  • Abdominal–perineal resection
	  • Laparoscopic colectomy
	• Radiation
	• Chemotherapy

CBC, complete blood cell count; *CT,* computed tomographic (scan); *MRI,* magnetic resonance imaging.

Colonoscopy is the procedure of choice. Synchronous lesions may be present at other sites in the colon, and tissue diagnosis may be made by biopsy during the procedure. Other procedures include endorectal ultrasonography and *CT colonography (virtual colonoscopy)* to localize the lesion and determine its size or the presence of metastases.

Laboratory studies should include a CBC to check for anemia, clotting studies, and liver function tests. A CT scan of the abdomen may be helpful in detecting liver metastases, retroperitoneal and pelvic disease, and depth of penetration of the tumour into the bowel wall. A CT scan should be done before surgery. Liver function tests are performed to determine the presence of liver metastases.

A carcinoembryonic antigen (CEA) test is often performed, although it is not specific for colorectal cancer. A normal level of CEA does not exclude the possibility of a malignant condition. This test is used most effectively in following the progress of a patient after surgery. Return to normal of a previously elevated CEA indicates successful removal of the tumour. In

contrast, postoperative CEA levels that are persistently elevated or that increase suggest the presence of residual tumour or tumour spread.

Collaborative Care

Prognosis and treatment correlate with pathological staging of the disease. Several methods of staging are available, with the TNM (tumour–nodes–metastasis) system (Table 45-31) being the most widely used. It describes a patient's cancer based on the degree of invasion of the primary tumour, lymph node involvement, and presence of metastasis. The stage at diagnosis is key in determining prognosis and appropriate treatment.

TABLE 45-31

TUMOUR–NODES–METASTASIS (TNM) CLASSIFICATION OF COLORECTAL CANCER

T	**Primary Tumour**		
T_x	Primary tumour cannot be assessed because of incomplete information.		
T_{is}	Carcinoma in situ. Cancer is in earliest stage and has not grown beyond mucosa layer.		
T_1	Tumour has grown beyond mucosa into the submucosa.		
T_2	Tumour has grown through submucosa into muscularis propria.		
T_3	Tumour has grown through the muscularis propria into the subserosa but not to neighbouring organs or tissues.		
T_4	Tumour has spread completely through the colon or rectal wall and into nearby tissues or organs.		
N	**Lymph Node Involvement**		
N_x	Lymph nodes cannot be assessed.		
N_0	No regional lymph node involvement is found.		
N_1	Cancer is found in one to three nearby lymph nodes.		
N_2	Cancer is found in four or more nearby lymph nodes.		
M	**Metastasis**		
M_x	Presence of distant metastasis cannot be assessed.		
M_0	No distant metastasis is seen.		
M_1	Distant metastasis is present.		
Stage	**TNM**		
0	T_{is}	N_0	M_0
IA	T_1	N_0	M_0
IB	T_2	N_0	M_0
II	T_1	N_2	M_0
	T_2	N_1	M_0
	T_3	N_0	M_0
IIIA	T_2	N_2	M_0
	T_3	$N_{1–2}$	M_0
IIIB	T_4	$N_{0–1}$	M_0
IV	T_4	N_2	M_0
	$T_{1–4}$	$N_{0–2}$	M_1

Several noninvasive procedures may be performed through a colonoscope to effectively treat certain types of colorectal cancer. Endoscopic polypectomy is a highly effective and safe procedure. Adequate treatment can be obtained if the resected margin of the polyp is free of cancer, the cancer is well differentiated, and there is no apparent lymphatic or blood vessel involvement. Laser therapy may be used to ablate nonresectable tumours. This is usually used only as palliative therapy in patients with obstructive symptoms.

Surgical Therapy.

The location and the extent of the cancer determine the type of surgery performed. Success of surgery depends on resection of the tumour with an adequate margin of healthy bowel and resection of the regional lymph nodes.

Right hemicolectomy is performed when the cancer is located in the cecum, the ascending colon, the hepatic flexure, or the transverse colon to the right of the middle colic artery. A portion of the terminal ileum, the ileocecal valve, and the appendix are removed, and an ileotransverse anastomosis is performed. A left hemicolectomy involves resection of the left transverse colon, the splenic flexure, the descending colon, the sigmoid colon, and the upper portion of the rectum.

Clear margins are most difficult to obtain with rectal carcinoma. Location of the rectal lesion determines the surgical procedure to be performed. There must be enough rectum left to ensure a secure anastomosis and preservation of anal sphincter function, or an abdominal–perineal resection is indicated. Abdominal–perineal resection is most often performed when the cancer is located within 5 cm of the anus, although ultra-low anterior resections can be performed (within 1 to 2 cm of the anus) by skilled surgeons.

In the abdominal–perineal resection, an abdominal incision is made, and the proximal sigmoid is brought through the abdominal wall as a permanent colostomy. The distal sigmoid, rectum, and anus are removed through a perineal incision. The perineal wound may be primarily closed with a drain or left open with appropriate dressings to allow healing by secondary intention. Complications that can occur are delayed wound healing, hemorrhage, persistent perineal sinus tracts, infections, and urinary tract and sexual dysfunctions.

Low anterior resection may be indicated for tumours of the rectosigmoid and the mid-to-upper rectum. The use of EEA (end-to-end anastomosis) staplers has allowed lower and more secure anastomoses.

The stapler is passed through the anus, where the colon is stapled to the rectum. This technique has made it possible to resect lesions to a point as low as 1 to 2 cm from the anus.

Sphincter-sparing procedures are being performed on patients who are a poor operative risk and on patients with early disease. The number of these procedures may increase with continued early detection and surveillance. In these procedures, a local resection is performed, and the anal sphincters are left intact.

Laparoscopic colectomy may be an option in earlier stage cancers. Potential benefits are faster return of bowel function, fewer incisional infections, shortened hospital stay, and improved cosmetic appearance (Colorectal Cancer Association of Canada, 2016d).

Chemotherapy and Radiation Therapy.

Chemotherapy is recommended when a patient has positive lymph nodes at the time of surgery or has metastatic disease. Chemotherapy is used both as an adjuvant therapy following colon resection and as primary treatment for nonresectable colorectal cancer. Various chemotherapy agents including Capecitabine (Xeloda), Fluorouracil (Efudex), folinic acid (leucovorin), and other drugs are used, with choice being based on the stage of the disease (Colorectal Cancer Association of Canada, 2016d).

Drug Alert

Capecitabine (Xeloda)

- Nurse instructs patient not to get immunizations without physician's approval.
- Nurse reports temperature of >38°C immediately.

Radiation may be used preoperatively as an adjuvant to colon resection and chemotherapy or as a palliative measure for patients with advanced lesions. As a palliative measure, its primary objective is to reduce tumour size and provide symptomatic relief. (For a discussion of radiation therapy, see Chapter 18.)

Nursing Management Colorectal Cancer

Nursing Assessment

Subjective and objective data that should be obtained from a patient with colorectal cancer are presented in Table 45-32.

TABLE 45-32

NURSING ASSESSMENT
Colorectal Cancer

Subjective Data
Important Health Information
Past health history: Previous breast or ovarian cancer, familial adenomatous polyposis (FAP), callous adenoma, adenomatous polyps, inflammatory bowel disease; family history of colorectal, breast, or ovarian cancer *Medications:* Use of any medication affecting bowel function (e.g., cathartics, antidiarrheal agents)
Symptoms
• Weakness, fatigue • Anorexia, weight loss; nausea and vomiting • Change in bowel habits; alternating diarrhea and constipation, defecation urgency; rectal bleeding; mucoid stools; black, tarry stools; increased flatus, decrease in stool calibre; feelings of incomplete evacuation • Abdominal and low back pain, tenesmus
Objective Data
General
Pallor, cachexia, lymphadenopathy (later signs)
Gastro-Intestinal
Palpable abdominal mass (late sign), distension, ascites, and hepatomegaly (liver metastasis)
Possible Findings
Anemia; positive fecal occult blood; palpable mass on digital rectal examination; positive sigmoidoscopy, colonoscopy, barium enema, or CT scan; positive biopsy

CT, computed tomographic (scan).

Nursing Diagnoses

Nursing diagnoses for the patient with cancer of the colon or the rectum include, but are not limited to, the following:

- *Constipation* related to *decrease in gastro-intestional motility*
- *Anxiety* related to *threat to current status, threat of death*

- *Ineffective coping* related to *inadequate opportunity to prepare for stressor, insufficient sense of control* (diagnosis of cancer, adverse effects of treatment)

Planning

The overall goals are that the patient with colorectal cancer will have (1) appropriate treatment (removal of tumour, adjunctive therapy), (2) normal bowel elimination patterns, (3) quality of life appropriate to disease prognosis, (4) relief of pain, and (5) feelings of comfort and well-being.

Nursing Implementation

Health Promotion.

The current recommendations from the Canadian Cancer Society (2016) for colorectal cancer screening in patients who are not at high risk include FOBT or FIT performed every 2 years starting at the age of 50. Positive findings should be followed with flexible sigmoidoscopy, colonoscopy, or double-contrast barium enema.

Screening for high-risk patients should begin before age 50, usually beginning with colonoscopy and continuing at more frequent intervals that vary according to risk factors (Canadian Cancer Society, 2016).

A number of epidemiology studies reported that use of NSAIDs (e.g., ibuprofen [Advil]) or long-term use of ASA (Aspirin) may reduce the development of adenomatous colorectal polyps and reduce the risk for colorectal cancer (Friis, Riis, Erichsen, et al., 2015).

Acute Intervention

Preoperative Care.

Acute nursing care for the patient with a colon resection is similar to the care of the patient having a laparotomy (see NCP 45-2, available on the Evolve website). In addition to general preoperative teaching and ostomy care instructions, the patient undergoing abdominal–perineal resection should be informed of the extent of the surgical procedure and the potential for sexual dysfunction after surgery. Comfortable positioning may be difficult with either an open or a closed perineal wound. Side-to-side positioning in bed and the use of pressure-reducing support surfaces for the bed and chair may be helpful. Doughnut cushions should not be

used because these delay wound healing. The patient may experience phantom rectal sensation because the sympathetic nerves responsible for rectal control are not severed during the surgery. The nurse must be astute in distinguishing phantom sensations from perineal abscess pain.

Postoperative Care.

After an abdominal–perineal resection, there are two wounds, and a stoma is surgically constructed in the left lower quadrant. There is an abdominal incision through which the colon is resected, and an incision is made in the perineum. The management of a perineal incision differs according to the type of wound. Different approaches may be taken with the perineal wound: (1) packing of the entire open wound or (2) primary closure of the perineal wound with closed-suction drainage of the pelvic cavity. The type of management of the perineal wound is individualized. The open and packed method is used in patients with extensive bleeding in the perineal wound or when there are concerns about local wound infection. A Jackson-Pratt or a Hemovac suction device placed through the buttocks into the pelvic cavity is commonly used to provide drainage of the operative site during the early postoperative period.

A patient who has open and packed wounds requires meticulous postoperative care. During the immediate postoperative period, the perineal dressing may quickly become saturated with serosanguineous drainage. Proper containment of the drainage with appropriate topical dressings such as calcium alginates or hydrofibres will assist in the management of the wound. All drainage is carefully assessed for amount, colour, and consistency.

The nurse should examine the wound regularly and record bleeding, excessive drainage, and unusual odour. The perineal wound is usually irrigated with a normal saline solution when the dressings are changed. Topical dressing selection should be made applying wound care principles: reduce bacterial burden, facilitate moist wound healing, contain drainage, and protect periwound skin. Negative-pressure therapy may be an option to enhance wound healing. Aseptic technique is always used.

When the perineal wound is closed, the drains are left in place for approximately 3 to 5 days. During this time, the drainage is examined and observations recorded. The area around the drains is observed for signs of inflammation and is kept clean and dry. The nurse should observe for signs of induration, erythema, purulent drainage around the suture line, fever, and elevated WBC count. Perineal wound closure may be done with

removable or dissolvable sutures. If removable sutures are used, these are generally left in place for 2 to 3 weeks.

If the patient complains of pain and itching in and around the wound, carefully inspect the wound for signs of local infection, maceration from wound drainage, or yeast. Use of a pressure-reducing chair cushion provides comfort when sitting, and side-to-side positioning in bed will help with comfort.

Sexual dysfunction is a possible complication of an abdominal–perineal resection and should be included in the plan of care. Although the effect of the procedure depends on the extent of pelvic dissection, the surgeon must inform the patient of the risk preoperatively. The nurse should understand that erection, ejaculation, and orgasm involve different nerve pathways and that a dysfunction of one does not mean total sexual dysfunction. The ET nurse is an important member of the team and can often provide factual information concerning sexual dysfunction and management options.

Ambulatory and Home Care.

Psychological support for the patient and family is important. The relative 5-year survival rate for patients with colorectal cancer is 64%. This presents a problem for the patient and health care providers because of the often painful, debilitating, and demoralizing manifestations produced by the recurrent disease and the lack of any effective palliative therapy. Chemotherapy may be used as an adjuvant measure for the patient with evidence of local or distant metastasis. (The special needs of the patient with cancer are discussed in Chapter 18.)

The open perineal wound may not be completely healed before discharge. After discharge, the health care provider, home health nurse, and ET nurse usually see the patient. Regular reassessment of the wound to determine progress and ideal topical dressing management should be done. Clipping the buttock hair close to the perineal wound will aid dressing adherence and prevent wound bed irritation from long hairs. The nurse should report persistent drainage or prolonged wound healing because it may also indicate the presence of a foreign body, fistula, or rectal tissue not removed during surgery. The patient and significant others may be taught assessment and management of the wound. The patient and the family should be aware of all community services available for assistance.

Patients with colostomies need to know how to care for them. Even when patients do not have stomas, they may experience diarrhea, constipation, incontinence, or difficulty passing stool, depending on the section of the colon removed and the surgical procedure performed. Patients need to know about diet; incontinence products; and strategies for managing bloating, diarrhea, and bowel evacuation. Often, a combination of dietary changes and drugs is used to control diarrhea and constipation.

Patients with sphincter-sparing surgery frequently experience diarrhea and incontinence of feces and gas. They often need antidiarrheal drugs or bulking agents to control the diarrhea, but may overuse them and become constipated. Consultation with a dietitian would help patients and caregivers understand how to choose foods that are less likely to cause diarrhea and odour and could help them discover which foods are problematic for them.

Evaluation

The following are expected outcomes for the patient with colorectal cancer:

- The patient will have regular bowel elimination patterns.
- The patient will have relief of pain.
- The patient will have balanced nutritional intake.
- The patient will have quality of life appropriate to disease prognosis.
- The patient will have feelings of comfort and well-being.

Ostomy Surgery

Types

The creation of an **ostomy** is a surgical procedure in which an opening is made to allow passage of urine from the bladder, or intestinal contents from the bowel, to an incision or stoma surgically created in the wall of the abdomen. In the context of intestinal reconstruction, the bowel is brought through an opening in the abdominal wall. The edges of the bowel are sutured to the surrounding skin, exposing the inner lining of the bowel

(mucosa); this opening is the stoma. Bowel excretion will now occur through the stoma. The stoma may be permanent or temporary, depending upon the underlying reason for the surgery.

When the ileum is brought through the abdominal wall, it is called an *ileostomy* (Figure 45-8). It is commonly used in surgical treatment of UC, Crohn's disease, and FAP and may be used to temporarily protect distal anastomoses, such as in a low anterior resection.

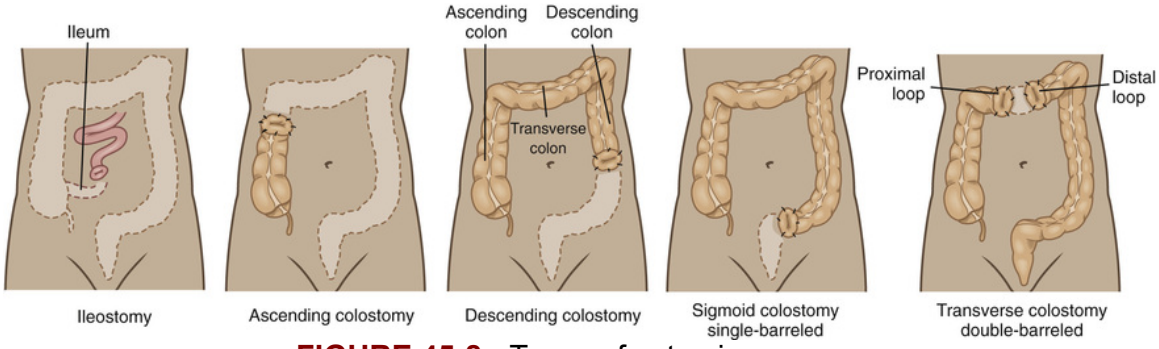

FIGURE 45-8 Types of ostomies.

