Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

About the Authors

Sharon L. Lewis, RN, PhD, FAAN

Sharon Lewis received her Bachelor of Science in nursing from the University of Wisconsin–Madison, Master of Science in nursing with a minor in biological sciences from the University of Colorado–Denver, and PhD in immunology from the Department of Pathology at the University of New Mexico School of Medicine. She had a 2-year postdoctoral fellowship from the National Kidney Foundation. Her more than 45 years of teaching experience include inservice education and teaching in associate degree, baccalaureate, master's degree, and doctoral programs in Maryland, Illinois, Wisconsin, New Mexico, and Texas. Favourite teaching areas are pathophysiology, immunology, and family caregiving. She has been actively involved in clinical research for the past 35 years, investigating altered immune responses in various disorders and developing a stress management program for family caregivers. Her current primary professional responsibility is disseminating the Stress-Busting for Family Caregivers Program that she developed. Her free time is spent biking, landscaping, gardening, and being a grandmother.

Linda Bucher, RN, PhD, CEN, CNE

Linda Bucher is an Emerita Professor in the School of Nursing at the University of Delaware in Newark, Delaware. She received her Bachelor of Science in nursing from Thomas Jefferson University in Philadelphia, her Master of Science in adult health and illness from the University of Pennsylvania in Philadelphia, and her doctorate in nursing from Widener University in Chester, Pennsylvania. Her 40 years of nursing experience have spanned staff and patient education, acute and critical care nursing, and teaching in associate, baccalaureate, and graduate nursing programs in New Jersey, Pennsylvania, and Delaware. Her preferred teaching areas include emergency and cardiac nursing and evidence-based practice. She maintains her clinical practice by working as an emergency nurse, actively participates in the American Association of Critical Care Nurses, and volunteers as a postoperative nurse for Operation Smile. In her free time, she enjoys traveling and skiing with her family.

Margaret McLean Heitkemper, RN, PhD, FAAN

Margaret Heitkemper is Professor and Chairperson, Department of Biobehavioral Nursing and Health Systems at the School of Nursing, and Adjunct Professor, Division of Gastroenterology at the School of Medicine at the University of Washington. She is also Director of the National Institutes of Health-National Institute for Nursing Research–funded Center for Research on Management of Sleep Disturbances at the University of Washington. In the fall of 2006, Dr. Heitkemper was appointed the Elizabeth Sterling Soule Endowed Chair in Nursing. Dr. Heitkemper received her Bachelor of Science in nursing from Seattle University, a Master of Nursing in gerontologic nursing from the University of Washington, and a doctorate in Physiology and Biophysics from the University of Illinois–Chicago. She has been on faculty at the University of Washington since 1981 and has been the recipient of three School of Nursing Excellence in Teaching awards and the University of Washington Distinguished Teaching Award. In addition, in 2002 she received the Distinguished Nutrition Support Nurse Award from the American Society for Parenteral and Enteral Nutrition (ASPEN), in 2003 the American Gastroenterological Association and Janssen Award for Clinical Research in Gastroenterology, and in 2005 she was the first recipient of the Pfizer and Friends of the National Institutes for Nursing Research Award for Research in Women's Health.

Mariann M. Harding, RN, PhD, CNE

Mariann Harding is an Associate Professor of Nursing at Kent State University Tuscarawas, New Philadelphia, Ohio, where she has been on the faculty since 2005. She received her diploma in nursing from Mt. Carmel School of Nursing in Columbus, Ohio, her Bachelor of Science in nursing from Ohio University in Athens, Ohio, her Master of Science in Nursing as an adult nurse practitioner from the Catholic University of America in Washington D.C., and her doctorate in nursing from West Virginia University in Morgantown, West Virginia. Her 29 years of nursing experience has primarily been in critical care nursing, and teaching in licensed practical, associate, and baccalaureate nursing programs. She currently teaches medical-surgical nursing, health care policy, and evidence-based practice. Her research has focused on promoting student success and health promotion among individuals with gout and facing cancer. Free time is spent with her family or travelling, walking, and reading.

Maureen A. Barry, RN, MScN

Maureen A. Barry is an Associate Professor, Teaching Stream, and Director, Undergraduate Program at the Lawrence S. Bloomberg Faculty of Nursing at the University of Toronto. She received her Bachelor of Science in Nursing from the University of Windsor and her Master of Science in Nursing from the University of Toronto. She has been involved in nursing education for over twenty-five years and has taught in Nova Scotia, Quebec, and Ontario. Her clinical background is adult medicine and surgery and critical care. She has extensive experience in global health, having worked for 5 years in clinics in rural Kenya and Ethiopia and taught medical English in China. More recently, she has done volunteer work while on sabbatical in Zimbabwe, South Africa, and Uganda. She currently teaches medical–surgical nursing and persistent illness. She has won the Teaching Innovation Award from the Council of Ontario University Programs in Nursing (COUPN) as well as multiple teaching awards from the University of Toronto. Her primary areas of interest and expertise are clinical education, simulation, online learning and technology in nursing education, test theory and development, and global health issues.

Jana Lok, RN, MN, PhD, ENC(C)

Jana Lok is an Assistant Professor, Teaching Stream, for the undergraduate program at the Lawrence S. Bloomberg Faculty of Nursing at the University of Toronto. She completed her undergraduate and graduate nursing degrees at the University of Toronto. Her clinical background is in emergency and trauma nursing, as well as pre-hospital emergency care. She holds a national CNA credential in Emergency Nursing. Dr. Lok has been involved in nursing education for nearly 15 years. She has spent almost 20 years of service with the Canadian Armed Forces (CAF) as both a Medic and Nursing Officer. She has overseen the training of CAF medical service personnel who have served on national and international operations. She received the Canadian Forces Decoration and Queen's Golden Jubilee Medal in recognition for her exemplary military service. She currently teaches pathophysiology and persistent illness and is part of the simulation team for the Faculty of Nursing undergraduate program. Her areas of interest and expertise include emergency and trauma nursing, emergency preparedness and disaster management, complementary therapies, clinical teaching and simulation.