A *colostomy* describes the colon being brought through the abdominal wall. *Colostomy* is a generic term and may be used to describe any part of the colon (large intestine) that is brought to the surface. Locations for colostomies are shown in Figure 45-8. A temporary colostomy may be created as an emergency measure following bowel obstruction (e.g., malignant tumour), abdominal trauma (e.g., gunshot wound), or a perforated diverticulum. A loop colostomy (see Figure 45-9) and double-barrelled colostomy (see Figure 45-8) may be created as temporary colostomies, but they may be permanent if the reason for surgery is palliation for obstructing cancer. A comparison of colostomies and ileostomy is shown in Table 45-33.

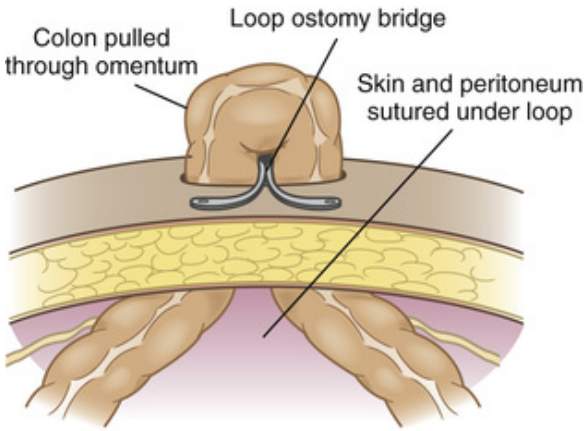

FIGURE 45-9 Loop colostomy.

TABLE 45-33
COMPARISON OF COLOSTOMIES AND ILEOSTOMY

	Colostomy		Ileostomy
	Transverse	**Sigmoid**	
Stool consistency	Semiliquid to semiformed	Formed	Liquid to pasty
Fluid requirement	Possibly increased	No change	Increased
Bowel regulation	No	Yes (if there is a history of a regular bowel pattern)	No
Pouch and skin barriers	Yes	Dependent on regulation	Yes
Irrigation	No	Possible every 24–48 hr (if patient meets criteria)	No
Indications for surgery	Palliation for distal, nonoperable obstructing cancers; trauma	Cancer of the rectum or rectosigmoid area; perforated diverticulitis; trauma; invading gynecological cancers	Ulcerative colitis, Crohn's disease, diseased or injured colon, birth defect, familial adenomatous polyposis; trauma; cancer; ischemic colitis

Surgical Therapy

End Stoma.

An *end stoma* is surgically constructed by dividing the bowel and bringing out the proximal end as a single stoma. The distal portion of the GI tract is either surgically removed or the distal segment is oversewn and left in the abdominal cavity with its mesentery intact. An end colostomy or ileostomy is then constructed. When the distal bowel is oversewn rather than removed, the result of the procedure is known as a *Hartmann pouch* (Figure 45-10). If the distal bowel is removed, the stoma is permanent; if

the distal bowel remains intact and oversewn, the potential exists for the bowel to be reanastomosed and the stoma to be closed (referred to as a *takedown*).

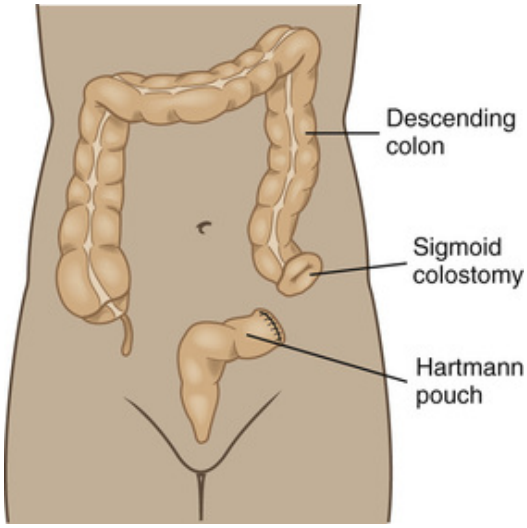

FIGURE 45-10 Sigmoid colostomy. Distal bowel is oversewn and left in place to create a Hartmann pouch.

Loop Stoma.

A *loop stoma* is constructed by bringing a loop of bowel to the abdominal surface and then opening the anterior wall of the bowel to provide fecal diversion. This results in one stoma with a proximal and distal opening as well as an intact posterior wall that separates the two openings. The loop of bowel may be supported by a plastic rod for 3 to 7 days after surgery to prevent it from slipping back into the abdominal cavity (see Figure 45-9). A loop stoma is usually temporary.

Double-Barrelled Stoma.

When the bowel is divided, both the proximal and the distal ends are brought through the abdominal wall as two separate stomas (see Figure 45-8). The proximal one is the functioning stoma; the distal stoma is referred to as the mucous fistula. The double-barrelled stoma is usually temporary.

Ileoanal Reservoir.

As described in the section on UC earlier in this chapter, this procedure involves total colectomy and ileoanal anastomosis, with the formation of

an ileal reservoir (see Figure 45-3).

Nursing Management Ostomy Surgery

Preoperative Care

It is important to review the information the patient has received from the health care provider. Psychological preparation and support are very important. The family and the patient usually have many questions concerning the procedures. If available, an ET nurse should visit with the patient and the family. An ET nurse is a nurse with additional education and training who specializes in the care and management of individuals with ostomies. The nurse or the ET nurse must determine the patient's ability to perform self-care, identify support systems, and determine potential adverse factors that could be modified to facilitate learning during rehabilitation. Preoperative assessment must be comprehensive and include physical, psychological, social, cultural, and educational components. Assessment is ongoing, including both the patient and the family. The ET nurse marks the stoma site before surgery. An improperly placed stoma complicates rehabilitation by increasing patient dependency on nursing support and increasing time, frequency, and expense of pouch change routine. It can also contribute to skin irritation and poor adaptation. Stomas should be placed within the rectus muscle, on the superior aspect of a skinfold, within the patient's visual field, above or below the beltline, and away from obvious creases and folds. The patient and the family should understand the extent of surgery, the type of stoma, and its care. Trained visitors from ostomy support groups may also provide reassurance and guidance for the patient and family. The patient and family have the opportunity to see a person who has adjusted well and who has experienced some of the same feelings and concerns. Bowel preparation before surgery may be required. Orally administered osmotic lavages (e.g., GoLYTELY) have shortened the classic 72-hour preparation with clear liquids, cathartics, and enemas. Preoperative IV antibiotics are given.

Colostomy Care

Postoperative nursing care should focus on assessing the stoma, protecting the skin and the stoma, selecting the pouch, providing patient education on ostomy self-care, and assisting the patient to adapt psychologically to a

changed body. Nursing care for the patient with a colostomy is presented in NCP 45-4, available on the Evolve website.

The stoma should be pink or red. A dusky purple stoma indicates ischemia, and a brown-black stoma indicates necrosis. The nurse should assess and document stoma colour every 4 to 8 hours for the first 72 hours after surgery, when necrosis is more likely to occur. There is initial mild to moderate swelling of the stoma, which will settle 4 to 6 weeks after surgery (Table 45-34). Application of an appropriate skin barrier is important to protect the peristomal skin. Several pouching options are available from ostomy supply companies. The peristomal skin should be cleansed with warm water and dried thoroughly before the new barrier is applied.

TABLE 45-34
POSTOPERATIVE CHARACTERISTICS OF STOMA

Characteristic	Description or Cause
Colour*	
Pink, rose to brick red	Viable stoma mucosa
Pale pink	May indicate anemia
Blanching, dark red to purple	May indicate inadequate blood supply to the stoma, low flow state, excessive tension on the bowel mesentery at the time of construction, or venous congestion; usually occurs in the first 72 hr after surgery
Edema†	
Mild to moderate edema	Normal in the initial postoperative period Trauma to the stoma Any medical condition that results in edema
Moderate to severe edema	Obstruction proximal to the stoma
Bleeding	
Small amount	Oozing from the stomal mucosa when touched or cleansed is normal because of its vascularity
Moderate to large amount‡	Moderate to large amount of bleeding from stomal mucosa could indicate coagulation factor deficiency; trauma to the stoma Moderate to large amount of bleeding from intestinal stoma could indicate lower gastrointestinal bleeding

*Sustained colour changes must be reported to surgeon.

†Closely observe, monitor, and report to the surgeon.

‡Report moderate to large amounts of bleeding to surgeon.

Principles of ostomy care and pouching selection include (1) protection of peristomal skin from effluent, trauma, or both; (2) protection of the stoma from trauma; (3) secured containment of odour and effluent; (4) preservation of patient dignity; and (5) cost containment of pouching system. An ET nurse can assist with the education of the patient and selection of the most appropriate appliance. Openings to the traditional

skin barrier should be cut 3 to 4 mm larger than the base of the stoma to allow for normal stomal peristalsis. Newer, mouldable barriers eliminate the need for precise measuring and simplify the care for patients.

The volume, colour, and consistency of the drainage are recorded. Each time the pouch is changed, the condition of the skin and stoma are observed. If any abnormalities are noted (rash, blisters, ulcers), an ET nurse should be consulted for assessment and management.

A colostomy in the transverse colon has semiliquid to pasty stools and moderate to large volumes of flatus. A colostomy in the sigmoid or the descending colon has semiformed or formed stools and can sometimes be regulated by the irrigation method. Patients may choose to use drainable, closed-end pouches or pouch liners to manage the stool.

For most patients with colostomies, there are few, if any, dietary restrictions. A well-balanced diet and adequate fluid intake are important. The patient's medical and surgical history must be considered when individualizing dietary instructions. Table 45-35 lists foods and their effects on stoma output.

TABLE 45-35

NUTRITIONAL THERAPY
Effects of Food and Liquids on Stoma Output

Odour Producing*	**Diarrhea Causing***
• Eggs • Garlic • Onions • Fish • Asparagus • Cabbage • Broccoli • Cauliflower • Alcohol • Spicy foods	• Alcohol • Beer • Cabbage family • Spinach • Green beans • Coffee • Spicy foods • Fruits and vegetables (raw)
Gas Forming*	**Potential Obstruction in Ileostomy†**
• Beans and legumes • Cabbage family • Onions • Beer • Carbonated beverages • Cheeses (strong) • Asian vegetables	• Nuts • Raisins • Popcorn • Seeds • Fruits and vegetables (raw)

*The effect of food on stoma output is individual. Patients are not discouraged from eating the above-listed foods and beverages.

†Patients are encouraged to chew high-roughage food well, or cook the foods and limit the amounts in the initial postoperative period (4–6 wk after surgery), and to drink increased amounts of fluids.

Colostomy Irrigations.

Colostomy irrigations can be used to regulate bowel function, treat constipation, or prepare the bowel for surgery. When done to achieve a regular bowel pattern, the irrigations habituate the bowel to function at a specific time every day or every other day. If control is achieved, there should be little or no spillage between irrigations. The patient who establishes regularity may need to wear only a pad or small pouch over the stoma. Not all patients can be managed with irrigations. An ET nurse can help to assess whether this is an appropriate management technique. The patient who is not eligible for irrigations or chooses not to establish regularity by irrigations must wear a pouch at all times.

All equipment should be assembled before irrigation. Usually, a commercially obtained irrigation set has all the equipment needed. The nurse should encourage the patient to watch the procedure and should explain each step to the patient. The cone tip on the tubing controls the depth of insertion and prevents the water from prematurely coming out from the stoma. If resistance is met, force should not be used because perforation of the intestine can result. However, this occurrence is unlikely when using a stoma cone. A hard plastic catheter is not recommended because of the risk for intestinal perforation. The procedure should not be rushed; the patient should feel relaxed. The patient or a family member must be instructed in the procedure and must be able to demonstrate the ability to irrigate before doing so independently. This can be done in the outpatient setting. Habituation of the bowel takes 3 to 6 weeks.

The patient should be able to perform a pouch change, care for skin and stoma, control odour, and identify signs and symptoms of complications. The patient should know the importance of fluids and food in the diet, have access to community resources, and know when to seek medical care. Home care and outpatient follow-up by an ET nurse are highly recommended. Patients should be discharged with written instructions for pouch change, teaching literature relevant to the type of stoma they have, a list and samples of products they use, a list of product retailers (including names and phone numbers), outpatient follow-up appointments with the surgeon and the ET nurse, and the phone numbers of the surgeon and the nurse. The patient and caregiver teaching guidelines are included in Table 45-36.

TABLE 45-36

PATIENT & CAREGIVER TEACHING GUIDE
Ostomy Self-Care

The following guidelines should be included when teaching the patient and caregiver about ostomy care. The nurse should:

1. Explain the following principles of ostomy care:
   - Routinely change appliances, cleanse skin, and inspect stoma and skin.
   - Empty pouch before it is one-third full.
   - Use deodorants as needed.
   - The nurse should explain how to contact the enterostomal therapy nurse.
   - The nurse should explain how to obtain additional supplies or accessories.
   - Ensure access to home health services.
2. Identify a well-balanced diet and dietary supplements if necessary to prevent nutritional deficiencies, and teach the following dietary and fluid intake guidelines:
   - Identify foods to reduce diarrhea, gas, or obstruction (with ileostomy).
   - Identify foods to reduce constipation and gas (with colostomy).
   - Drink at least 1 500–3 000 mL/day of fluid to prevent dehydration (unless contraindicated).
   - Increase fluid intake during hot weather, excessive perspiration, or diarrhea to replace losses and prevent dehydration.
   - Get to know the signs and symptoms of dehydration and when to seek help from a health care provider.
   - Contact your registered dietitian with any questions.
3. Describe potential resources to assist with emotional and psychological adjustment, and teach the patient to:
   - Identify people available to provide emotional support.
   - Identify community resources for psychosocial support.
   - Contact local ostomy support groups for information or peer support.
4. Explain the importance of follow-up care and reporting any signs and symptoms of the following:
   - Fluid and electrolyte deficits (dehydration)
   - Fever
   - Diarrhea
   - Constipation
   - Other stoma problems, including a change in appearance of the stoma or its function, a change in the peristomal skin, tenderness, erythema, or pain

Ileostomy Care

Care of the ileostomy is presented in NCP 45-4, available on the Evolve website. Ileostomy stomal protrusion of at least 2 cm makes care easier. When the stoma is flat, stool can undermine the seal and cause altered skin integrity. Stomal function is frequent, and the stool is extremely irritating to the skin. Regularity cannot be established, so a pouch must be worn at all times. An open-ended, drainable pouch is worn by the patient so that effluent can be emptied when the pouch is one-third full. Usually, the drainable pouch is worn for 4 to 7 days before being changed, as long as leakage does not occur under the pouching system. If pouch leakage occurs, the pouch should be promptly removed, the skin should be cleansed, and a new pouching system applied. Frequent leaks of the appliance warrant assessment of appropriateness of the pouching by an ET nurse. A transparent pouch may be used in the initial postoperative period

to facilitate assessment of stoma viability and stoma function, but opaque pouches for discharge and home enhance aesthetics.

Immediately after surgery, intake and output must be accurately monitored. The patient should be observed for signs and symptoms of fluid and electrolyte imbalance, particularly potassium, sodium, and fluid deficits. In the first 24 to 48 hours after surgery, the amount of drainage from the stoma may be negligible. A person with an ileostomy has lost the absorptive functions provided by the colon as well as the delay feature provided by the ileocecal valve. Once peristalsis returns, the patient may experience a period of high-volume bilious output of 1 200 to 1 800 mL/day. Later, the amount can average 800 mL daily because the proximal small bowel adapts and absorbs more fluid. If the small bowel has been shortened as a result of surgical resections, the drainage from the ileostomy may be greater. The patient must understand the importance of fluid and electrolyte balance. A dietitian is helpful in assessing and determining patient food and fluid requirements.

The patient should be instructed to drink at least 1.5 to 2 L of fluid daily; more may be necessary when diarrhea occurs and when perspiration is increased. Diarrhea from an ileostomy can produce dehydration and acidosis from the loss of bicarbonate. The patient may require brief hospitalization for IV fluid rehydration if large volumes of diarrhea occur.

Usually a low-residue diet is ordered initially. Insoluble fibre–containing foods are reintroduced gradually. Later, there are few dietary restrictions. It is important to limit the amount of high-roughage foods (e.g., popcorn), chew them well, and accompany them with fluids. The goal for the patient is a return to a normal, presurgical diet.

The stoma may bleed easily when it is touched or cleansed because it has a high vascular supply. The patient should be told that minimal oozing of blood is normal. If the terminal ileum has been removed, the patient may need cobalamin (vitamin B_{12}) supplementation.

Adaptation to an Ostomy

Adaptation to the ostomy is a gradual process. The patient experiences a grief reaction to the loss of a body part and an alteration in body image. Each person uses different coping mechanisms. The adjustment period for the person depends on the individual. Psychological support during the grieving process is needed. There are many concerns, including body image, sexual activity, family responsibilities, and changes in lifestyle. The patient may become resentful and have fears of odour or leakage.

Supportive measures by nurses include helping the patient acquire knowledge, providing or recommending support services, and identifying coping mechanisms that are effective. The nurse provides support by responding to the physiological needs of stoma care and psychosocial needs related to self-esteem.

Gradual involvement of the patient in self-care of the ostomy should be encouraged. Although initial visualization of the stoma and participation in care is distressing, supportive teaching from the nurse will enhance confidence and independence in care. Teaching at the appropriate time is an important part of the care and can contribute to a smooth adjustment process.

Gradual resumption of activities of daily living can occur within 2 to 3 weeks. Heavy lifting, physical exertion, and participation in sports should be avoided for 6 to 8 weeks. The patient's physical condition determines when sexual activity may be resumed. Bathing and swimming are not prohibited. Refer patients to the Ostomy Canada Society for information and support (www.ostomycanada.ca).

Sexual Dysfunction After Ostomy Surgery

Discussion of sexuality and sexual function must be incorporated in the plan of care. The nurse can help the patient understand that sexual function or sexual activity may be affected but that sexuality does not have to be altered.

Pelvic surgery can disrupt nerve and vascular supply to the genitals. Radiation, chemotherapy, and medications can also alter sexual function. Hormones and overall physical health of the patient influence desire. Certain pain medications and antiemetics can lower libido. Generalized fatigue caused by illness can also influence desire. By communicating this information to patients, they can plan sexual activity around a drug schedule and energy levels. Any pelvic surgery that removes the rectum has the potential of damaging the parasympathetic nerve plexus. Erection in men depends on the parasympathetic nerves that control blood flow and vascular supply to the pelvis and the pudendal nerves that transmit sensory responses from the genital area. Nerve-sparing surgical techniques are used when possible to preserve sexual function. Radiation therapy to the pelvis can reduce blood vascularity to the pelvis by causing scarring in the small blood vessels. Pelvic surgery usually does not affect a woman's arousal unless part of or the entire vagina is removed. Radiation therapy can affect vaginal expansion and lubrication.

Muscular contraction and the genital pleasure that occur during orgasm are not disrupted by pelvic surgery. If the sympathetic nerves in the presacral area are damaged, the male mechanism of emission can be disrupted. This can occur with an abdominal–perineal resection. Orgasms can occur in both men and women who have had stoma surgery, although other aspects of the sexual response may be affected.

The psychological impact of the stoma and how it affects the patient's body image and self-esteem must be discussed. Emotional factors can contribute to sexual problems. A life-threatening illness can override concerns about sexual function. The nurse can assist a patient to identify ways of coping with depression and anxiety resulting from illness, surgery, or postoperative problems.

The social impact of the stoma is interrelated with its psychological, physical, and sexual aspects. Concerns of people with stomas include the ability to resume sexual activity, altering clothing styles, the effect on daily activities, sleeping while wearing a pouch, passing gas, the presence of odour, cleanliness, and deciding when or whether to tell others about the stoma. The fear of rejection from a partner or the fear that others will not find them desirable as a sexual partner can be a concern. The nurse should encourage open communication about feelings and should realize that the patient needs time to adjust to the pouch and to body changes before feeling secure in her or his sexual functioning.

Pregnancy is possible with an ostomy. As the abdomen expands in the second and third trimesters, the stoma may retract and alternate pouching may be required. A woman with an ostomy who becomes pregnant should have regular medical care and assessment by an ET nurse.

Diverticulosis and Diverticulitis

A **diverticulum** is an outpouching of the mucosa through the circular smooth muscle of the intestinal wall. Diverticula may occur at any point within the GI tract but are most commonly found in the sigmoid colon. Clinically, diverticular disease occurs in two forms: diverticulosis and diverticulitis. With *diverticulosis*, multiple noninflamed diverticula are present; the patient is most often free of symptoms or may have alternating periods of constipation and diarrhea. In *diverticulitis*, inflammation of the diverticula occurs (Figure 45-11).

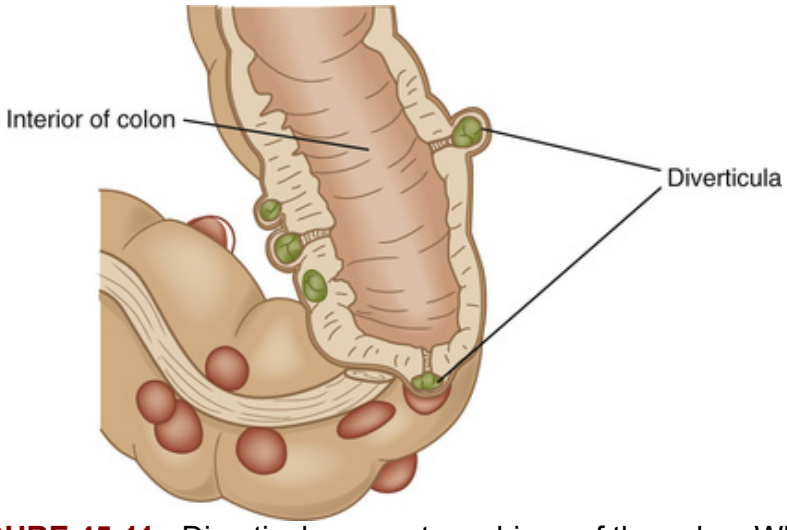

FIGURE 45-11 Diverticula are outpouchings of the colon. When they become inflamed, the condition is diverticulitis. The inflammatory process can spread to the surrounding area in the intestine.

Etiology and Pathophysiology

Diverticular disease is a common GI disorder that affects over 50% of Canadians over the age of 80 (Canadian Digestive Health Foundation, 2017). A diverticulum is a saccular dilation or outpouching of the mucosa through the circular smooth muscle of the intestinal wall. It affects men and women equally, but men seem to have a higher rate of complications. Most people with diverticular disease are asymptomatic and are unaware that they have the disease.

There is no known cause of diverticular disease, but deficiency in dietary fibre has been associated with it. The disease is more prevalent in Western populations that consume diets low in fibre and high in refined carbohydrates.

When diverticula form, the smooth muscle of the colon wall becomes thickened. Lack of dietary fibre slows transit time, and more water is absorbed from the stool, making its passage through the lumen more difficult. Decreased bulk of the stool, combined with a more acutely narrowed lumen in the sigmoid colon, causes high intraluminal pressures. These factors are believed to contribute to the formation of diverticula.

The cause of diverticulitis is related to the retention of stool and bacteria in the diverticulum, forming a hardened mass called a *fecalith.* This occurrence causes inflammation and usually small perforations. Inflammation of the diverticulum spreads to the surrounding tissues

(Figure 45-12), causing it to become edematous. Abscesses may form, or complete perforation with peritonitis may occur.

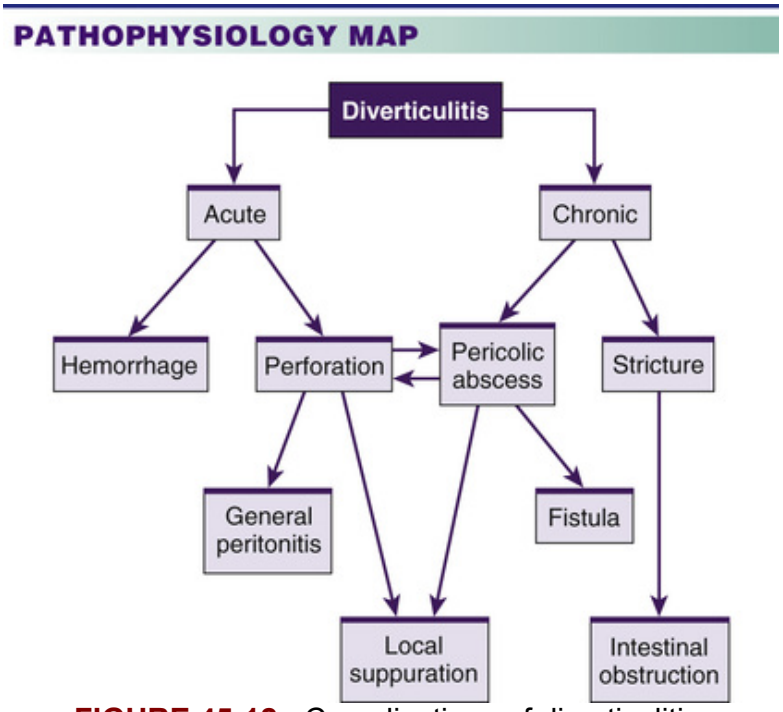

FIGURE 45-12 Complications of diverticulitis.

Clinical Manifestations

The majority of patients with diverticulosis have no symptoms. Those with symptoms typically have crampy abdominal pain located in the left lower quadrant that is usually relieved by passage of flatus or bowel movement. Alternating constipation and diarrhea may be present.

In patients with diverticulitis, abdominal pain is localized over the involved area of the colon. A tender left lower quadrant mass may be felt on palpation of the abdomen. Fever, chills, nausea, anorexia, and elevated WBC count may be present. Older adults with diverticulitis are frequently afebrile, with a normal WBC count and little, if any, abdominal tenderness.

Complications of diverticulitis include perforation with peritonitis, abscess and fistula formation, bowel obstruction, ureteral obstruction, and bleeding. Diverticular bleeding is the most common cause of lower GI bleeding. Bleeding usually stops spontaneously.

Diagnostic Studies

A CT scan with oral contrast is the test of choice for diverticulitis. A CBC, urinalysis, and FOBT should be performed (Table 45-37). A barium enema is used to determine narrowing or obstruction of the colonic lumen. A colonoscopy may be performed to rule out possible hidden polyps or lesions. A patient with acute diverticulitis should not have a barium enema or colonoscopy because of the possibility of perforation and peritonitis.

TABLE 45-37

COLLABORATIVE CARE
Diverticulosis and Diverticulitis

Diagnostic	Collaborative Therapy
• History and physical examination • Testing of stool for occult blood • Barium enema • Sigmoidoscopy • Colonoscopy • CBC • CT scan with contrast • Urinalysis • Blood culture • Abdominal radiograph • Chest radiograph	***Ambulatory and Home Care***
	• High-fibre diet (during nonsymptomatic periods) • Dietary fibre supplements (during nonsymptomatic periods) • Stool softeners • Clear liquid diet • Oral antibiotics • Bulk laxatives • Weight reduction (if overweight)
	Acute Care: Diverticulitis
	• IV antibiotics • NPO status • IV fluids • Possible colon resection for perforation, obstruction, or hemorrhage • Bed rest

CBC, complete blood cell count; *CT,* computed tomographic (scan); *IV,* intravenous; *NPO,* nothing by mouth.

Nursing and Collaborative Management Diverticulosis and Diverticulitis

Uncomplicated diverticular disease is treated with a high-fibre diet (see Table 45-9) and bulk laxatives, such as psyllium hydrophilic mucilloid (Metamucil). In acute diverticulitis, the goal of treatment is to allow the colon to rest and the inflammation to subside. The patient is kept on NPO status with parenteral fluids for hydration. The patient should be observed for signs of possible peritonitis. In acute diverticulitis, broad-spectrum antibiotic therapy is required. The temperature and the WBC count are monitored.

When the acute attack subsides, oral fluids are allowed, progressing to a semisolid diet. At this stage, the patient should be observed for a recurrent attack. If the patient has a bowel resection or colostomy, the nursing care is the same as for these procedures.

Surgical intervention is necessary to drain abscesses and to resect an obstructing inflammatory mass or perforated segment. The usual surgical procedures involve resection of the involved colon with a temporary diverting colostomy. The bowel is reanastomosed after the colon has healed.

The patient should be provided with a full explanation of the condition. Consultation with a dietitian regarding high-fibre diets is recommended.

Hernias

A **hernia** is a protrusion of a viscus through an abnormal opening or a weakened area in the wall of the cavity in which it is normally contained. If the hernia can be placed back into the abdominal cavity, it is known as *reducible.* The hernia can be reduced by manipulation, or reduction can occur spontaneously when the person lies down. If the hernia cannot be placed back into the abdominal cavity, it is known as *irreducible or* incarcerated, and the intestinal flow may be obstructed. When the hernia is irreducible and the intestinal flow and blood supply are obstructed, the hernia is *strangulated*. The result is an acute intestinal obstruction and ischemia, necessitating surgery.

Types

The *inguinal hernia* is the most common type of hernia and occurs at the point of weakness in the abdominal wall where the spermatic cord emerges in men and the round ligament in women (Figure 45-13). When the protrusion escapes through the inguinal ring and follows the spermatic cord or the round ligament, it is termed an *indirect* hernia. When it escapes through the posterior inguinal wall, it is a *direct* hernia. An inguinal hernia is more common in men.

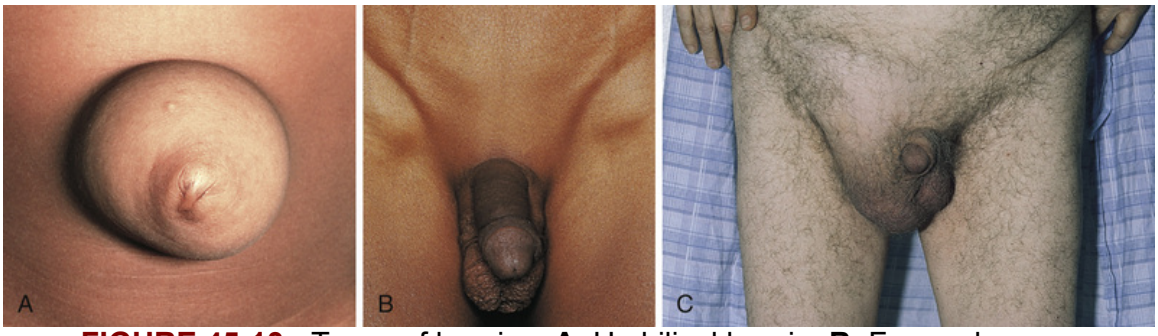

FIGURE 45-13 Types of hernias. **A,** Umbilical hernia. **B,** Femoral hernias (note swelling below the inguinal ligaments). **C,** Indirect inguinal hernia. Source: **A** and **B,** from Zitelli, B. J., McIntire, S. C., & Nowalk, A. J. (2012). *Zitelli and Davis' atlas of pediatric physical diagnosis* (6th ed.), Philadelphia: Saunders; **C,** from Swartz, M. H. (2010). *Textbook of physical diagnosis: History and examination* (6th ed., p. 545). Philadelphia: Saunders.

A *femoral hernia* occurs when there is a protrusion through the femoral ring into the femoral canal. It occurs below the inguinal (Poupart) ligament as a bulge. It becomes strangulated easily and occurs more often in women. The umbilical hernia occurs when the rectus muscle is weak or the umbilical opening fails to close after birth.

Ventral, or incisional, hernia is caused by weakness of the abdominal wall at the site of a previous incision. It is found most commonly in patients who are obese, who have had multiple surgical procedures in the same area, and who have had inadequate wound healing because of poor nutrition or infection.

Clinical Manifestations

Commonly, a hernia occurs over the involved area when the patient stands or strains. Severe pain is caused if the hernia becomes strangulated. In this situation, the clinical manifestations of a bowel obstruction, such as vomiting, crampy abdominal pain, and distension, are found.

Nursing and Collaborative Management Hernias

Diagnosis is based on history and physical examination findings. Surgery is the treatment of choice for hernias to prevent the possible complication of strangulation. The surgical repair of a hernia is known as a *herniorrhaphy.* The reinforcement of the weakened area with fascia or mesh is known as a *hernioplasty*. When there is strangulation, necrosis and gangrene may develop if immediate care is not given. A bowel resection of the involved area or a temporary ostomy may be needed to treat a strangulated hernia.

Some patients with inguinal hernias wear a truss, a firm pad placed over the hernia and held in place with a belt. The truss is worn to keep the hernia from protruding. The truss should be applied when the hernia is reduced. If the hernia cannot be reduced, the truss should not be used. If a patient wears a truss, the nurse should check for skin irritation caused by the continual rubbing and pressure of the truss.