Jane Tyerman, RN, MScN, PhD

Jane Tyerman is a nursing professor at the Trent/Fleming School of Nursing in Peterborough, Ontario. She has over 25 years of experience in acute care clinical practice and 15 years academic BScN teaching experience. She received her Bachelor of Arts from the University of Ottawa, Bachelor of Nursing from Athabasca University, and her Master of Science and PhD from Queen's University. She is an Advanced Cardiac Life Support (ACLS) and Pediatric Advanced Life Support (PALS) instructor with the Canadian Heart and Stroke Foundation. She is a Canadian Hesi Live Review Educator, in which capacity she delivers onsite personalized courses to further prepare new graduate nurses for their NCLEX board examination. Dr. Tyerman has been nominated for and received many awards for her teaching innovation and excellence. Her research and publications focus on nursing simulation design, development, curriculum implementation, and virtual simulation using serious games. She is currently the co-president of the Ontario Simulation Alliance (OSA) and the national Canadian Alliance of Nurse educators using Simulation (CAN-Sim). Other research interests include neurofeedback, the impact of shiftwork on nurses' mental health, and psychiatric nursing care practices of acute care nurses.

Sandra Goldsworthy, RN, MSc, PhD, CNCC(C), CMSN(C)

Sandra Goldsworthy is a recognized critical care expert, having worked in this field for more than 25 years. Dr. Goldsworthy received her Honours Bachelor of Science in Nursing from Lakehead University, her Masters of Science (Nursing) from Queen's University, and her doctorate in Nursing from the University of British Columbia. As an Associate Professor in the Faculty of Nursing at the University of Calgary, with a Research Professorship in Simulation Education, she is also an accomplished practitioner, researcher and author. Dr. Goldsworthy holds two national CNA credentials in Critical Care and Medical Surgical Nursing. Her research focus is simulation and transfer of learning, job readiness and transition of new graduates. She has conducted and published research involving the use of simulation and technology in nursing education. Her recent publications and national and international presentations have concentrated on critical care and technology in nursing. Dr. Goldsworthy has eight texts to her credit including all four editions of *Medical-Surgical Nursing in Canada, Simulation Simplified: A Practical Guide for Nurse Educators,* and *Arrhythmia and 12-Lead EKG Interpretation.*

Section Editors for the US 10th Edition

Jeffrey Kwong, DNP, MPH, ANP-BC, FAANP

Jeffrey Kwong is an Assistant Professor of Nursing at Columbia University School of Nursing where he also serves as Director of the Adult-Gerontology Primary Care Nurse Practitioner Program. He has worked in the area of adult primary care with a special focus on HIV for over 20 years. He received his undergraduate degree from the University of California–Berkeley, his nurse practitioner degree from the University of California–San Francisco, and completed his doctoral training at the University of Colorado–Denver. He also has a Master's Degree in Public Health with a focus on Health Education and Behavioral Sciences from the University of Califorina–Los Angeles and was appointed a Hartford Geriatric Interprofessional Scholar while completing his gerontology education at NYU. In addition to teaching, Dr. Kwong maintains a clinical practice at Gotham Medical Group in New York City. In 2015 he was inducted as a Fellow in the American Association of Nurse Practitioners.

Dottie Roberts, RN, EdD, MSN, MACI, RN, OCNS-C, CMSRN, CNE

Dottie Roberts received her Bachelor of Science in nursing from Beth-El College of Nursing, Colorado Springs, Colorado, Master of Science in adult health nursing from Beth-El College of Nursing and Health Sciences, Master of Arts in curriculum and instruction from Colorado Christian University, Colorado Springs, Colorado, and EdD in healthcare education from Nova Southeastern University, Ft. Lauderdale, Florida. She has over 25 years of experience in medical-surgical and orthopaedic nursing, and holds certifications in both specialties. She has also taught in two baccalaureate programs in the Southeast and is certified as a nurse educator. For her dissertation, Dottie completed a phenomenological study on facilitation of critical-thinking skills by clinical faculty in a baccalaureate nursing program. She has been Executive Director of the Orthopaedic Nurses

Certification Board since 2005 and editor of "*MEDSURG Nursing*," official journal of the Academy of Medical-Surgical Nurses, since 2003. Her free time is spent travelling, reading, and cross-stitching.

To the Profession of Nursing and to the Important People in Our Lives

Sharon

My husband Peter and our grandchildren Malia, Halle, Aidan, Cian, Layla, Ryker, and Archer

Linda

My nieces, Stefany and Jayme, who so admirably reflect the ideals of the nursing profession and my godchild, Liz, for her love of written words.

Margaret

My husband David, our daughters Elizabeth and Ellen, and our grandsons Jaxon James and Axel

Mariann

My husband Jeff and our daughters Kate and Sarah

Maureen

My students past, present, and future.

Jana

To Shannon, who inspired me to become a nurse, and my family, colleagues and friends for your ongoing love and support.

Jane

My husband Glenn, our children Kaitlyn, Kelsey, and Aiden, my mother Jessica.

Sandra

My husband Brian and our three sons Ryan, Matthew, and Kent for always being there for me.

Preface

The Fourth Canadian Edition of *Medical-Surgical Nursing in Canada: Assessment and Management of Clinical Problems* has been thoroughly revised for the Canadian student and incorporates the most current medical-surgical nursing information presented in an easy-to-use format. More than just a textbook, this is a comprehensive resource set in the Canadian context, containing essential information that nursing students need to prepare for lectures, classroom activities, examinations, clinical assignments, and the safe, comprehensive care of patients. In addition to the readable writing style and full-colour illustrations, the text and accompanying resources include many special features to help students learn key medical-surgical nursing content, such as sections that highlight the determinants of health, patient and caregiver teaching, age-related considerations, collaborative care, cultural considerations, nutrition, home care, evidence-informed practice, patient safety, and much more.

The comprehensive content, special features, attractive layout, and student-friendly writing style combine to make this the number one medical-surgical nursing textbook, used in more nursing schools in Canada than any other medical-surgical nursing textbook.

The latest edition of *Medical-Surgical Nursing in Canada* retains the strengths of the first three editions, including the use of the nursing process as an organizational theme for nursing management. New features have been added to address some of the rapid changes in practice, and many diagrams and photos are new or improved. The content has been updated using the most recent important research and newest practice guidelines by Canadian contributors selected for their acknowledged excellence in specific content areas, ensuring a continuous thread of evidence-informed practice throughout the text. Specialists in the subject area have reviewed each chapter to ensure accuracy, and the editors have undertaken final rewriting and editing to achieve internal consistency. In other words, all efforts

have been made to build on the recognized strengths of the previous Canadian editions.

Organization

The content of this book is organized in two major divisions. The first division, Section 1 (Chapters 1 through 13), discusses concepts related to adult patients. The second division, Sections 2 through 12 (Chapters 14 through 72), presents nursing assessment and nursing management of medical-surgical problems.

The various body systems are grouped in such a way as to reflect their interrelated functions. Each section is organized around two central themes: assessment and management. Each chapter that deals with the assessment of a body system includes a discussion of the following:

1. A brief review of anatomy and physiology, focusing on information that will promote understanding of nursing care
2. Health history and noninvasive physical assessment skills to expand the knowledge base on which decisions are made
3. Common diagnostic studies, expected results, and related nursing responsibilities to provide easily accessible information

Management chapters focus on the pathophysiology, clinical manifestations, laboratory and diagnostic study results, collaborative care, and nursing management of various diseases and disorders. Nursing management sections are organized into assessment, nursing diagnoses, planning, implementation, and evaluation sections, following the steps of the nursing process. To emphasize the importance of patient care in various clinical settings, nursing implementation of all major health problems is organized by the following levels of care:

1. Health promotion
2. Acute intervention
3. Ambulatory and home care

Classic Features

- **Canadian context.** Once again, we are pleased to offer you a book that reflects the wide range of expertise of nurses from across Canada. In an effort to better reflect the nursing environments across the country, all chapters have been revised with enhanced Canadian research and statistics. SI units and metric measurements are used throughout the text, and the updated APA format, including digital object identifiers (DOIs), is used for the references.
- **Most recent research and clinical guidelines**. Every effort has been made to use the most recent research, statistics, and clinical guidelines available. References older than 5 years at the time of writing are included because they were seminal studies, or remain the most recent, authoritative source. Those references are marked "Seminal" in the References list.
- **Nursing management** is presented in a consistent and comprehensive format, with headings for Health Promotion, Acute Intervention, and Ambulatory and Home Care. In addition, over 60 customizable **Nursing Care Plans** on the Evolve website and in the text help students to understand possible nursing

diagnoses, goals and nursing interventions for each condition.

- **Collaborative care** is highlighted in special Collaborative Care sections in each of the management chapters and in Collaborative Care tables throughout the text.
- **Patient and caregiver teaching** is an ongoing theme throughout the text. Chapter 4: *Patient and Caregiver Teaching* and numerous **Patient & Caregiver Teaching Guides** throughout the text emphasize the increasing importance and prevalence of patient management of chronic illnesses and conditions and the role of the caregiver in patient care.
- **Culturally competent care** is treated in Chapter 2, *Cultural Competence and Health Equity in Nursing Care,* which discusses the necessity for culturally competent nursing care; culture as a determinant of health, with particular reference to Indigenous populations; health equity and health equality issues as they relate to marginalized groups in Canada; and practical suggestions for developing cultural competence in nursing care.
- **Coverage of prioritization** includes:
    - Prioritization questions in case studies and Review Questions

    - Nursing diagnoses and interventions throughout the text listed in order of priority

- **Focused Assessment boxes** in all assessment chapters provide brief checklists that help students do a more practical "assessment on the run" or bedside approach to assessment.
- **Safety Alerts** highlight important safety issues in relation to patient care as they arise.
- **Pathophysiology Maps** outline complex concepts related to diseases in flowchart format, making them easier to understand.
- **Community-based nursing and home care** are also emphasized in this Fourth Canadian Edition. Chapter 6 contains a comprehensive discussion, which is continued throughout the text.
- **Determinants of Health boxes** focus on the determinants of health as outlined by Health Canada and the Public Health Agency of Canada, as they affect a particular disorder. The determinants are introduced and discussed in detail in Chapter 1, and then returned to throughout the text by way of Determinants of Health boxes, which have been extensively updated and revised for the new edition. Each box identifies a health issue specific to the chapter, lists the relevant determinants affecting

the issue, supported by the most recent research, and includes references for further investigation.
- **Extensive drug therapy content** includes Drug Therapy tables and concise new **Drug Alerts** highlighting important safety considerations for key drugs.
- **Chronic illness,** which has become Canada's most pressing health care challenge, is discussed in depth in Chapter 5. Nurses are increasingly called on to be active and engaged partners in assisting patients with chronic conditions to live well; this chapter places chronic illness within the larger context of Canadian society.
- **Older adults** are covered in detail in Chapter 7, and are discussed throughout the text under the headings "Age-Related Considerations," and also in **Age-Related Differences in Assessment tables**.
- **Nutrition** is highlighted throughout the book, particularly in Chapter 42, *Nutritional Problems*, and in **Nutritional Therapy tables** throughout that summarize nutritional interventions and promote healthy lifestyles for patients with various health problems. Chapter 43, *Obesity*, looks in depth at this major factor contributing to so many other pathologies.
- **Complementary and alternative therapies** are discussed in Chapter 12, which addresses timely

issues in today's health care settings related to these therapies, and in Complementary & Alternative Therapies boxes where relevant throughout the rest of the book that summarize what nurses need to know about therapies such as herbal remedies, acupuncture, and biofeedback, etc.

- **Sleep and sleep disorders** are explored in Chapter 9; they are key topics that impact multiple disorders and body systems, as well as nearly every aspect of daily functioning.
- **Genetics in Clinical Practice boxes** build on the foundation of Chapter 15, and highlight genetic screening and testing, as well as the clinical implications of key genetic disorders that affect adults, as rapid advances in the field of genetics continue to change the way nurses practise.
- **Ethical Dilemmas boxes** promote critical thinking with regard to timely and sensitive issues that nursing students deal with in clinical practice such as informed consent, treatment decision making, advance directives, and confidentiality.
- **Emergency Management tables** outline the emergency treatment of health problems that are most likely to require rapid intervention.

- **Assessment Abnormalities tables** in the assessment chapters alert the nursing student to abnormalities frequently encountered in practice, as well as their possible etiologies.
- **Nursing Assessment tables** summarize important subjective and objective data related to common diseases, with a sharper focus on issues most relevant to the body system under review. This focus provides for more rapid identification of salient assessment parameters and more effective use of student time.
- **Health History tables** in assessment chapters present relevant questions related to a specific disease or disorder that will be asked in patient interviews.
- **Student-friendly pedagogy:**
    - **Learning Objectives** at the beginning of each chapter help students identify the key content for a specific body system or disorder.
    - **Key Terms** lists provide a list of the chapter's most important terms and where they are discussed in the chapter. A comprehensive key terms **Glossary** with definitions may be found at the end of the book.
    - **Electronic Resources** sections at the start of each chapter draw students' attention

to the wealth of supplemental content and exercises provided on the Evolve website, making it easier than ever for them to integrate the textbook content with media supplements such as animations, video and audio clips, interactive case studies, and much more.