After an inguinal hernia repair, the patient may have difficulty voiding; thus, the nurse should observe for a distended bladder. An accurate intake and output record is important. Scrotal edema is a painful complication after an inguinal hernia repair. A scrotal support may help relieve discomfort. Coughing is not encouraged, but deep breathing and turning should be done. If the patient needs to cough or sneeze, the incision should be splinted during these functions. After discharge, the patient may be restricted from heavy lifting or activities for 6 to 8 weeks. Some surgeons do not put any limitations on physical activities.

Anorectal Problems

Hemorrhoids

Hemorrhoids are varicosities in the lower rectum or the anus caused by congestion in the veins of the hemorrhoidal plexus. They may be *internal* (occurring above the internal sphincter) or *external* (occurring outside the external sphincter) (Figures 45-14 and 45-15). Symptoms of hemorrhoids, including bleeding, pruritus, prolapse, and pain, are common in all age groups. In affected people, hemorrhoids appear periodically, depending on the amount of anorectal pressure.

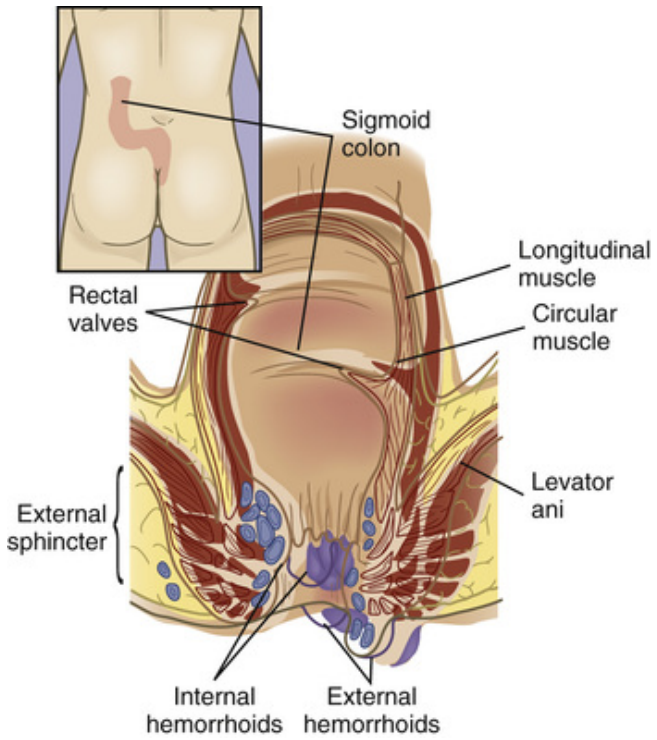

FIGURE 45-14 Anatomical structures of the rectum and the anus with external and internal hemorrhoids.

FIGURE 45-15 Thrombosed external hemorrhoids. Source: Townsend, C. M., Beauchamp, R. D., Evers, B. M., et al. (Eds.). (2012). *Sabiston textbook of surgery: The biological basis of modern surgical practice* (19th ed.). Saunders: Philadelphia.

Etiology and Pathophysiology

Hemorrhoids are thought to develop as a result of shearing forces during defecation. This force damages supporting muscles. When supporting tissues in the anal canal weaken, usually as a result of straining at defecation, venules become dilated. In addition, blood flow through the veins of the hemorrhoidal plexus is impaired. An intravascular clot in the venule results in a thrombosed external hemorrhoid. They are the most common cause of bleeding with defecation. The amount of blood lost at one time may be small but may lead to iron-deficiency anemia over time.

Hemorrhoids may be precipitated by many factors, including pregnancy, prolonged constipation, straining in an effort to defecate, heavy lifting, prolonged standing and sitting, and portal hypertension (as found in cirrhosis).

Clinical Manifestations

The patient with internal hemorrhoids may be asymptomatic. However, when internal hemorrhoids become constricted, the patient will report pain. Internal hemorrhoids can bleed, resulting in blood on toilet paper after defecation or blood on the outside of stool. The patient may report a chronic, dull, aching discomfort, particularly when the hemorrhoids have prolapsed.

External hemorrhoids are reddish blue and seldom bleed or cause pain unless a vein ruptures. If the blood clots in external hemorrhoids, they become inflamed and painful and are said to be thrombosed. External

hemorrhoids cause intermittent pain, pain on palpation, itching, and burning. Patients also report bleeding associated with defecation. Constipation or diarrhea can aggravate these symptoms.

Diagnostic Studies and Collaborative Care

Internal hemorrhoids are diagnosed by digital examination, anoscopy, or sigmoidoscopy. External hemorrhoids can be diagnosed by visual inspection and digital examination. Therapy should be directed toward the causes and the patient's symptoms. A high-fibre diet and increased fluid intake prevent constipation and reduce straining, which allows engorgement of the veins to subside. Ointments, creams, suppositories, and impregnated pads that contain anti-inflammatory agents (e.g., hydrocortisone), or astringents and anaesthetics (e.g., witch hazel, benzocaine) may be used to shrink the mucous membranes and relieve discomfort. Stool softeners may be ordered to keep the stools soft; sitz baths may be ordered to relieve pain.

Surgical excision and clot removal are generally recommended for thrombosed external hemorrhoids. For internal hemorrhoids, one of four nonsurgical approaches can be used. The first is *band ligation.* Through an anoscope, the hemorrhoid is identified and then ligated with a rubber band. The constrictive effect impairs circulation, and the tissue becomes necrotic, separates, and sloughs off. There is some local discomfort with this procedure, but no anaesthetic is required. *Infrared coagulation* can be used to treat bleeding internal hemorrhoids. In this procedure, either infrared or electrical current reduces local inflammation. *Cryotherapy* involves rapid freezing of the hemorrhoid. Because this method can result in acute pain, it is used less often. Finally, *laser treatment* can be used to treat internal hemorrhoids. This procedure involves expensive equipment and tends to be more costly than band ligation and coagulation therapies.

A *hemorrhoidectomy* is the surgical excision of hemorrhoids. Surgery is indicated when there is prolapse, excessive pain or bleeding, or large hemorrhoids. In general, hemorrhoidectomy is reserved for patients with severe symptoms related to multiple thrombosed hemorrhoids or marked protrusion. Surgical removal may be done by cautery, clamp, or excision. One surgical approach is to leave the area open so that healing takes place by secondary intention. In another approach, the hemorrhoids are removed, the tissue is sutured, and healing takes place by primary intention wound healing.

Nursing Management Hemorrhoids

Conservative nursing management for the patient with hemorrhoids includes teaching measures regarding prevention of constipation, avoidance of prolonged standing or sitting, proper use of OTC drugs available for hemorrhoidal symptoms, and the need to seek medical care for severe symptoms of hemorrhoids (e.g., excessive pain and bleeding, prolapsed hemorrhoids) when necessary. Sitz baths (15–20 minutes), two to three times each day for 7 to 10 days, may be helpful to reduce the discomfort and swelling associated with hemorrhoids.

Pain caused by sphincter spasm is a common problem after a hemorrhoidectomy. The nurse must be aware that, although the procedure is minor, the pain is severe. Opioids are usually given initially. Sitz baths are started 1 to 2 days after surgery. A warm sitz bath provides comfort and keeps the anal area clean. Initially, the patient should not be left alone because of the possibility of weakness or fainting.

Packing may be inserted into the rectum to absorb drainage. A T-binder may hold the dressing in place. If packing is inserted, it usually is removed on the first or second postoperative day. The nurse should assess for rectal bleeding. The patient may be embarrassed when the dressing is changed, and privacy should be provided. The patient usually dreads the first bowel movement and often resists the urge to defecate. Pain medication may be given before the bowel movement to reduce discomfort.

A stool softener such as docusate (Colace) is usually ordered for the first few postoperative days. If the patient does not have a bowel movement within 2 to 3 days, other oral laxatives may be given.

Patients are taught the importance of diet, care of the anal area, symptoms of complications (especially bleeding), and avoidance of constipation and straining. Sitz baths are recommended for 1 to 2 weeks. The health care provider may order a stool softener to be taken for a time. Hemorrhoids may recur. Occasionally, anal strictures develop and dilation is necessary. Regular checkups are important in the prevention of any further problems.

Anal Fissure

An **anal fissure** is a skin ulcer or a crack in the lining of the anal wall that is caused by trauma, local infection, or inflammation. Fissures are considered either primary or secondary, based on their etiology. *Primary*

fissures usually occur as a result of local trauma associated with defecation or anal intercourse. When there is high pressure in the internal anal sphincter, it can result in ischemia, which can lead to fissuring. Thus, sexual practices and conditions that promote constipation are likely to be associated with fissure development. *Secondary fissures* are caused by a variety of conditions, including IBD, prior anal surgery, infection (syphilis, tuberculosis, chlamydia, gonorrhea, herpes simplex virus), and human immunodeficiency virus (HIV) infection.

The most common clinical manifestations are painful spasms of the anal sphincter and severe, burning pain during defecation. Some bleeding may occur, and constipation results because of fear of pain associated with bowel movements.

Anal fissures are diagnosed through physical examination. Treatment of anal fissures is directed at correcting the underlying conditions, such as hard stools. Most acute fissures require 2 to 4 weeks to heal. Conservative treatment consists of bowel regulation with mineral oil and stool softeners. Warm sitz baths (15–20 minutes, three times a day) and anal anaesthetic suppositories (Anusol) are also ordered. Topical preparations, including nitrates and calcium channel blockers, are used to decrease rectal and anal pressure to allow the fissure to heal without sphincter damage. Local injections of botulinum toxin are also used to decrease rectal and anal pressure and are most effective when combined with nitrates.

For chronic fissures, other invasive procedures may be needed. These include coagulation therapy or surgical treatment (sphincterotomy). Surgical treatment involves excision of the fissure. Postoperative nursing care is the same as the care for the patient who has had a hemorrhoidectomy.

Anorectal Abscess

Anorectal abscesses are undrained collections of perianal pus (Figure 45-16). They are the result of obstruction of the anal glands, leading to infection and subsequent abscess formation. Abscess formation can occur secondary to anal fissures, trauma, or IBD.

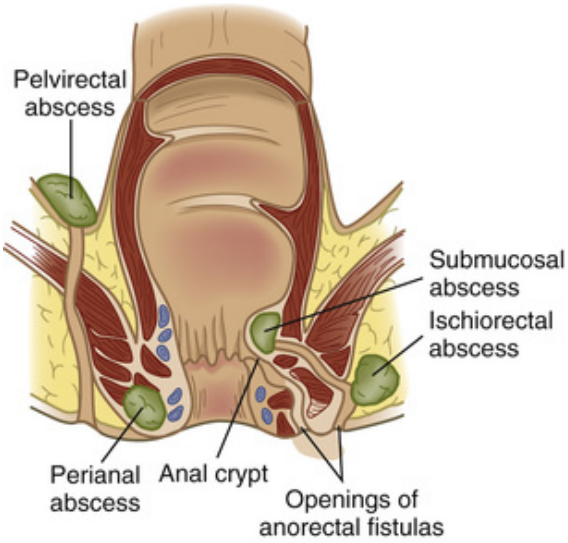

FIGURE 45-16 Common sites of anorectal abscesses and fistula formation.

The most common causative organisms are *Escherichia coli*, staphylococci, and streptococci. Clinical manifestations include local pain and swelling, foul-smelling drainage, tenderness, and elevated temperature. Sepsis can occur as a complication. Anorectal abscesses are diagnosed by rectal examination.

Surgical therapy consists of drainage of abscesses. The wound will be left open and allowed to heal by secondary intention. Topical dressing selection is determined based on wound care principles (maintain moist wound environment, manage bacterial burden, protect from further trauma). Care must be taken to avoid soiling the dressing during urination or defecation. A low-residue diet is given. Discharge teaching should include access to home health care, wound care, and the importance of sitz baths; thorough cleaning after bowel movements; and follow-up visits to a health care provider.

Anal Fistula

An **anal fistula** is an abnormal tunnel leading out from the anus or the rectum. It may extend to the outside of the skin, the vagina, or the buttocks. Anal fistulas are a complication of Crohn's disease (occurring in the perianal area). This condition often precedes an anorectal abscess.

Feces enter the fistula and may cause a localized infection. There may be persistent, blood-stained, purulent discharge or stool leakage from the fistula. The patient may need to use dressings to contain the drainage and protect perifistular skin.

Surgical therapy may involve a fistulotomy or a fistulectomy. In a *fistulotomy*, the fistula is opened and healthy tissue is allowed to granulate. A *fistulectomy* is an excision of the entire fistulous tract. Appropriate topical therapy is used, and the wound is allowed to heal by secondary intention. In severe cases of perianal disease caused by Crohn's disease, a diverting loop ileostomy may be required to manage the fistulas. Care is the same as that given after a hemorrhoidectomy.

Anal Cancer

Anal cancer is uncommon in the general population, but the incidence is increasing. Human papillomavirus (HPV) is associated with about 80% of the cases of anal cancer. Risk factors include having many sexual partners, genital warts (which are caused by HPV), smoking, receptive anal sex, and HIV infection.

Most frequently, the initial symptom is rectal bleeding. Other symptoms include rectal pain and sensation of a rectal mass. Some patients have no symptoms, which leads to delayed diagnosis and treatment.

It is especially important to screen high-risk individuals. A swab of the anal mucosa can be obtained during a digital rectal examination. Identification of cell changes (e.g., dysplasia, neoplasia) can be determined. High-resolution anoscopy allows for visualization of the mucosa and biopsy. An endo-anal *(endorectal) ultrasound* may also be done.

The use of condoms to reduce the transmission of HPV is recommended. The HPV vaccine Gardasil is used for the prevention of anal cancer and associated precancerous lesions caused by HPV types 6, 11, 16, and 18. Another HPV vaccine, Cervarix, may also be useful in the prevention of HPV-associated anal cancer. After vaccination with HPV vaccine, patients at risk need to continue their recommended screening program.

Treatment of anal cancer depends on the size and depth of the lesions. Topical therapy with bichloroacetic or trichloroacetic acid may be used to kill the HPV virus. Imiquimod (Aldara), an immuno-modulator, is also used as a topical agent. Therapy also includes surgery, radiation, and chemotherapy.

Pilonidal Sinus

A **pilonidal sinus** is a small tract under the skin between the buttocks in the sacrococcygeal area. It is thought to be of congenital origin. It may

have several openings and is lined with epithelium and hair, thus given the name *pilonidal* ("a nest of hair").

The skin in the sacrococcygeal region is moist, and the movement of the buttocks causes the short, wiry hair to penetrate the skin. The irritated skin becomes infected and forms a pilonidal cyst or abscess. There are no symptoms unless there is an infection. If it becomes infected, the patient complains of pain and swelling at the base of the spine, and there may be spontaneous drainage of pus.

The formed abscess requires incision and drainage. The wound may be primarily closed or left open to heal by secondary intention. The wound is packed with appropriate topical therapeutic material. The wounds are often very painful, and the patient may require premedication before dressing changes. The patient is usually more comfortable lying on the abdomen or side. Sitting for prolonged periods of time may be difficult. Activities that contribute to shear in the area (running, sports, long walks) should be avoided until the wound heals. Because the area is poorly vascularized, healing of open pilonidal wounds may be prolonged. Ensuring that surrounding hair is clipped and kept out of the wound bed is imperative. Unfortunately, despite excision of the tract, pilonidal cysts or abscesses may reoccur.

Case Study

Colorectal Cancer

Source: Anton_Ivanov/ Shutterstock.com.

Patient Profile

Lyle Collins, a 58-year-old man, is from Drury, Ontario. Mr. Collins's wife and family drove 50 kilometres to take him to the hospital because of his deteriorating health (see the case study in Chapter 41).

Subjective Data

See the case study in Chapter 41.

Objective Data

Physical Examination

See the case study in Chapter 41.

Laboratory Tests

- CT scan and colonoscopy show two medium-sized tumours in the transverse colon.

Collaborative Care

Surgical Procedure

- Transverse hemicolectomy performed and lymph node biopsies taken.
- Pathology results indicate that the adenocarcinoma tumour has invaded the muscle wall of the colon, and two out of five lymph nodes are positive for cancer.

Postoperative

- Feels like his life has ended and does not want to leave hospital.
- States that there is no one to take care of him at his home and he is far away from the hospital.

Follow-Up Treatment

- Scheduled for outpatient chemotherapy.

Discussion Questions

1. What are the signs and symptoms of colorectal cancer that Mr. Collins has manifested (see the case study in Chapter 41)?
2. What types of diagnostic information are available from a colonoscopy versus a sigmoidoscopy?
3. What stage of CRC does Mr. Collins probably have? What treatment is recommended for this stage of CRC?
4. How could the nurse provide emotional support to Mr. Collins and his family?
5. What is a culturally sensitive way for the nurse to support Mr. Collins and his family in making decisions about his continued health care?
6. ***Priority decision:*** Based on the assessment data, what are the priority nursing diagnoses? Are there any collaborative problems?
7. ***Priority decision:*** What are the priority nursing interventions for Mr. Collins at this stage of his illness?
8. ***Evidence-informed practice:*** Mr. Collins had not had a previous colonoscopy. He is worried that other members of his family may have colon cancer. What can the nurse tell him about the recommendations for colorectal cancer screening?

Review Questions

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. The appropriate collaborative therapy for the client with acute diarrhea caused by a viral infection is to do which of the following?
   a. Increase fluid intake
   b. Administer an antibiotic
   c. Administer antimotility drugs
   d. Quarantine the client to prevent spread of the virus
2. When a 35-year-old female client is admitted to the emergency department with acute abdominal pain, which possible diagnosis should the nurse consider that may be the cause of her pain? *(Select all that apply)*
   a. Gastro-enteritis
   b. Ectopic pregnancy
   c. Gastro-intestinal bleeding
   d. Irritable bowel syndrome
   e. Inflammatory bowel disease
3. Assessment findings suggestive of peritonitis include which of the following?
   a. Rebound abdominal pain
   b. A soft, distended abdomen
   c. Dull, continuous abdominal pain
   d. Restlessness
4. In planning care for the client with Crohn's disease, the nurse recognizes which major factor about Crohn's disease that differentiates it from ulcerative colitis?
   a. It frequently results in toxic megacolon.
   b. It causes fewer nutritional deficiencies than ulcerative colitis.
   c. It often recurs after surgery, whereas ulcerative colitis is curable with a colectomy.
   d. It is manifested by rectal bleeding and anemia more frequently than ulcerative colitis is.

5. The nurse performs a detailed assessment of the abdomen of a client with a possible bowel obstruction, knowing that which of the following are manifestations of an obstruction in the large intestine? *(Select all that apply)*
   a. Persistent abdominal pain
   b. Marked abdominal distention
   c. Diarrhea that is loose or liquid
   d. Colicky, severe, intermittent pain
   e. Profuse vomiting that relieves abdominal pain
6. A client with stage I colorectal cancer is scheduled for surgery. Teaching for this client would include an explanation of which of the following?
   a. That chemotherapy will begin after recovery from the surgery
   b. That both chemotherapy and radiation can be used as palliative treatments
   c. That follow-up colonoscopies will be needed to ensure that the cancer does not recur
   d. That a wound nurse, ostomy nurse, and continence nurse will visit to identify an abdominal site for the ostomy
7. The nurse explains to the client undergoing ostomy surgery that the procedure that maintains the most normal functioning of the bowel is which of the following?
   a. A sigmoid colostomy
   b. A transverse colostomy
   c. A descending colostomy
   d. An ascending colostomy
8. In contrast to the client with diverticulitis, which of the following is true for the client with diverticulosis?
   a. Has rectal bleeding
   b. Often has no symptoms
   c. Has localized cramping pain
   d. Frequently develops peritonitis
9. Which of the following is a nursing intervention that is most appropriate to decrease postoperative edema and pain after an inguinal herniorrhaphy?
   a. Applying a truss to the hernia site

b. Allowing the client to stand to void

c. Supporting the incision during coughing

d. Applying a scrotal support with ice bag

10. The nurse determines that the goals of dietary teaching have been met when the client with celiac disease selects which of the following from the menu?

a. Scrambled eggs and sausage

b. Buckwheat pancakes with syrup

c. Oatmeal, skim milk, and orange juice

d. Yogourt, strawberries, and rye toast with butter

11. What should a client be taught after a hemorrhoidectomy?

a. Take mineral oil before bedtime.

b. Eat a low-fibre diet to rest the colon.

c. Administer oil-retention enema to empty the colon.

d. Use prescribed pain medication before a bowel movement.

1. a, 2. a, b, c, d, e, 3. a, 4. c, 5. a, b, 6. c, 7. a, 8. b, 9. d, 10. a, 11. d.

CHAPTER 46

Nursing Management

Liver, Pancreas, and Biliary Tract Problems

Written by, Kathy H. Wu

Adapted by, Colina Yim

LEARNING OBJECTIVES

1. Define *jaundice,* and describe the manifestations associated with the different causes of jaundice.
2. Differentiate among the types of viral hepatitis, including etiology, pathophysiology, clinical manifestations, complications, and collaborative care.
3. Describe the nursing management of patients with viral hepatitis.
4. Explain the etiology, pathophysiology, clinical manifestations, complications, collaborative care, and nursing management of patients with cirrhosis.
5. Describe the pathophysiology, clinical manifestations, complications, and collaborative care of patients with nonalcoholic fatty liver disease.
6. Describe the clinical manifestations and management of hepato-cellular carcinoma.
7. Differentiate between acute and chronic pancreatitis related to the pathophysiology, clinical manifestations, complications,

collaborative care, and nursing management.
8. Explain the clinical manifestations, collaborative care, and nursing management of patients with pancreatic cancer.
9. Explain the pathophysiology, clinical manifestations, complications, and collaborative care, including surgical therapy, of patients with gallbladder disorders.
10. Describe the nursing management of patients undergoing surgical treatment of cholecystitis and cholelithiasis.

The liver, the pancreas, and the biliary tract are critical organs that are responsible for many functions vital to life. Nursing management of patients with liver, pancreatic, and gallbladder problems is the focus of this chapter. Viral hepatitis, cirrhosis, acute pancreatitis, cholecystitis, and cholelithiasis are described in detail.

Jaundice

Jaundice, a yellowish discoloration of body tissues, results when the concentration of bilirubin in the blood becomes abnormally increased. It is a symptom rather than a disease. The term *jaundice* is often used interchangeably with *hyperbilirubinemia*. However, a careful clinical examination cannot detect jaundice until the serum bilirubin level is higher than 34 mcmol/L, twice the normal upper limit. Jaundice is usually first observed in the sclera and later in the skin (Figure 46-1).

FIGURE 46-1 Patient with jaundice. Source: Butcher, G. P. (2004). *Gastroenterology: An illustrated colour text.* London, UK: Churchill Livingstone.

Most of the body's bilirubin is formed from the breakdown of hemoglobin (from red blood cells) by macrophages (see Chapter 41, Figure 41-4). This unconjugated (indirect) bilirubin is released into the blood circulation tightly bound to albumin and is not water soluble. Because the unconjugated bilirubin is not water soluble, it

cannot be filtered in the kidneys and is not excreted in the urine. In the liver, the unconjugated bilirubin is conjugated with glucuronic acid to form conjugated (direct) bilirubin, which is water soluble. Conjugated bilirubin is secreted into bile, which flows through the hepatic and the biliary duct systems into the small intestine. In the large intestine, bilirubin is converted to stercobilinogen and urobilinogen by bacterial action. Stercobilinogen is responsible for the characteristic brown colour of feces. Some urobilinogen is reabsorbed into the portal circulation and returned to the liver. Normally, a very small amount of urobilinogen is excreted in urine.

Jaundice can be classified as prehepatic, hepatic, and posthepatic (or cholestatic). There is, however, much overlap, particularly between the hepatic and posthepatic varieties.

Prehepatic Jaundice

Prehepatic jaundice results from an increase in the load of bilirubin before the bile arrives at the liver. The most common cause of this increased load is overproduction of unconjugated bilirubin, as in hemolysis (excessive breakdown of red blood cells). Hemolysis can be related to blood transfusion reactions, sickle cell crisis, and hemolytic anemia. In benign hereditary conditions, such as Gilbert syndrome, the amount of unconjugated bilirubin in the blood is increased. The liver is unable to handle this increased bilirubin load. Bilirubin cannot be detected in the urine.

Hepatic Jaundice

Hepatic jaundice results from an alteration in the liver's ability to take up bilirubin from the blood or to conjugate or excrete it into bile. In hepato-cellular disease, the hepatocytes are damaged and leak bilirubin; thus levels of conjugated bilirubin are increased. In severe liver injuries, levels of both unconjugated and conjugated bilirubin are elevated as a result of both the inability of hepatocytes to conjugate bilirubin and the continued leaking of conjugated bilirubin from cells. Through reflux, conjugated bilirubin returns to the circulation and is excreted in urine because it is water soluble. The

most common causes of hepatic jaundice are hepatitis, cirrhosis, and hepato-cellular carcinoma (HCC).

Posthepatic (Cholestatic) Jaundice

Posthepatic jaundice is caused by failure of bile to reach the duodenum, mostly because of obstruction of bile flow through the liver or through the biliary duct system. The obstruction may be intrahepatic or extrahepatic. Intrahepatic obstructions result from swelling or fibrosis of the liver's canaliculi and bile ducts. The swelling can be caused by damage from liver tumours, hepatitis, or cirrhosis. Causes of extrahepatic obstruction include obstruction of the common bile duct by a stone, sclerosing cholangitis, and pancreatic cancer. Laboratory findings show an elevation of levels of both unconjugated and conjugated bilirubin and urine bilirubin.0 Because bilirubin does not enter the intestines, the level of fecal or urinary urobilinogen is decreased or nonexistent. When obstruction is complete, the stools are clay coloured.

Disorders of the Liver

Viral Hepatitis

Hepatitis is a broad term meaning inflammation of the liver. The most common cause of hepatitis is a viral infection. The common types of viral hepatitis are A, B, C, D, and E. Other viruses—such as cytomegalovirus, Epstein-Barr virus, herpesvirus, coxsackievirus, and rubella virus—may cause hepatitis, but the liver is usually not the primary infected organ. Hepatitis may also be caused by chemicals and drugs (including alcohol; see Chapter 41, Table 41-6), autoimmune diseases, metabolic disorders, and genetic abnormalities.

Viral hepatitis is a major public health concern. Surveillance of these viruses is carried out by the National Notifiable Disease Reporting System of Health Canada, and confirmed cases must therefore be reported. The only definitive way to distinguish among the various forms of viral hepatitis is by the presence of the antigens and the subsequent development of antibodies to them. However, the person who is immune to one virus can still develop another type of viral hepatitis. The major characteristics of the hepatitis viruses are presented in Table 46-1. Each type of viral hepatitis is discussed in detail later in this chapter.

TABLE 46-1
CHARACTERISTICS OF HEPATITIS VIRUSES

Incubation Period and Mode of Transmission	Sources of Infection	Infectivity
Hepatitis A Virus (HAV)		
15–50 days (average 28) Fecal–oral route (primarily fecal contamination and oral ingestion)	Crowded conditions (e.g., day care, nursing home). Poor personal hygiene. Poor sanitation. Contaminated food, water, shellfish. Persons with subclinical infections, infected food handlers. Sexual contact with infected partner. IV drug users.	Most infectious during 2 wk before onset of symptoms. Infectious until 1–2 wk after the start of symptoms.
Hepatitis B Virus (HBV)		
45–180 days (average 56–96) Percutaneous (parenteral) or permucosal exposure to blood or blood products Sexual contact Perinatal transmission	Contaminated needles, syringes, and blood products. Sexual activity with infected partner. Contact with asymptomatic carrier. Tattoos or body piercing with contaminated needles.	Before and after symptoms appear. Infectious for 4–6 mo. Carriers continue to be infectious for life.
Hepatitis C Virus (HCV)		
14–180 days (average 56) Percutaneous (parenteral) or mucosal exposure to blood or blood products High-risk sexual contact Perinatal contact	Blood and blood products. Needles and syringes. Sexual activity with infected partners.	1–2 wk before symptoms appear. Continues during clinical course. 75%–85% go on to develop chronic hepatitis C and remain infectious.
Hepatitis D Virus (HDV)		
2–26 wk HBV must precede HDV Chronic carriers of HBV always at risk	Same as HBV. Can cause infection only when HBV is present. Routes of transmission same as for HBV.	Blood infectious at all stages of HDV infection.

Incubation Period and Mode of Transmission	Sources of Infection	Infectivity
Hepatitis E Virus (HEV)		
15–64 days (average 26–42 days) Fecal–oral route Outbreaks associated with contaminated water supply in developing countries	Contaminated water, poor sanitation. Found in Asia, Africa, and Mexico. Not common in United States.	Not known. May be similar to HAV.

IV, intravenous.

Determinants of Health

Hepatitis C Virus (HCV) Infection

Culture and Ethnicity

- The incidence of acute hepatitis C infection among Indigenous males is 1.5 times higher than in the non-Indigenous Canadian-born population; the incidence rate for Indigenous females is 3.9 times higher.*

Personal Health Practices and Coping Skills

- Due to their tendency to engage in high-risk behaviours, prison inmates are at greater risk for HCV exposure than the general Canadian population is.†
- Injection drug users who shared drug preparation equipment are more likely than people who do not use injection drugs to contract HCV infection.‡

Gender

- The rates of HCV infection are higher in younger women. In Canadian street youth, the incidence of HCV was doubled in females due to concurrent high-risk behaviours (e.g., unprotected sex, drug use).¶

Pathophysiological Features

Liver.

The pathophysiological changes in the various types of viral hepatitis are similar. Hepatitis involves widespread inflammation of liver tissue. During an acute viral hepatitis infection, liver damage is mediated by cytotoxic cytokines and natural killer cells that cause lysis of infected hepatocytes (liver cells). Liver cell damage results in liver cell necrosis (death). Inflammation may interrupt bile flow, causing cholestasis (impaired flow of bile). Liver cells can normally regenerate through cellular replication, and if no complications occur, they should resume their normal function. If liver cell loss is massive, cellular replication may not be possible.

A chronic viral hepatitis infection causes chronic inflammation and can cause fibrosis that, over decades, can progress to cirrhosis. (Cirrhosis is discussed later in this chapter.)

Systemic Effects.

The antigen–antibody complexes between the virus and its corresponding antibody form a circulating immune complex in the early phases of hepatitis. The circulating immune complexes activate the complement system (see Chapter 16). The clinical manifestations of this activation are rash, angioedema, arthritis, fever, and malaise. *Cryoglobulinemia* (presence of abnormal proteins in the blood), glomerulo-nephritis, and vasculitis have also been found secondary to immune complex activation.

Clinical Manifestations

The clinical manifestations of viral hepatitis can be classified into acute and chronic hepatitis (Table 46-2). Many individuals with acute hepatitis have no symptoms. Individuals who are immuno-suppressed may also have no symptoms. As a result, many acute infections are often not diagnosed.

TABLE 46-2
CLINICAL MANIFESTATIONS OF HEPATITIS

Acute
• Altered taste and smell • Anorexia • Arthralgias • Constipation or diarrhea • Dark urine • Fatigue • Fever • Headache • Hepatomegaly • Jaundice • Light stools • Malaise • Nausea, vomiting • Pruritus • Right upper quadrant discomfort • Splenomegaly • Urticaria • Weight loss
Chronic
• Easy fatigability • Hepatomegaly • Malaise • Myalgia and arthralgia

The clinical symptoms, if present, in acute infections are similar across all types of hepatitis viruses. However, the course of infections varies among the types of hepatitis (discussed in detail in individual sections on viral hepatitis).

Acute Phase.

The acute phase of a viral hepatitis infection usually lasts 1 to 4 months. During the incubation period, symptoms may include anorexia, nausea, occasional vomiting, and right upper quadrant discomfort. The infected person may find food or alcohol repugnant and, if a smoker, may develop a distaste for cigarettes. Other symptoms may include malaise, fatigue, headache, low-grade fever, arthralgias, and skin rashes. Physical examination may reveal hepatomegaly, lymphadenopathy, and sometimes splenomegaly. The acute phase is the period of maximal infectivity.

The acute phase may be icteric (jaundice) or anicteric (no jaundice). Jaundice results when bilirubin diffuses into the tissues. The urine may darken because of excretion of excess bilirubin by the kidneys. If conjugated bilirubin cannot flow out of the liver because of obstruction or inflammation of the bile ducts, the stools become light or clay coloured. Pruritus sometimes accompanies the jaundice and occurs as a result of the accumulation of bile salts beneath the skin.

The convalescent phase begins as jaundice is disappearing and lasts from weeks to months; the average is 2 to 4 months. During this period, the patient's major complaint is malaise and easy fatigability. Hepatomegaly remains for several weeks, but splenomegaly usually subsides.

Chronic Phase.

The disappearance of jaundice does not mean resolution of the virus infection. Many hepatitis B and C infections result in chronic, lifelong disease. Almost all cases of acute hepatitis A resolve with no progression to a chronic state. Most patients with chronic viral hepatitis B or C have no symptoms. Others may have nonspecific symptoms, including malaise, fatigue, myalgias, arthralgias, and hepatomegaly (see Table 46-2). Chronic hepatitis B and C can

progress to severe scarring of the liver (cirrhosis) and liver failure if left untreated.