- **Case Studies** with photos bring patients to life. Management chapters have case studies at the end of the chapters that help students learn how to prioritize care and manage patients in the clinical setting. Unfolding case studies are included in each assessment chapter. Discussion questions that focus on prioritization and evidence-informed practice are included in most case studies. Answer guidelines are provided on the Evolve website.
- **Review Questions** at the end of the chapter correspond to the Learning Objectives at the beginning, and thus help reinforce the important points in the chapter. Answers are provided on the same page, making the Review Questions a convenient self-study tool.
- **Resources** at the end of each chapter contain links to nursing and health care

organizations and tools that provide patient teaching and information on diseases and disorders.

New Features

In addition to the classic strengths of this text, we are pleased to include several exciting new features:

- *New* **Unfolding assessment case** studies in every assessment chapter are an engaging tool to help students apply nursing concepts in real-life patient care. Appearing in three or four parts throughout the chapter, they introduce a patient, and then follow that patient through subjective and objective assessment to diagnostic studies and results, and include additional discussion questions to facilitate critical thinking.
- *New* **Expanded evidence-informed practice content** includes new *Translating Research into Practice* boxes that challenge students to develop critical thinking skills and apply the best available evidence to patient care scenarios; updated *Research Highlight* boxes that explore recent research in greater depth; and evidence-informed practice questions in many case studies.
- *New* **Informatics boxes** throughout the text reflect the current use and importance of technology, and touch on everything from the proper handling of social media in the context of patient privacy, to teaching patients to manage

self-care using smartphone apps, to using smart infusion pumps.
• *New* **Drug Alerts** concisely highlight important safety considerations for key drugs.
• **Safety Alerts** have been expanded throughout the book to cover surveillance for high-risk situations.
• *New* **art** enhances the book's visual appeal and lends a more contemporary look throughout.
• *Revised* **Chapter 1**: ***Introduction to Medical-Surgical Nursing Practice in Canada*** situates nursing practice within the unique societal contexts that continue to shape the profession of nursing in Canada. Patient-centred care, interprofessional practice and information-communication technologies are forces that have an impact on and are affected by nurses. This chapter has a new section on patient safety and quality improvement. The teamwork and interprofessional collaboration content has also been expanded to include delegation and assignment.
• **Revised** **Chapter 15**: ***Genetics*** has been substantially expanded to include current changes in Canadian clinical practice, such as the use of Non-Invasive Prenatal Testing (NIPT) for the detection of genetic disorders in the developing fetus; as well as promising

advancements in gene therapy strategies, such as the advent of a genome editing technology, CRISPR-Cas9.

A Word on Terminology

As a result of the Truth and Reconciliation Commission (TRC) recommendations, we have used the term “Indigenous peoples” when referring to First Nations, Inuit, and Métis populations in Canada as a whole. The term “Aboriginal” is no longer used as it does not recognize the inherent rights or treaty rights of the various groups.

A Word on Laboratory Values

SI units are used for the laboratory values cited throughout the textbook. **Appendix B: *Laboratory Values*** lists SI units first, followed by U.S. conventional units in parentheses in all relevant instances. It is important to note that reference ranges for laboratory values may vary among laboratories, depending on the testing techniques used. If discrepancies should exist between the body of the text and Appendix B, the appendix should be considered the final authority.

Learning Supplements for the Student

- The handy **Clinical Companion** presents approximately 200 common medical–surgical conditions and procedures in a concise, alphabetical format for quick clinical reference. Designed for portability, this popular reference includes the essential, need-to-know information for treatments and procedures for which nurses play a major role. An attractive and functional four-colour design highlights key information for quick, easy reference. This edition features a strong focus on treatments and procedures in which the nurse plays a major role.
- **Evolve Student Resources** are available online at http://evolve.elsevier.com/Canada/Lewis/medsurg and include the following valuable learning aids that are organized by chapter:
    - 45 Interactive **Student Case Studies** with state-of-the-art animations and a variety of learning activities that provide students with immediate feedback
    - Printable **Key Points** summaries for each chapter
    - 560+ **Review Questions**

- **Answer guidelines** to the case studies in the textbook
- 60+ Customizable **Nursing Care Plans**
- **Conceptual Care Map Creator** and **Conceptual Care Maps** for selected case studies in the textbook
- **New "Managing Multiple Patients" case studies and answers for RN** present scenarios with multiple patients requiring care simultaneously to develop prioritization and delegation skills
- Fluids and Electrolytes **Tutorial**
- **Audio glossary** of key terms, available as a comprehensive alphabetical glossary
- Supporting **animations** and **audio** for selected chapters

- **Virtual Clinical Excursions (VCE)** is an exciting learning tool that brings learning to life in a "virtual" hospital setting. VCE simulates a realistic, yet safe, nursing environment where the routine and rigours of the average clinical rotation abound. Students can conduct a complete assessment of a patient and set priorities for care, collect data, analyze and interpret data, prepare and administer medications, and reach conclusions about complex problems. Each lesson has a textbook reading assignment and online activities based on

“visiting” patients in the hospital. Instructors receive an Implementation Manual with directions for using VCE as a teaching tool.
• More than just words on a screen, **Elsevier eBooks** come with a wealth of built-in study tools and interactive functionality to help students better connect with the course material and their instructors. Plus, with the ability to fit an entire library of books on one portable device, students can study when, where, and how they want.

Teaching Supplements for Instructors

- **Evolve Instructor Resources** (available online at http://evolve.elsevier.com/Canada/Lewis/medsurg) remain the most comprehensive set of instructor's materials available, containing the following:
    - **TEACH for Nurses Lesson Plans** with electronic resources organized by chapter to help instructors develop and manage the course curriculum. This exciting resource includes the following:
        - Objectives
        - Teaching focus
        - Key terms
        - Student and instructor chapter resource listings
        - Detailed chapter outlines
        - Teaching strategies with learning activities and assessment methods tied to learning outcomes
        - Case studies with answer guidelines
    - The **Test Bank** features over 1500 examination test questions with text page

references and answers coded for nursing process and cognitive level. The ExamView software allows instructors to create new tests; edit, add, and delete test questions; sort questions by category, cognitive level, difficulty, and question type; and administer and grade online tests.

- The **Image Collection** contains more than 800 full-colour images from the text for use in lectures.
- An extensive collection of **PowerPoint Presentations** includes presentations focused on the most common diseases and disorders. The presentations have been thoroughly revised to include helpful instructor notes/teaching tips, new illustrations and photos, and new animations.