Complications

The overall mortality rate for acute viral hepatitis is less than 1%. The risk for death is higher in older adults and those with underlying debilitating illnesses, including existing liver disease. Complications that can occur include acute liver failure, chronic hepatitis, cirrhosis of the liver, hepato-cellular carcinoma, and fulminant hepatitis.

Fulminant hepatitis is an acute clinical syndrome that results in severe impairment or necrosis of liver cells and potential liver failure. It occurs only in a small percentage of patients. It may develop in co-infection with HBV and HDV. It is less frequent with acute HCV infection and rarely occurs with acute HAV. Liver failure usually causes death unless liver transplantation is performed. (Fulminant hepatitis is further discussed later in this chapter.)

Diagnostic Studies

Viral Serological Tests.

The viral antigens and antibodies are serological markers used to diagnose the different types of viral hepatitis. The specific markers and their interpretations for each type of viral hepatitis are explained under the headings of the particular viruses.

Serum Liver Enzymes.

These tests cannot differentiate one type of hepatitis from another, but they are helpful in determining the type of liver injury, whether it is related to liver cell injury or bile duct abnormalities.

Aspartate aminotransferase (AST) and alanine aminotransferase (ALT) are liver enzymes whose levels can indicate liver cell injury. In severe acute viral hepatitis, the levels can be markedly increased to more than 1 000 U/L. Elevated levels of alkaline phosphatase (ALP) and γ-glutamyl transpeptidase (GGT) are usually associated with

bile duct injuries, but these levels can rise to a lesser extent in viral hepatitis infections.

Liver Function Tests.

The term *liver function tests* (LFTs) has often been used broadly to include liver enzyme measurements, but that use is misleading. The LFTs that more accurately reflect liver function are serum albumin, serum bilirubin, and prothrombin time, which is standardized to the international normalized ratio (INR). In mild acute viral hepatitis, serum albumin, serum bilirubin, and INR remain normal. When jaundice is detectable on physical examination, the serum bilirubin level is usually at least twice the normal upper limit (>34 mcmol/L). Deteriorating liver function is demonstrated by increased INR and serum bilirubin and decreased serum albumin.

Hepatitis A

Canada has a relatively low incidence of hepatitis A (World Health Organization [WHO], 2010), and it has been slowly decreasing since the introduction of hepatitis A vaccine in 1996. The World Health Organization estimates an annual total of 1.5 million cases of hepatitis A worldwide (WHO, 2013), but seroprevalence data imply there are tens of millions of HAV infections annually (Public Health Agency of Canada [PHAC], 2011). In developing countries, hepatitis A infection is nearly universal during childhood.

Hepatitis A Virus (HAV).

HAV is an RNA virus. The virus is found in feces 2 weeks or more before the onset of symptoms and up to 1 week after the onset of jaundice (Figure 46-2). Anti-HAV immunoglobulin M (IgM) appears in the serum as the stool becomes negative for the virus. The presence of anti-HAV IgM indicates acute hepatitis. A positive anti-HAV IgG indicates a past infection or an immune response as a result of vaccination. Its presence provides lifelong immunity (Table 46-3).

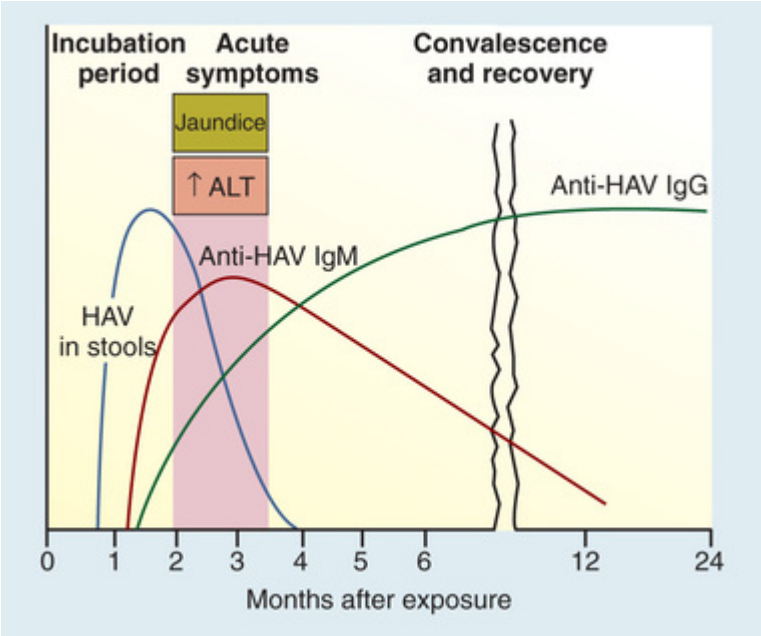

FIGURE 46-2 Course of infection with hepatitis A virus (HAV). *ALT,* alanine aminotransferase; *anti-HAV IgG,* immunoglobulin G class antibody to hepatitis A virus; *anti-HAV IgM,* immunoglobulin M class antibody to hepatitis A virus. Source: McCance, K. L., & Huether, S. E. (2010). *Pathophysiology: The biologic basis for disease in adults and children* (6th ed., p. 1488). St. Louis: Mosby.

TABLE 46-3

SEROLOGY TESTS FOR HAV INFECTION

Tests	Significance of a Positive Finding
Anti-HAV IgM (antibody to HAV, immunoglobulin M)	Acute infection
Anti-HAV IgG (antibody to HAV, immunoglobulin G)	Long-term immunity, due to either a past infection or vaccination

HAV, Hepatitis A virus.

The mode of transmission of HAV is usually fecal–oral (mainly by ingesting food or liquid infected with the virus) and rarely parenteral. Poor hygiene, improper handling of food, crowded situations, and poor sanitary conditions are related factors. Foodborne hepatitis A outbreaks usually result from contamination of food during preparation by an infected food handler. The risk for

transmission is highest before clinical symptoms are apparent. The virus can also be transmitted by patients with anicteric (asymptomatic) hepatitis A.

Clinical Manifestations.

Hepatitis A usually causes acute symptoms in adults but not in younger children. Typical symptoms include anorexia, nausea, fatigue, fever, and jaundice (see Table 46-2). The symptom severity increases with age. Fewer than 10% of affected children younger than 6 years develop jaundice. Recovery usually takes 4 to 6 weeks, but it may take months. Hepatitis A does not lead to chronicity and rarely causes fulminant hepatic failure. There is no specific treatment for hepatitis A. Hospitalization is normally unnecessary unless the patient is severely dehydrated. Management is focused on relief of symptoms. Recovery from HAV infection confers lifelong immunity against the virus.

Hepatitis B

Hepatitis B is an important vaccine-preventable infectious disease in Canada. Worldwide, nearly 2 billion people are infected with HBV and, of these, 350 million have been unable to clear the infection and have become chronically infected. In Canada, the overall reported incidence of HBV was 0.6 cases per 100 000 people (PHAC, 2014a). Because of the heterogeneity of the Canadian population, immigrants—particularly those from regions highly endemic for hepatitis B—constitute the largest group of carriers of chronic hepatitis B.

Hepatitis B Virus (HBV).

HBV is a deoxyribonucleic acid (DNA) virus that is far more infectious than the human immunodeficiency virus (HIV). It can live outside a human body for up to 7 days.

HBV has a complex structure. It expresses a few viral proteins or antigens that can be measured in blood. Each antigen has a corresponding antibody that may develop in response to the HBV infection. Hepatitis B surface antigen (HBsAg) represents the outer

protein coat of the virus. The persistence of HBsAg in the blood for 6 to 12 months or longer indicates a chronic hepatitis B state. Development of antibody toward HBsAg (anti-HBs) signifies immunity. The HBV core antigen (HBcAg) can be observed only in the liver and not in blood, but its antibody (anti-HBc) can be measured, and its presence in blood indicates infection. Hepatitis B e antigen (HBeAg) is a third viral protein excreted by the virus. Its presence is associated with an active viral replication state and high infectivity. The absence of HBeAg, however, does not always rule out active disease, because some people can have mutant viruses that cannot express e antigen, and hence they have active e antigen negative chronic hepatitis B. The different serological markers of hepatitis B are explained in Table 46-4.

TABLE 46-4

SEROLOGY TESTS FOR HBV INFECTION

Test	Significance of a Positive Finding
HBsAg (hepatitis B surface antigen)	Infection; persistence of positive result >6 months indicates chronic infection
HBeAg (hepatitis B e antigen)	High virus activity and high degree of infectiousness
Anti-HBe (antibody to hepatitis B e antigen)	Associated with lower rate of virus replication and less infectious state; in cases of mutated viruses, positive result can be associated with active virus replication and high infectivity
Anti-HBc total (total antibody to hepatitis B core antigen)	Past or ongoing infection; seropositivity persists for life; does not appear after vaccination
Anti-HBc IgM (IgM class antibody to hepatitis B core antigen)	Acute infection
Anti-HBs (antibody to hepatitis B surface antigen)	Protective antibody produced with recovery from infection or in response to vaccination

HBV, hepatitis B virus; *IgM,* immunoglobulin M.

HBV is transmitted perinatally by mothers who have the viral infection; percutaneously (e.g., intravenous [IV] drug use, accidental needle-stick punctures, tattoos); sexually; or horizontally by permucosal exposure to infectious blood, blood products, or other body fluids (e.g., semen, vaginal secretions). Transmission occurs

when infected blood or other body fluids enter the body of a person who is not immune to the virus.

In people with HBV, HBsAg has been detected in almost every bodily fluid. Infected semen and saliva contain much lower concentrations of HBV than blood, and the risk of virus transmission via these secretions is very low. There is no evidence that urine, feces, tears, and sweat are infective.

Breastfeeding is safe and is not a risk factor for mother-to-child transmission (Chen, Chen, Wen, et al., 2013). All infants born to HBsAg-infected mothers must receive both vaccination and immune globulins at birth. All breastfeeding mothers should take good care of their nipples to avoid cracking and bleeding. Kissing, hugging, sharing food, and casual contacts with infected individuals does not transmit HBV infection.

According to the *Primary Care Management of Hepatitis B Guide* (PHAC, 2014b), the at-risk groups that should be screened and tested for hepatitis B include injection or inhalation drug users, people who have unprotected sex with multiple sexual partners, those who have spent time in prison, homosexual men, and individuals from areas of the world where the virus is common.

Acute Hepatitis B.

Most acutely infected individuals, especially neonates and young children born to mothers with hepatitis B, have no symptoms. Fulminant hepatitis is uncommon.

The course of an acute HBV infection that spontaneously resolves is shown in Figure 46-3. After an acute infection, the percentage of infected people in whom the infection does not resolve and becomes chronic varies with age. Up to 90% of neonates who contract HBV at birth become chronically infected. In contrast, more than 95% of adults can clear the HBV infection except for those who are immuno-compromised, such as those with HIV co-infection. Children under age 6 with HBV have a 30% to 50% risk of it developing into a chronic infection (WHO, 2017).

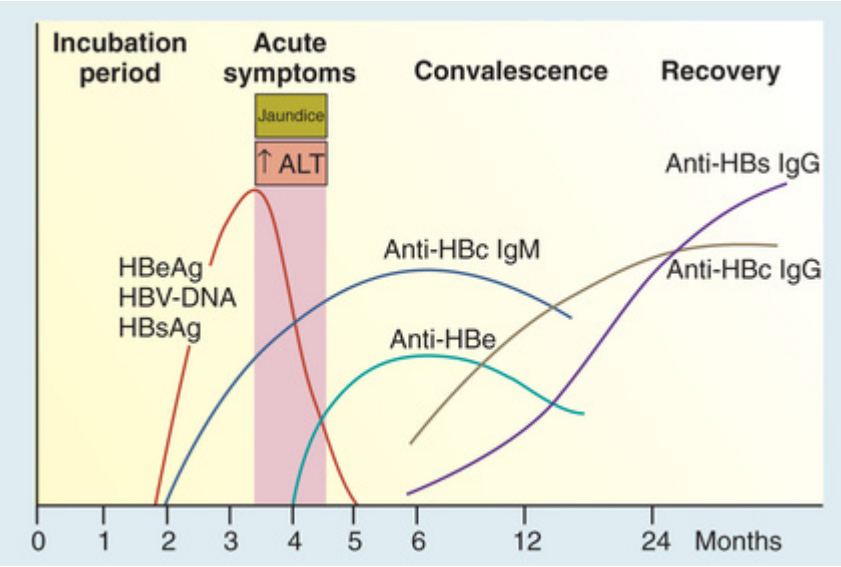

FIGURE 46-3 Course of a resolved hepatitis B (HBV) infection. *ALT,* alanine aminotransferase; *anti-HBc,* antibody to hepatitis B core antigen; *anti-HBe,* antibody to HBeAg; *anti-HBs,* antibody to HBsAg; *HBeAg,* hepatitis B e antigen; *HBsAg,* hepatitis B surface antigen; *HBV,* hepatitis B virus; *IgG,* immunoglobulin G; *IgM,* immunoglobulin M. Source: McCance, K. L., & Huether, S. E. (2014). *Pathophysiology: The biologic basis for disease in adults and children* (7th ed., p. 1458). St. Louis: Mosby.

Acute hepatitis B normally does not necessitate antiviral treatment. Management focuses on relief of symptoms and counselling to prevent virus transmission, including contacts tracing.

Chronic Hepatitis B.

The course of chronic hepatitis B is highly variable and rather complex. Some infected individuals may have exacerbations and remissions of inflammatory activity in the liver, some have continuous active inflammation, and others have no inflammation whatsoever for life. The course of a chronic hepatitis B infection (Figure 46-4) in those who were infected at a young age can be divided into four phases:

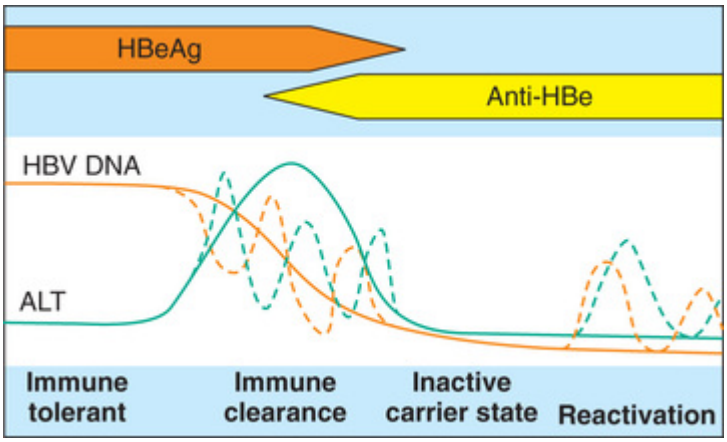

FIGURE 46-4 Phases of chronic hepatitis B infection. *ALT,* alanine aminotransferase; *Anti-HBe,* antibody to hepatitis B e antigen (HBeAg); *HBV,* hepatitis B virus. Source: From Dooley, J. S., Lok, A. S. F., Burroughs, A., & Heathcote, E. J. (2011). *Sherlock's diseases of the liver and biliary system* (12th ed., p. 378). Copyright © 2011, John Wiley and Sons.

1. The so-called immune-tolerant phase is characterized by a high level of virus replication (HBV DNA or viral load) in the blood but no or minimal hepatic inflammation. Affected individuals are HBeAg seropositive but have normal ALT levels (<40 IU/mL) because of the lack of immune response to the virus.
2. In the immune clearance phase, hepatitis is intermittent, with varying degrees of inflammatory activity. HBV DNA in this phase is also high, and liver enzyme levels are abnormal because the immune response against the virus has begun. Seroconversion from HBeAg positivity to anti-HBe positivity may occur during this phase.
3. The third phase is an inactive stage during which the viral load is low and there is no inflammatory activity in the liver, so liver enzyme levels are normal and HBV DNA is low or undetectable. Some individuals remain in this phase and have inactive hepatitis B throughout life.
4. Others progress to the final phase. They develop a high viral load and abnormal liver enzyme levels, signalling the reactivation of HBV infection.

Every year, about 1% of patients become cleared of HBsAg. Patients with chronic hepatitis B are at risk for the development of hepato-cellular carcinoma.

Drug Therapy.

Drug therapy for chronic HBV includes interferon (IFN) and oral antiviral agents. Therapy focuses on decreasing the viral load and liver enzymes and slowing the rate of disease progression. The long-term goals are to prevent cirrhosis, liver failure, and hepato-cellular carcinoma. Current drug therapies for chronic HBV suppress but do not eradicate the virus (Terrault, Bzowej, Chang, et al., 2016).

Interferon.

IFN has both antiviral and immuno-modulatory activity. IFN is available in two forms: conventional (Intron A) and pegylated. Conventional IFN has a short half-life, which necessitates frequent subcutaneous administrations, and is rarely used these days. Pegylated IFN, a long-acting weekly subcutaneous injection, is preferred over the conventional IFN for simplicity (Terrault, Bzowej, Chang, et al., 2016). The long-acting preparations are made by conjugating a conventional IFN with polyethylene glycol (PEG) in a process known as *pegylation*.

In patients with HBV who are receiving IFN, one-third exhibit a significant reduction of viral load, normalization of ALT levels, and loss of HBeAg. The response to treatment may vary on the basis of viral genotype. IFN treatment is associated with a number of adverse drug events (Table 46-5). These adverse events are dosage related and tend to decrease in severity with continued treatment. For patients receiving IFN, blood cell counts and liver enzyme levels should be measured at least every 4 weeks, but more often if needed. Treatment duration of 48 weeks is recommended (Terrault, Bzowej, Chang, et al., 2016).

TABLE 46-5
HCV DRUG THERAPY: MOST COMMON ADVERSE EFFECTS

Interferon	Ribavirin
Influenza-Like Symptoms	• Anemia • Anorexia • Cough • Dyspnea • Insomnia • Pruritus • Rash • Teratogenicity (interferes with normal fetal development)
• Arthralgia • Asthenia • Chills • Fatigue • Headache • Low-grade fever • Nausea	
Other Effects	
• Depression • Thinning hair • Insomnia • Irritability • Itching or dry skin • Mood swings • Thyroid dysfunction • Weight loss	

HCV, hepatitis C virus.

Nucleoside and Nucleotide Analogues.

The oral nucleoside analogue classes of antiviral agents used to treat HBV infection include lamivudine (Heptovir), telbivudine (Sebivo), and entecavir (Baraclude); the nucleotide analogues are adefovir (Hepsera) and tenofovir (Viread). These drugs are given when there is evidence of active viral replication. They inhibit viral DNA synthesis and thereby reduce the amount of virus in the blood, decreasing liver damage and normalizing liver enzymes. Most patients with HBV infection require long-term treatment with these medications.

Development of drug resistance is an issue with oral antiviral drugs. Of patients who take lamivudine for more than 3 years, up to 70% develop resistance. Patients with lamivudine-resistant HBV infection can be treated with another class of drugs (i.e., adefovir or tenofovir). Because adefovir is considerably less potent and associated with an increasing rate of resistance, it is no longer commonly prescribed. Adefovir and entecavir should not be taken by women who are pregnant. Tenofovir demonstrated no drug

resistance development in a 7-year follow-up study (Buti, Tsai, Petersen, et al., 2015). Acute, severe exacerbations of hepatitis B have been reported after discontinuation of these drugs. If these drugs are discontinued, liver function should be monitored closely for several months.

Drug Alert

Adefovir (Hepsera) and Tenofovir (Viread)

- These drugs can cause nephrotoxicity.
- Serum creatinine levels should be monitored, especially in patients at risk, including those with pre-existing renal disease and those taking nephrotoxic drugs (e.g., cyclosporine, aminoglycoside, vancomycin).

Drug Alert

Adefovir (Hepsera) and Entecavir (Baraclude)

- These drugs should not be taken by pregnant women.

Hepatitis C

Approximately 138 600 Canadians (0.5% of the population) are affected by hepatitis C (Myers, Shah, Burak, et al., 2015). These figures are likely an underestimate because the Canadian Health Survey excluded several high-risk groups, including incarcerated persons, Indigenous peoples, and persons who inject drugs (PWIDs).

Of all the forms of hepatitis, hepatitis C is the most likely to cause long-term liver damage; up to 80% of people with HCV infection develop a chronic infection. Although the overall prevalence of chronic hepatitis C is declining, its complications are increasing due

to aging of the infected population and the progression of the disease. Modelling data suggest that cases of decompensated cirrhosis, hepato-cellular carcinoma, and liver-related mortality is expected to rise through 2025 (Myers, Shah, Burak, et al., 2015).

Hepatitis C Virus (HCV).

HCV is an ribonucleic acid (RNA) virus that is primarily transmitted percutaneously. In Canada, the most common mode of HCV transmission is the sharing of contaminated needles and equipment among PWIDs. Transmission during blood transfusion has been eliminated. The proportion of cases related to high-risk sexual behaviour (unprotected sex, multiple partners) has increased in recent years. However, sexual transmission among monogamous heterosexual partners remains rare. The risk for perinatal transmission is approximately 5% but is higher in women with HIV–HCV co-infection. People who were born in regions where HCV is common are also at risk because of the lack of universal precautions and medical practices in which contaminated equipment is used (e.g., during childhood immunization). Other transmission risks are related to needle-stick injuries and hemodialysis.

Diagnostic Tests.

The initial test for HCV infection is antibody testing. Unlike antibodies to HAV and HBV, antibodies to HCV are not protective and their presence in the blood does not indicate immunity. A positive result of an anti-HCV test can be related to either a past or current exposure (Table 46-6). To confirm if disease is active or not, HCV RNA (the presence of replicating HCV) should be tested. In those whose HCV infection has resolved, anti-HCV results remain positive but HCV RNA are negative.

TABLE 46-6

SEROLOGY TESTS FOR HCV INFECTION

Test	Significance
Anti-HCV (antibody to hepatitis C virus)	Positive result indicates either past exposure or current infection An initial screening test for HCV
HCV RNA	Quantitative result indicates active ongoing viral multiplication, also referred to as *viral load*

HCV, hepatitis C virus; *RNA,* ribonucleic acid.

After initial exposure to the virus, HCV RNA appears in blood earlier than anti-HCV, and patients can test positive at approximately 2 weeks after exposure. Therefore, HCV RNA helps identify the presence of the virus in exposed individuals (e.g., health care workers) before antibodies develop. HCV RNA detection is particularly useful in immuno-compromised patients (e.g., patients with HIV) who have active disease but whose anti-HCV is negative because antibody production is very low (below the detection level of the antibody tests).

HCV has six genotypes and more than 50 subtypes. In Canada, 75% of HCV infections are caused by HCV genotype 1. Genotyping currently plays an important role in the management of patients receiving treatment, but it may not have any impact once a pan-genotypic treatment becomes available.

Drug Therapy

Acute Hepatitis C.

The rate of spontaneous clearance of acute hepatitis C (AHC) has been reported as more than 50% in some studies. The younger the patient is when infected, the higher the likelihood of spontaneous clearance. Patients with symptoms also have a higher chance of eliminating the infection.

Chronic Hepatitis C.

Unlike hepatitis B, chronic hepatitis C can be cured with drug therapy (Table 46-6) that can completely eradicate the virus, termed a sustained virological response (SVR), and thus prevent HCV-

related complications. The treatment landscape of hepatitis C has changed rapidly since the introduction of direct-acting antiviral agents (DAAs) in 2011. Before then, the standard therapy was a combination of pegylated IFN-α-2a (Pegasys) plus ribavirin (combination was Pegasys RBV) or IFN-α-2b (PEG-Intron) plus ribavirin (combination is Pegetron), which can cause many intolerable adverse effects. These combination therapies are now rarely used. The second wave of newer DAAs introduced in 2014 have much improved efficacy and tolerability and shorter treatment durations and provide the option of IFN- and ribavirin-free therapy. In contrast to the many adverse effects from IFN, the newer DAAs have only a few common adverse effects, including headaches and fatigue. The all-oral DAAs therapy is a major advance in the field of viral hepatitis. Currently, the most commonly used DAAs in Canada include sofosbuvir (Sovaldi), sofosbuvir/ledipasvir (Harvoni), ombitasvir/paritaprevir/ritonavir/dasabuvir (Holkira pak), daclatasvir (Daklinza), and elbasvir/grazoprevir (Zepatier). The treatment choice depends very much on patients' access to third-party insurance coverage, the severity of their liver disease, and the HCV genotypes. Detailed treatment regimens, dosing schedule, duration, and monitoring can be found in the 2015 Canadian guidelines on the management of chronic hepatitis C (Myers, Shah, Burak, et al., 2015).

The currently approved medications for HCV and their most common adverse effects are listed in Table 46-6.

Drug Alert

Ribavirin

- During treatment, pregnancy must be avoided, both by women taking the drug and by women whose male partners are taking the drug.

Many patients with HIV infection also have HCV infection. Patients who have stable HIV infection and relatively intact immune systems ($CD4^+$ counts >200/mcL) are treated for hepatitis C with the goal of eradicating HCV infection and reducing the risk for progression to cirrhosis. Their treatment cure rates in the era of DAAs are comparable to those with non–HIV-infected individuals (Karageorgopoulos, Allen, Bhagani, et al., 2015).

Hepatitis D

Hepatitis D virus (HDV), also called *delta virus,* is a defective single-stranded RNA virus that cannot survive on its own. Of the 350 million people infected with HBV worldwide, 15 million are co-infected with HDV. Although the prevalence of HDV in Canada is extremely low, people who are at risk for HBV infection (e.g., people who use injection drugs) should also be screened for HDV.

HDV requires HBV to replicate. It can be acquired at the same time as HBV (co-infection) or at a later time in an existing HBV infection (super-infection). HBV–HDV co-infection can cause fulminant hepatitis and more severe disease than HBV infection alone. A positive anti-HDV (hepatitis D antibody) test indicates exposure to HDV whereas HDV RNA confirms active disease. Currently in Canada, HDV RNA testing can be performed only in government-approved laboratories.

HDV, similar to HBV, is transmitted percutaneously. HDV is rarely acquired through sexual transmission. The symptoms of acute infection are the same as those of other viral hepatitis infection. People at risk for HDV infection are only those at risk for HBV. No vaccine for HDV is available; however, vaccination against HBV reduces risk for HDV co-infection. Treatment of HDV infection is with IFN-α. However, response rates are poor (<30%), and relapse is common.

Hepatitis E

Hepatitis E virus (HEV) is an RNA virus transmitted via the fecal–oral route, most commonly through drinking contaminated water. Infection with HEV, initially thought to occur primarily in

developing countries, has been reported in increasing numbers in many developed countries, including the United States (Kamar, Dalton, Abravanel, et al., 2014). Current prevalence of hepatitis E in Canada remains unknown, and the virus has not been reported as a public health threat. HEV infection causes acute self-limiting hepatitis. Pregnant women, however, are at risk for more severe disease. In immuno-suppressed people, hepatitis E may progress to a chronic infection and even cirrhosis. The diagnosis is confirmed through detection of IgM anti-HEV antibodies.

Table 46-7 shows the collaborative care for viral hepatitis.

TABLE 46-7
COLLABORATIVE CARE
Viral Hepatitis

Diagnostic

• History and physical examination
• Liver enzyme measurements
  • Alanine aminotransferase (ALT)
  • Aspartate aminotransferase (AST)
• Liver function tests
  • Albumin, bilirubin, INR
• Hepatitis tests
  • Anti-HAV: IgM or IgG
  • HBsAg
  • Anti-HBs
  • Anti-HBc: IgM or total (IgM + IgG)
  • HBV DNA
  • Anti-HCV
  • HCV RNA
• Genotyping for HBV, HCV
  • Anti-HDV

Collaborative Therapy
Acute and Chronic
• Well-balanced diet • Vitamin supplements if needed • Rest (degree of strictness varies) • Avoidance of alcohol and hepatotoxic drugs
Chronic HBV

• Interferon therapy
  • Conventional IFN (Intron A), pegylated IFN-α-2a (Pegasys), pegylated IFN-α-2b
• Oral antiviral agents
  • Lamivudine (Heptovir), adefovir (Hepsera), telbivudine (Sebivo), entecavir (Baraclude), tenofovir (Viread)

Chronic HCV
• Pegylated IFN-α-2a (Pegasys) + ribavirin (combination is Pegasys RBV), pegylated IFN α-2b (PegIntron) + ribavirin (combination is Pegetron) • Sofosbuvir (Sovaldi), sofosbuvir/ledipasvir (Harvoni), ombitasvir/paritaprevir/ritonavir/dasabuvir (Holkira pak), daclatasvir (Daklinza), elbasvir/grazoprevir (Zepatier)

Nursing Management Viral Hepatitis

Nursing Assessment

Subjective and objective data that should be obtained from a person with hepatitis are presented in Table 46-8.

TABLE 46-8

NURSING ASSESSMENT
Hepatitis

Subjective Data
Important Health Information
Past health history: Family history of or exposure to person infected with viral hepatitis; exposure to benzene, carbon tetrachloride or other hepatotoxic agents; recent travel; ingestion of contaminated food or water; exposure to contaminated needles including medical or dental equipment; hemodialysis; blood or blood product transfusions; organ transplantation; misuse of alcohol; previous injection drug use; previous cocaine use; smoking history; high-risk sexual behaviour; exposure as health care worker; chronic care institution resident; incarceration *Medications:* Exposure to new drug therapies; misuse of acetaminophen, new prescriptions, over-the-counter or herbal medications or supplements
Symptoms
• Weight loss, anorexia, vomiting, feeling of fullness in right upper quadrant • Malaise; taste change • Skin rashes or hives, pruritus • Right upper quadrant pain and tenderness • Jaundice, dark urine; light-coloured stools • Fatigue, arthralgias, myalgias
Objective Data
General
Low-grade fever, lethargy, lymphadenopathy
Integumentary
Rash, other skin changes, jaundice, icteric sclera, interferon injection sites
Gastro-Intestinal
Hepatomegaly, splenomegaly
Possible Diagnostic Findings
Abnormal results of liver enzyme studies: ↑ serum total bilirubin level, hypoalbuminemia, anemia, bilirubin in urine, and ↑ urobilinogen; prolonged prothrombin time (INR); positive test results for hepatitis, including anti-HAV IgM, anti-HAV IgG, HBsAg, HBeAg, anti-HBc IgM, HBV DNA, anti-HCV, HCV RNA, and anti-HDV; abnormal findings on radiological imaging

DNA, deoxyribonucleic acid; *HAV,* Hepatitis A virus; *HBc,* hepatitis B core antigen; *HBeAg,* hepatitis B e antigen; *HBsAg,* hepatitis B surface antigen; *HBV,* hepatitis B virus; *HCV,* hepatitis C virus; *HDV,* hepatitis D virus; *IgG,* immunoglobulin G; *IgM,* immunoglobulin M; *INR,* international normalized ratio; *RNA,* ribonucleic acid.

Nursing Diagnoses

Nursing diagnoses for the patient with hepatitis may include but are not limited to the following:

- *Imbalanced nutrition: less than body requirements* related to *insufficient dietary intake* (anorexia and nausea)
- *Activity intolerance* related to *physical deconditioning* (fatigue and weakness)
- *Risk for impaired liver function* (as evidenced by viral infection)

Additional information on nursing diagnoses for the patient with hepatitis is presented in Nursing Care Plan (NCP) 46-1, available on the Evolve website.

Planning

The overall goals are that the patient with viral hepatitis will (a) have relief of discomfort, (b) be able to resume normal activities, and (c) experience a return to normal liver function without complications.

Nursing Implementation

Health Promotion.

Viral hepatitis is a public health problem. The nurse has a significant role in the control and prevention of this infectious disease. The nurse must first understand the epidemiology of the different types of viral hepatitis, including risk factors for acquisition, before considering appropriate control measures.

Hepatitis A.

HAV is usually the cause of outbreaks of viral hepatitis. Preventive measures include personal and environmental hygiene and health education to promote good sanitation. Careful handwashing, especially after bowel movements and before eating, is probably the most important precaution. Both hepatitis A vaccine and immune globulin are administered for prevention. (See Table 46-9 for more information on hepatitis A health promotion and prevention.)

From a public health perspective, vaccination, or active immunization, is an effective means of controlling hepatitis A and the best protection against HAV infection. Canada currently does not have a universal HAV immunization program. Adults at risk are advised to receive the vaccine as pre-exposure prophylaxis. These include people who travel to HAV-endemic regions, illicit drug users, men who have sex with men, persons with chronic liver disease, persons with clotting factor disorders (e.g., hemophilia), and residents of communities where hepatitis A is highly endemic (PHAC, 2016).