- **Course management system**
- Access to all student resources listed above
- The **Simulation Learning System** (SLS) is an online toolkit that helps instructors and facilitators effectively incorporate medium- to high-fidelity simulation into their nursing curriculum. Detailed patient scenarios promote and enhance the clinical decision-making skills of students at all levels. The SLS provides detailed

instructions for preparation and implementation of the simulation experience, debriefing questions that encourage critical thinking, and learning resources to reinforce student comprehension. Each scenario in the SLS complements the textbook content and helps bridge the gap between lecture and clinical. The SLS provides the perfect environment for students to practise what they are learning in the text for a true-to-life, hands-on learning experience.

Acknowledgements

The editors are grateful to the entire editorial team at Elsevier for their leadership and dedication in the preparation of this very comprehensive, but much needed, Canadian medical-surgical textbook. In particular, we wish to thank Acquisitions Editor, Roberta A. Spinosa-Millman, for her invaluable assistance, and Dawn Slawecki for her professionalism, sense of humour, patience, and graciousness despite pressing deadlines and for her commitment to the Canadian Lewis project from first to fourth edition. We would also like to thank Sarah Ibrahim for her help with the Lab Values appendix.

We would like to recognize the commitment and expertise of all the authors, representing diverse areas of practice and regions of Canada. It has been a genuine pleasure to work with both the first-time and returning authors on this project. We are also very grateful to the many reviewers for their valuable feedback on earlier versions of this textbook. It takes a large and coordinated team to create a textbook such as this, and we thank everyone for their individual contributions. We are proud to be able to provide a medical-surgical nursing textbook written from a Canadian perspective that provides current and accurate information to enrich the learning of our nursing students.

SECTION 1

Concepts in Nursing Practice

OUTLINE

Introduction

CHAPTER 1

Introduction to Medical-Surgical Nursing Practice in Canada

Written by, Mariann M. Harding

Adapted by, Maureen Barry

LEARNING OBJECTIVES

1. Describe key challenges facing the current Canadian health care system.
2. Describe the practice of professional nursing in relation to the health care team.
3. Explain how teamwork and interprofessional collaboration contribute to high-quality patient outcomes.
4. Discuss the role of integrating patient-centred care and safety and quality improvement processes into nursing practice.
5. Evaluate the role of informatics and technology in nursing practice.
6. Describe the key attributes of the practice of medical-surgical nursing.
7. Apply concepts of evidence-informed practice to nursing practice.
8. Describe the role of critical thinking and clinical reasoning skills and use of the nursing process to provide patient-centred care.

KEY TERMS

advanced nursing practice, p. 7
assessment, p. 13
clinical (critical) pathway, p. 16
collaborative problems, p. 15

The Canadian Health Care Context

Health care is a subject of keen interest to the public. Repeatedly in public opinion polls, public health care has ranked as the most important public policy issue for Canadians (Canadian Federation of Nurses Unions [CFNU], 2015). In Canada, everyone has access to health care through a government-funded universal program, the costs of which are shared by the federal and the provincial/territorial governments. *The Canada Health Act* mandates that all provinces and territories provide coverage for medically necessary procedures. These include most services provided in hospitals and by family doctors. The level of health care funding from the federal government to the provinces and territories depends on the economic health of the country.

In 2003, the first ministers agreed to a 10-year Accord on Health Care Renewal. The Accord committed federal and provincial/territorial governments to work toward targeted reforms to improve access, quality, and long-term sustainability of the Canadian health care system (Health Canada, 2012). This accord expired in 2014. A new multiple-year health accord with a long-term funding agreement is in the process of being renegotiated between the federal and provincial/territorial governments with many changes expected to result in the way health care is delivered in Canada (Philpott, 2016). There is widespread agreement that the health care system has not kept pace with the changing needs of Canadians. According to the Minister of Health Mandate letter, the new accord is directed to support action in the areas of long-term funding, home care, innovation in digital technology, affordable access to prescription drugs, public health, and access to mental health services (Trudeau, 2015).

In September 2012, the Canadian Nurses Association (CNA) published a report titled *A Nursing Call to Action: The Health of Our Nation, the Future of Our Health System.* This report was written by an independent National Expert Commission established by CNA with leaders from disciplines such business, academia, economics, nursing, health care policy, medicine, and law. The report made recommendations to put individuals, families, and communities first in health care, with a renewed focus on quality care in both community and institutional settings. The findings of this commission, as well as other initiatives designed to re-engineer our health care system, will have a lasting effect on how nurses practise within the Canadian context.

The Canadian health care system continues to deal with major challenges, including concerns about patient safety, service delivery, fiscal constraints, age-related demographics, and the high cost of new technology and drugs. The Romanow report (Commission on the Future of Health Care in Canada, 2002), the Standing Committee on Social Affairs, Science and Technology (2002), the Mazankowski report (Premier's Advisory Council on Health for Alberta, 2001), the Commission on Medicare (Fyke, 2001), and Dagnone (2009) all emphasized the need to accelerate changes within the health care system to ensure sustainability of the system and promote the patient-centred approach desired by the public.

Together with the Canadian Medical Association, the CNA has defined a set of key principles designed to guide health care transformation in Canada. These principles are listed in Table 1-1 and are important considerations for all nurses because they will shape the re-engineered health care system of the future.

TABLE 1-1

PRINCIPLES TO GUIDE HEALTH CARE TRANSFORMATION IN CANADA

- *Patient-centred:* Patients must be at the centre of health care, with seamless access to the continuum of care on the basis of their needs.
- *Quality:* Canadians deserve quality services that are appropriate for patient needs, are respectful of individual choice, and are delivered in a manner that is timely, safe, effective, and according to the most currently available scientific knowledge.
- *Health promotion and illness prevention:* The health system must support Canadians in the prevention of illness and the enhancement of their well-being, with attention paid to broader social determinants of health.
- *Equitable:* The health care system has a duty to Canadians to provide and advocate for equitable access to quality care and commonly adopted policies to address the social determinants of health.
- *Sustainable:* Sustainable health care requires universal access to quality health services that are adequately resourced and delivered across the board in a timely and cost-effective manner.
- *Accountable:* The public, patients, families, providers, and funders all have a responsibility for ensuring that the system is effective and accountable.

Complex Health Care Environments

Nurses practise in virtually all health care settings and communities across the country. They are the frontline providers of health care (Figure 1-1). Rapidly changing technology and dramatically expanding knowledge are adding to the complexity of health care environments. Advanced

communication technologies have created a more global environment that affects the delivery of health care worldwide. The number and complexity of advances in patient care technology are transforming how care is delivered. The Human Genome Project and advances in genetics affect the prevention, diagnosis, and treatment of health problems. With advances in knowledge, ethical dilemmas and controversy arise with regard to the use of new scientific knowledge and the disparities that exist in patients' access to more technologically advanced health care. Throughout this book, expanding knowledge and technology's effect on nursing practice are highlighted in “Genetics in Clinical Practice,” “Informatics in Practice,” and “Ethical Dilemmas” boxes.