The HAV vaccine is inactivated hepatitis A virus and is currently available in several forms, including Havrix, Vaqta, and Avaxim. Primary immunization consists of a single dose administered intramuscularly in the deltoid muscle. A booster is recommended between 6 and 12 months after the primary dose to ensure adequate antibody titres and long-term protection. The primary immunization provides immunity within 30 days after a single dose in more than 95% of those vaccinated. Twinrix, a combined HAV and HBV vaccine, is available for children and adults. The primary immunization consists of three doses, given on a 0-, 1-, and 6-month schedule, the same schedule used for the single HBV vaccine. Booster doses are not needed in people who completed the primary three doses. Twinrix may be given to individuals at high risk for hepatitis infection, as previously mentioned. The adverse effects of the vaccine are mild and are usually limited to soreness and redness at the injection site.

Hepatitis A immune globulin can be administered either before or after exposure. Immune globulin provides temporary (6 to 8 weeks) passive immunity and is effective for preventing hepatitis A if given within 1 to 2 weeks after exposure. Immune globulin is recommended for those without anti-HAV antibodies who are exposed to hepatitis A by close contact (e.g., household, day care centre) with people who have HAV or through foodborne exposure. Although immune globulin may not prevent infection in all persons, it may modify the illness to a subclinical infection. It may also be administered as a prophylactic measure for travellers to countries that have a high incidence of hepatitis A.

The patient with acute hepatitis A is hospitalized only when symptoms are severe. Isolation is generally not required for hepatitis A; however, infection-control precautions must be used (see Chapter 17, Table 17-8). A private room is indicated if the patient is incontinent of stool or has poor personal hygiene.

Hepatitis B.

The best way to reduce HBV infection is to identify those at risk, screen them for HBV, and vaccinate those who are not infected (see Table 46-9). The nurse must be aware of which individuals are at risk for contracting hepatitis B and teach ways to reduce risks of transmission.

Hepatitis B vaccine is the most effective means of prevention. Since the late 1990s, universal immunization against HBV has been part of the vaccine programs offered by all provinces and territories in Canada. Although different jurisdictions offer the vaccines for people of different ages, the HBV vaccine programs ensure that every child is vaccinated by the end of high school. It is also important to vaccinate adults in at-risk groups, including people who use injection or inhalation drugs, those who live with or have sexual contact with hepatitis B carriers, persons with chronic liver disease, people with hemophilia, persons with chronic renal disease or undergoing dialysis, individuals infected with HIV, and health care providers (Government of Canada, 2016).

Hepatitis B vaccine is produced through recombinant DNA technology. The vaccines are Recombivax HB, Engerix-B, and Twinrix. These are given in a series of three injections in the deltoid muscle. The second dose is administered within 1 month of the first one, and the third one within 6 months of the first. A newer hepatitis B–containing vaccine, Infanrix Hexa, also contains diphtheria, tetanus toxoids, pertussis, poliomyelitis, and *Haemophilus influenzae* type b (DTap-HB-IPV-Hib vaccine) and is given at 2, 4, 6, and 12 to 23 months of age. Hepatitis B vaccine is more than 95% effective. Successful vaccination should result in anti-HBs titres of 10 IU/mL or greater. Boosters (additional doses) to increase the antibody levels are generally not recommended. Only minor adverse reactions have been reported with vaccination, including transient fever and soreness at the injection site. The vaccine is not contraindicated during pregnancy.

For postexposure prophylaxis, the vaccine and hepatitis B immune globulin (HBIG) are administered. HBIG contains antibodies to HBV and confers temporary passive immunity. It is prepared from plasma of donors with a high titre of anti-HBs and is expensive. HBIG is recommended for postexposure prophylaxis in cases of needle-stick, mucous membrane contact, or sexual exposure and for infants born to mothers who are positive for HBsAg. It should be given after exposure, preferably within 24 hours. The vaccine series should also be started.

Preventive measures should also include teaching individuals at high risk of contracting HBV to reduce risks. Good hygienic practices, including handwashing and using gloves when expecting contact with blood, are important. HBV-infected individuals should not share razors,

toothbrushes, and other personal items. Practising safer sex should be strongly recommended, particularly if the sexual partner's hepatitis B status is unknown.

Hepatitis C.

No vaccine is currently available for hepatitis C. The primary measures to prevent HCV transmission include screening of blood, organ, and tissue donors; use of infection-control precautions; and modification of high-risk behaviour. As with HBV prevention, the nurse should identify individuals at high risk for contracting HCV and teach methods to reduce risks. Individuals at risk include those who use injection drugs (or have used them in the past, even once or many years ago), people who received blood or blood products before 1992, patients who are or have been undergoing hemodialysis, workers in hemodialysis units and laboratories in which blood is handled, people with multiple sexual partners, prisoners, and sexual partners of individuals with HCV infection. Because of the number of people with hepatitis C who have not been diagnosed, birth-cohort screening (1945–1975) regardless of risk-factor status is cost-effective (Shah, Heathcote, & Feld, 2013).

Currently, the Public Health Agency of Canada does not recommend immune globulin for postexposure prophylaxis (e.g., needle-stick exposure from an infected person) for HCV infection. After an acute exposure (e.g., through needle-stick), baseline anti-HCV and ALT levels should be measured in both the person already infected (i.e., the source) and the person exposed to HCV. Follow-up testing for anti-HCV and ALT activity should be performed 4 to 6 months later. If the source is someone with known HCV infection, HCV RNA should be measured 2 weeks later to confirm viral transmission.

As with hepatitis B prevention, the use of universal precautions is important. The use of a condom is advised for sexual intercourse with an individual with HCV, and razors, toothbrushes, and other personal items should not be shared. Health promotion and preventive measures for hepatitis A, B, and C are summarized in Table 46-9.

TABLE 46-9

VIRAL HEPATITIS: HEALTH PROMOTION AND PREVENTATIVE MEASURES

Hepatitis A
General Measures
• Good handwashing • Proper personal hygiene • Environmental sanitation • Control and screening (signs, symptoms) of food handlers • Serological screening • Active immunization for people in at-risk groups
Use of Immune Globulin
• Early administration (1–2 wk after exposure) to those exposed • Prophylaxis for travellers to areas where hepatitis A is common if they have not previously received HAV vaccine
Special Considerations for Health Care Providers
• Wash hands after contact with an affected patient or after removal of gloves • Use infection-control precautions
Hepatitis B and C Percutaneous Transmission

• Screening of donated blood
  • Hepatitis B: HBsAg
  • Hepatitis C: anti-HCV
• Use of disposable needles and syringes

Sexual Transmission
• Acute exposure: HBIG administration to sexual partner of HBsAg-positive person • Administration of HBV vaccine series to uninfected sexual partners • Use of condoms for sexual intercourse
General Measures
• Good handwashing • Avoidance of sharing toothbrushes and razors • HBIG administration for one-time exposure (needle-stick, contact of mucous membranes with infectious material) • Active immunization: HBV vaccine
Special Considerations for Health Care Providers
• Using infection-control precautions • Considering the blood of all patients potentially infectious • Disposing of needles properly • Using needleless IV access devices when possible

HAV, hepatitis A virus; *HBIG,* Hepatitis B immunoglobulin; *HBsAg,* hepatitis B surface antigen; *HBV,* hepatitis B virus; *HCV,* hepatitis C virus; *IV,* intravenous.

Acute Intervention

Jaundice.

In patients with acute hepatitis, assess for jaundice. In light-skinned people, jaundice is usually observed first in the sclera of the eyes and later in the skin. In dark-skinned people, jaundice is observed in the hard palate of the mouth and the inner canthus of the eyes. The urine may be dark brown or brownish red because of the presence of bilirubin. Comfort

measures should be used to relieve fatigue, weakness, headache, and arthralgias (see NCP 46-1, available on the Evolve website).

Ensuring that the patient receives adequate nutrition can be a challenge. Anorexia and a distaste for food can cause nutritional problems. Dietary assessment should be performed. Small, frequent meals may be preferable to three large ones and may help prevent nausea. Measures to stimulate the appetite—such as mouth care, antiemetics, and attractively served meals in pleasant surroundings—should be included in the nursing care plan. Carbonated beverages, ginger, and avoidance of very hot or very cold foods may help counteract the symptom of nausea. Adequate hydration is important.

Rest.

Patients with symptomatic acute viral hepatitis have fatigue and decreased energy. Rest is important to help conserve energy. The nurse should help the patient space activities both to conserve energy and to avoid overexertion; assess the patient's response to the rest and activity plan; and modify it accordingly. Assessment of symptoms and liver function tests can be used as a guide to activity.

Ambulatory and Home Care.

Most individuals with acute viral hepatitis are cared for at home, and so the nurse needs to assess patients' knowledge of nutrition and provide the necessary dietary teaching. Rest and adequate nutrition are important for those with impaired liver synthetic functions. Patients should be cautioned about overexertion and the need to follow the health care provider's advice about when to return to work. Patients and their families should be taught how to prevent transmission among household members and what symptoms should be reported to the health care provider. Symptoms of worsening liver function include bleeding tendencies (caused by increased INR), abdominal swelling (from ascites), and confusion (caused by encephalopathy). Patients should be instructed to have regular follow-up for at least 1 year after the diagnosis of acute viral hepatitis. Those who are unable to resolve the acute infection and become chronic HBV or HCV carriers should be assessed for the need of a referral to a hepatologist, if it is not already done. All patients with chronic HBV or HCV infection should avoid excessive use of alcohol to prevent acceleration of disease progression.

Patients who remain seropositive for HBsAg should not donate blood, semen, or organs. Patients who receive IFN for the treatment of hepatitis B or C require education regarding this drug and its adverse effects. Patients and caregivers need to be taught how to administer a subcutaneous injection. They must also be informed about the numerous adverse effects with the therapy, including influenza-like symptoms (e.g., fever, malaise, fatigue, chills; see Table 46-6). (Additional information on interferon is presented in Chapters 16 and 18.)

Evaluation

Expected outcomes for the patient with viral hepatitis are addressed in NCP 46-1, available on the Evolve website.

Control of Viral Hepatitis in Health Care Providers

Hepatitis A.

Hepatitis A is rarely transmitted from patients to health care providers. When transmission does occur, it is associated with undiagnosed hepatitis A in patients who are being treated for other problems. If the patient is incontinent of stool, infection-control precautions must be strictly enforced to prevent transmission.

Hepatitis B.

Health care workers may be exposed to HBV from needle sticks, blood contamination, or transmission through mucous membranes or nonintact skin. After a needle-stick injury, the chance that the health care worker will become infected with HBV is 6% to 30% (Centers for Disease Control and Prevention, 2013). Vaccination is the most effective method of preventing HBV. All health care workers in Canada are strongly advised to be immunized against HBV. Many health care organizations provide free hepatitis B vaccinations through the occupational health department to their at-risk employees.

Hepatitis C.

Transmission usually results from percutaneous needle exposure or other blood exposure and undetected parenteral transmission. Measures to prevent transmission of the viruses from patients to health care providers are presented in Table 46-10. Of particular concern to the public has been the issue of health care workers infected with bloodborne agents such as

hepatitis virus and HIV. Many Canadian hospitals have committees that advise on the practice modifications needed for infected workers.

TABLE 46-10

MEASURES TO PREVENT TRANSMISSION OF HEPATITIS VIRUSES FROM PATIENTS TO HEALTH CARE PERSONNEL*

HAV	HBV and HCV
• Maintenance of good personal hygiene • Handwashing after contact with a patient or after removal of gloves • Use of infection-control precautions†	• Use of infection-control precautions† • Frequent handwashing and after each patient contact • Avoidance of direct contact with blood or blood-containing secretions • Handling the blood of all patients as potentially infective • Proper disposal of needles • Vaccination against HBV • Using needleless IV access devices when they are available

*To prevent the contraction of viral hepatitis from patients with diagnosed and undiagnosed hepatitis, health care providers should wear disposable gloves, goggles, and gown (sometimes) when fecal or blood contamination is likely in handling (a) soiled bedpans, urinals, and catheters and (b) patient's bed linens soiled by body excreta or secretions.

†See Chapter 17, Table 17-8.

Nonalcoholic Fatty Liver Disease and Nonalcoholic Steatohepatitis

Nonalcoholic fatty liver disease (NAFLD) refers to a spectrum of disease that ranges from simple fatty liver that causes no hepatic inflammation (steatosis) to **nonalcoholic steatohepatitis (NASH)** to severe liver scarring (cirrhosis). This spectrum of liver disease occurs in people who drink little or no alcohol and is characterized by the accumulation of fat in liver cells. In the case of NASH, this fat buildup causes inflammation and liver cell injury.

NASH is diagnosed histologically by evidence of liver cell ballooning and presence of Mallory bodies. NASH can progress and cause cirrhosis, which can lead to liver cancer and liver failure. When the liver fails, liver transplantation is the only treatment alternative.

Causes

NAFLD is a growing concern around the globe (Mahady & George, 2016). The most common cause of fatty liver disease is obesity. According to the *Obesity in Canada* report (Public Health Agency of Canada & Canadian Institute for Health Information, 2011), one in four Canadians is obese. Obesity rates almost doubled among both sexes in most age groups in the adult and youth categories. Obesity is linked to many chronic diseases, and fatty liver disease is one of them. About 75% of obese people are at risk of developing simple fatty liver, and, of those, up to 25% are at risk of developing fatty liver with inflammation (i.e., NASH).

NAFLD also occurs in patients with metabolic syndrome.

Clinical Manifestations and Diagnostic Studies

Most patients with NAFLD have no symptoms. NAFLD is usually diagnosed during routine medical checkup or during evaluation of other health problems such as hypertension, diabetes, or obesity. Elevations in liver enzyme levels (ALT, AST) are often the first signs of NAFLD. However, such elevations may be associated with other liver disorders. Symptoms, if present, are nonspecific and may include fatigue, malaise, and vague pain in the right upper abdominal quadrant. Enlarged liver (hepatomegaly) and enlarged spleen (splenomegaly) may be detected on first examination of the patient. Only a small number of patients exhibit signs of serious liver disease (e.g., ascites, anasarca, variceal hemorrhage). Jaundice occurs late in NASH and indicates advanced liver disease. As the disease progresses, serum albumin level decreases and serum bilirubin level and prothrombin time increase.

Definitive diagnosis is by liver biopsy. Ultrasonography and computed tomography (CT) are also used to diagnose NAFLD.

Collaborative Care

Patients with NAFLD who are older, are obese, or have diabetes are at risk for advanced liver disease. Currently, there is no definitive treatment available. Therapy is directed at reduction of risk factors, including treatment of diabetes, reduction in body weight, and elimination of harmful medications. No specific dietary therapy is recommended; however, a heart-healthy diet is appropriate. Lifestyle counselling interventions that focused on physical activities and eating behaviours have enabled significant improvement in liver function test results.

Health promotion and patient education are important in preventing the development of NAFLD. Ways to prevent fatty liver include maintaining a

healthy body mass index (≤25), avoiding increased abdominal fat (for men, keeping waist circumference <102 cm; for women, <88 cm), eating a heart-healthy diet, exercising at least three times weekly, limiting alcohol to no more than two drinks at a time, taking only medications that are needed, and following physicians' recommendations.

Alcohol and Drug-Induced Hepatitis

Alcohol Hepatitis

Alcohol consumption, frequently the cause of acute or chronic liver disease, can produce a spectrum of symptoms, ranging from mild elevation in liver enzymes (AST and ALT) to acute alcoholic hepatitis to advanced fibrosis and cirrhosis, which usually occur after decades of excessive alcohol intake. Patients may have serious liver disease caused by another chronic disease (e.g., chronic HCV infection) in combination with alcoholic liver disease.

Acute alcoholic hepatitis is a syndrome of hepatomegaly, jaundice, elevation in liver enzyme tests (AST, ALT, alkaline phosphate), low-grade fever, and possibly ascites and prolonged prothrombin time. These symptoms may improve with cessation of alcohol intake.

Patients may have undetected liver disease and be seen with complications of cirrhosis. Even at this stage, abstinence can result in significant reversal in some patients. If liver function does not recover after abstaining from alcohol for several months or longer, liver transplantation may be considered.

Drug-Induced Liver Injury (DILI)

Drug-induced liver injury (DILI) is one of the more common causes of jaundice. Many medications (prescription, over-the-counter [OTC], and herbal supplements) can cause an increase in liver enzymes and, in severe cases, jaundice and acute liver failure (Chalasani, Hayashi, Bonkovsky, et al., 2014). The pattern of injury depends on the drug causing the reaction. The most common cause of DILI is acetaminophen.

Drug Alert

Acetaminophen (Tylenol)

- Drug is safe if taken at recommended levels and not combined with alcohol. It is also present in a variety of pain relievers, fever reducers, and cough medicines as a somewhat "hidden" ingredient; thus patients taking several drugs may not realize that they are taking a higher amount of acetaminophen.