FIGURE 1-1 Nurses are frontline professionals of health care.
Source: Potstock/Shutterstock.com.

Ethical Dilemmas

Social Networking: Confidentiality and Privacy Violation

Situation

A nursing student logs into a closed group on a social networking site and reads a posting from a fellow nursing student. The posting describes in

detail the complex care the fellow student provided to an older patient in a local hospital the previous day. The fellow student comments on how stressful the day was and asks for advice on how to deal with similar patients in the future.

Ethical/Legal Points for Consideration

- Protecting and maintaining patient privacy and confidentiality are basic obligations defined in the Code of Ethics (CNA, 2017), which nurses and nursing students should uphold.
- Each province and territory has its own legislation to protect a patient's private health information. Some examples include the *Personal Information Protection Act* (PIPA) in British Columbia and the *Access to Information and Protection of Privacy Act* (ATIPPA) in Newfoundland and Labrador. Private health information is any information about the patients' past, present, or future physical or mental health. This includes not only specific details such as a patient's name or picture but also information that gives enough details that someone else may be able to identify that patient.
- A nurse may unintentionally breach privacy or confidentiality by posting patient information (diagnosis, condition, or situation) on a social networking site. Using privacy settings or being in a closed group does not guarantee the secrecy of posted information. Other users can copy and share any post without the poster's knowledge.
- Potential consequences for improperly using social networking vary according to the situation. These may include dismissal from a nursing program, termination of employment, or civil and criminal actions.
- A student nurse who experienced a stressful day and was looking for advice and support from peers could share the experience by clearly limiting the posts to the student's personal perspective (e.g., “Today my patient died. I wanted to cry”) and not sharing any identifying information.

Discussion Questions

- How would you deal with the situation involving the fellow nursing student?

- How would you handle a situation in which you observed a staff member violating the provincial/territorial legislation related to a patient's private health information?

Diverse Populations.

Patient demographics are more diverse than ever. Canadians are living longer, in part because of advances in medical science, technology, and health care delivery. As the population ages, the number of patients with chronic conditions increases. Unlike those who receive acute, episodic care, patients with chronic conditions have a multitude of needs and see a variety of health care providers in various settings over an extended period. Nurses are also caring for a more culturally and ethnically diverse population. Immigrants, particularly undocumented immigrants and refugees, often lack the resources necessary to access health care. Inability to pay for health care, as is often the case with undocumented immigrants, is associated with a tendency to delay seeking care; as a result, illnesses may become more serious.

Determinants of Health.

The **determinants of health** are the factors that influence the health of individuals and groups. Table 1-2 displays the determinants of health recognized by the Public Health Agency of Canada (PHAC, 2013). The primary factors that shape the health of Canadians are not medical treatments or lifestyle choices but rather the living conditions (the economic, social, and political) that they experience (Mikkonen & Raphael, 2010, p. 7; Provincial Health Services Authority, 2011). These determinants can either improve a person's health status or heighten an individual's risk for disease, injury, and illness. The challenges or advantages may be specific to the individual, or they may be structural and include factors such as income and social status; social support networks; education; employment/working conditions; social environments; physical environments; personal health practices and coping skills; healthy child development; biology and genetic endowment; gender; and culture (PHAC, 2013). Table 1-2 displays the determinants of health recognized by PHAC. Because these factors or determinants intersect with each other, the overall effect can be one of multiple exclusions that are beyond individual control and that lead to compounded adverse effects on health and well-being.

TABLE 1-2

PUBLIC HEALTH AGENCY OF CANADA: KEY DETERMINANTS OF HEALTH

Determinant of Health	Underlying Premise
Income and social status	Health status improves at each step up the income and social hierarchy. High income determines living conditions such as safe housing and ability to buy sufficient good food. The healthiest populations are those societies that are prosperous and have an equitable distribution of wealth.
Social support networks	Support from families, friends, and communities is associated with better health. Such social support networks could be very important in helping people solve problems and deal with adversity, as well as in maintaining a sense of mastery and control over life circumstances. The caring and respect that occurs in social relationships, and the resulting sense of satisfaction and well-being, seem to act as a buffer against health problems.
Education and literacy	Health status improves with level of education, which is, in turn, tied to socioeconomic status. Education contributes to health and prosperity by equipping people with knowledge and skills for problem solving and helps provide a sense of control and mastery over life circumstances. It increases opportunities for job and income security and job satisfaction. Education also improves people's ability to access and understand information to help keep them healthy.
Employment/working conditions	Unemployment, underemployment, and stressful or unsafe work are associated with poorer health. People who have more control over their work circumstances and fewer stress-related demands of the job are healthier and often live longer than those who have more stressful or riskier types of work and activities.
Social environments	The array of values and norms of a society influences in varying ways the health and well-being of individuals and populations. In addition, social stability, recognition of diversity, safety, good working relationships, and cohesive communities provide a supportive society that reduces or avoids many potential risks to good health. Social or community responses can add resources to an individual's repertoire of strategies to cope with changes and foster health.
Physical environments	The physical environment is an important determinant of health. At certain levels of exposure, contaminants in our air, water, food, and soil can cause a variety of adverse health effects, including cancer, birth defects, respiratory illness, and gastro-intestinal ailments. In the built environment, factors related to housing, indoor air quality, and the design of communities and transportation systems can significantly influence our physical and psychological well-being.
Personal health practices and coping skills	These refer to those actions by which individuals can prevent diseases and promote self-care, cope with challenges, develop self-reliance, solve problems, and make choices that enhance health. These influence lifestyle choice through at least five domains: personal life skills, stress, culture, social relationships and belonging, and a sense of control.
Healthy child development	New evidence on the effects of early experiences on brain development, school readiness, and health in later life has sparked a growing consensus about early child development as a powerful determinant of health in its own right. All of the other determinants of health, in turn, affect the physical, social, mental, emotional, and spiritual development of children and youth.
Biology and genetic endowment	The basic biology and organic makeup of the human body are a fundamental determinant of health. Genetic endowment provides an inherited predisposition to a wide range of individual responses that affect health status. Socioeconomic and environmental factors are important determinants of overall health, but in some circumstances, genetic endowment appears to predispose certain individuals to particular diseases or health problems.
Health services	Health services, particularly those designed to maintain and promote health, to prevent disease, and to restore health and function, contribute to the health of the overall population. The health services continuum of care includes treatment and secondary prevention.

Determinant of Health	Underlying Premise
Gender	Gender refers to the array of society-determined roles, personality traits, attitudes, behaviours, values, and relative power and influence that society ascribes to the two sexes on a differential basis. "Gendered" norms influence the health system's practices and priorities. Many health issues are a function of gender-based social status or roles.
Culture	Some persons or groups may face additional health risks due to a socioeconomic environment, which is largely determined by dominant cultural values that contribute to the perpetuation of conditions such as marginalization, stigmatization, loss or devaluation of language and culture, and lack of access to culturally appropriate health care and services.

Patient-Centred Care

Nurses have long demonstrated that they deliver patient-centred care that is based on each patient's unique needs and on an understanding of the patient's preferences, values, and beliefs. Patient-centred care is interrelated with both quality and safety. A **patient-centred approach** or a person- and family-centred care approach (Registered Nurses' Association of Ontario [RNAO], 2015) focuses on the "*whole person* as a unique individual and not just on their illness or disease" (p. 8). In Canada, numerous provincial initiatives are under way to improve the experience of the person and their family. Many initiatives are partnering with individual users to ensure that the patient (and the patient's family) is the focus of system reform (RNAO, 2015).

Patient Safety and Quality Improvement.

Patient safety is a cornerstone of nursing practice. Entry-to-practice competencies for nursing recognize the importance of the nurse's ability to assess and manage situations that may compromise patient safety (College and Association of Registered Nurses of Alberta, 2013). Although patients turn to the health care system for help with their health conditions, there is overwhelming evidence that significant numbers of patients are harmed as a result of the health care they receive, which results in permanent injury, increased lengths of hospital stay, and even death (World Health Organization, 2011). It is estimated that between 210,000 and 440,000 patients each year suffer some type of harm that contributes to their death because of preventable medical errors (James, 2013).

The 2004 “Canadian Adverse Events Study” confirmed that harmful incidents are a significant problem in Canadian hospitals (Baker, Norton, Flintoft, et al., 2004). A number of organizations such as the Canadian Patient Safety Institute (CPSI) are addressing patient safety issues by providing safety goals for health care organizations and identifying safety competencies for health care providers. Tools and programs in four priority areas—medication safety, surgical care safety, infection prevention and control, and home care safety—are available from the CPSI (2016).

By implementing various procedures and systems to improve health care delivery to meet safety goals, designers of health care systems are working to attain a culture of safety that minimizes the risk of harm to the patient. Because nurses have the greatest amount of interaction with patients, they are a vital part of promoting this culture of safety by providing care in a manner that reduces errors and actively promotes patient safety.

Quality and Safety Education for Nurses (QSEN).

Since 2000, a number of high-profile reports have highlighted problems with the quality of health care. In one of these reports, *The Future of Nursing: Leading Change, Advancing Health,* the Institute of Medicine (2011) acknowledged the link between professional nursing practice and health care delivery. The report described how health care providers, including nurses, are not being adequately prepared to provide the highest quality care possible. Changes are recommended so that nurses will have the skills to advance health care and play leadership roles in a reformed health care system (Institute of Medicine, 2011).

One initiative to address nursing's role in solving these problems is the Quality and Safety Education for Nurses (QSEN) Institute. The QSEN Institute has made a major contribution to nursing by defining specific competencies that nurses need to have to practise safely and effectively in today's complex health care system. Table 1-3 describes each of the QSEN competencies and the knowledge, skills, and attitudes (KSAs) necessary in six key areas: (a) patient-centred care, (b) teamwork and collaboration, (c) quality improvement, (d) safety, (e) informatics and technology, and (f) evidence-based practice (QSEN, 2014). Threaded throughout the remainder of this chapter is a discussion of how professional nursing practice is focusing on acquiring the knowledge, skills, and attitudes for these competencies.

TABLE 1-3

QUALITY AND SAFETY EDUCATION FOR NURSES (QSEN) COMPETENCIES

Competency	Knowledge, Skills, and Attitudes
Patient-Centred Care	
Recognize the patient or designee as the source of control and a full partner in providing compassionate and coordinated care that is based on respect for patient's preferences, values, and needs.	Provide care with sensitivity and respect, taking into consideration the patient's perspectives, beliefs, and cultural background. Assess the patient's level of comfort, and treat appropriately. Engage the patient in an active partnership that promotes health, well-being, and self-care management. Facilitate patient's informed consent for care.
Teamwork and Collaboration	
Function effectively within nursing and interprofessional teams, fostering open communication, mutual respect and shared decision-making to achieve quality patient care.	Value the expertise of each interprofessional member. Initiate referrals when appropriate. Follow communication practices that minimize risks associated with handoffs and transitions in care. Participate in interprofessional rounds.
Safety	
Minimize risk of harm to patients and providers through both system effectiveness and individual performance.	Follow recommendations from national safety campaigns. Appropriately communicate observations or concerns related to hazards and errors. Contribute to designing systems to improve safety.
Quality Improvement	
Use data to monitor the outcomes of care and use improvement methods to design and test changes to continuously improve the quality and safety of health care systems.	Use quality measures to understand performance. Identify gaps between local and best practices. Participate in investigating the circumstances surrounding a sentinel event or serious reportable event.
Informatics	
Use information and technology to communicate, manage knowledge, mitigate error, and support decision making.	Protect confidentiality of patient's protected health information. Document appropriately in electronic health records. Use communication technologies to coordinate patient care. Respond correctly to clinical decision-making alerts.
Evidence-Based or Evidence-Informed Practice	

Competency	Knowledge, Skills, and Attitudes
Integrate best current evidence with clinical expertise and the patient/family preferences and values for delivery of optimal health care.	Read research, clinical practice guidelines, and evidence reports related to area of practice. Base individual patient care plan on patient's values, clinical expertise, and evidence. Continuously improve clinical practice on the basis of new knowledge.

The Profession of Nursing in Canada

Health care in Canada is typically delivered by teams of workers with different responsibilities and scopes of practice. The term **regulated health care providers** refers to paid workers "covered by provincial/territorial and/or federal legislation and governed by a professional organization or regulatory authority" (Canadian Institute for Health Information [CIHI], 2013, p. 22). There are four regulated nursing groups: registered nurses (RNs), nurse practitioners, registered psychiatric nurses, or licensed practical nurses/registered practical nurses (LPN/RPNs; CNA, 2015a). In contrast, **unregulated care providers (UCPs)** or unregulated health workers are paid employees who are not licensed or registered by a regulatory body, who have no legally defined scope of practice, for whom education or practice standards may or may not be mandatory, who provide care under the direct or indirect supervision of a nurse, and who are accountable for their own actions and decisions (CIHI, 2013, p. 22; CNA, 2015a, p. 28). Some of the more common titles for UCPs include "health care aides," "personal support workers," "assistive personnel," "care team assistants," and "nursing aides."

Within Canada, nurses are granted the legal authority to use the designation "Registered Nurse" (RN) in accordance with provincial and territorial legislation and regulation. The provincial regulatory bodies set the standards for practice for RNs to protect the public in their province or territory (CNA, 2015a). RN practice is defined by the CNA (2015a) in the following way:

RNs are self-regulated health-care professionals who work autonomously and in collaboration with others to enable individuals, families, groups,

communities and populations to achieve their optimal levels of health. At all stages of life, in situations of health, illness, injury and disability, RNs deliver direct health-care services, coordinate care and support clients in managing their own health. RNs contribute to the health-care system through their leadership . . . in practice, education, administration, research and policy. (p. 5)

Because RNs work with other regulated providers, as well as with UCPs, they must be aware of both their own and other providers' scopes of practice. This is essential for safely enacting key nursing roles such as delegation and prioritization and for meeting the standards of practice.

Standards of Practice.

A **standard of practice** "sets out the legal and professional basis for nursing practice: describing the desirable and achievable level of performance expected of registered nurses in their practice, against which actual performance can be measured" (College of Registered Nurses of Nova Scotia [CRNNS], 2011, p. 4). Standards are intended to promote, guide, direct, and regulate professional nursing practice (CRNNS, 2011, p. 4). Standards of practice demonstrate to the public, government, and other stakeholders that a profession is dedicated to maintaining public trust and upholding the criteria of its professional practice. Standards of practice are based on the values of the profession and articulated in the Code of Ethics for Registered Nurses (CNA, 2017). Provincial and territorial regulatory bodies for nursing are legally required to set standards for practice for RNs in order to protect the public. These standards, together with the Code of Ethics, form the foundation for nursing practice in Canada.

Because of the rapid changes in resources, expectations, and technologies that characterize health care in Canada, the practice of nursing requires a commitment to lifelong learning in order to promote the highest quality of patient outcomes. **Continuing competence** refers to "the ongoing ability of a nurse to integrate and apply the knowledge, skills, judgement and personal attributes required to practise safely and ethically in a designated role and setting" (CNA/Canadian Association of Schools of Nursing [CASN], 2004).

RNs are initially prepared at the baccalaureate level and can go on to pursue further studies at the graduate level. Many nurses also seek recognition of their clinical expertise through certification in one of the 20 specialty areas of practice through the CNA (2016). Medical-surgical

nursing is one of the newer specialties to be recognized through the certification program.

Advanced Nursing Practice.

As the health care system in Canada undergoes changes, advanced nursing practice (ANP) roles are also evolving to optimize patient care within the system. According to the CNA (2008, p. 2), advanced nursing practice "build[s] nursing knowledge, advanc[es] the nursing profession and contribut[es] to a sustainable and effective health care system." ANP roles focus on health assessment, diagnosis, and treatment of conditions previously considered to be the physician's domain (Figure 1-2). According to the CNA (2008), **advanced nursing practice** is "an umbrella term describing an advanced level of clinical nursing practice that maximizes use of graduate educational preparation, in-depth nursing knowledge and expertise in meeting needs of individuals, families, groups, communities and populations. It involves analyzing and synthesizing knowledge; understanding, interpreting and applying nursing theory and research; and developing and advancing nursing knowledge and the profession as a whole" (CNA, 2008, p. 10). Examples of roles within ANP in Canada include those of the clinical nurse specialist and the nurse practitioner.

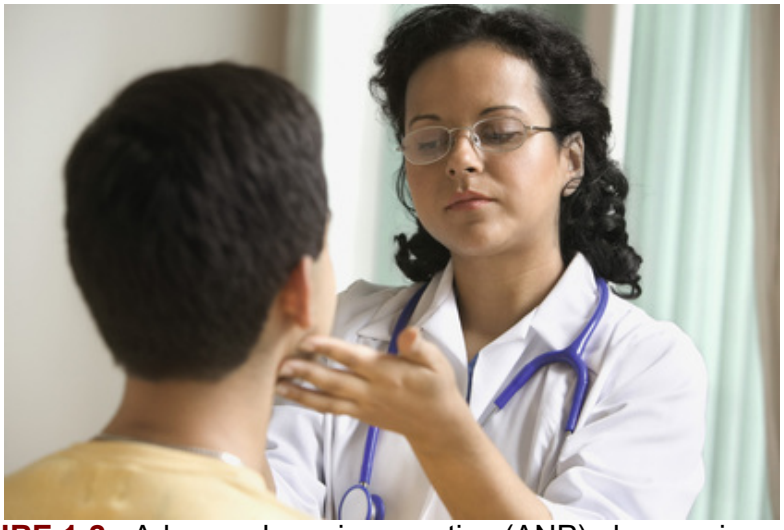

FIGURE 1-2 Advanced nursing practice (ANP) plays an important role in primary care delivery. Source: Blend Images/Shutterstock.com.

In addition to managing and delivering direct patient care, ANP nurses have significant roles in health promotion, case management, administration, and research. There is substantial variation among the provinces and territories in the framework for and specific roles of nurses working in ANP. Practice settings in which an ANP nurse may be employed include primary care, ambulatory care, long-term care, hospital care, and community care, as well as mental health care centres, physicians' offices, family health clinics, and community health facilities (CNA, 2008). In the ANP role, the nurse's focus may be, for example, the management of primary care and health promotion for a wide variety of health problems in various specialties; activities include physical examination, diagnosis, treatment of health problems, patient and family education, and counselling. In the management of complex patient care in various clinical specialty areas, the roles of ANP nurses may include direct care, consultation, research, education, case management, and administration.

Teamwork and Interprofessional Collaboration

Interprofessional Teams.

Because of the increasing acuity of illnesses among patients in the health care system and the growing complexity of interventions designed to promote, restore, and maintain health, no one health discipline can work in isolation. To help patients achieve optimal health, nurses work in collaboration with a wide range of professionals, including pharmacists, physicians, occupational therapists, physiotherapists, and social workers.

Successful collaboration with other health care providers has become a cornerstone of nursing practice. In the position statement *Interprofessional Collaboration,* the CNA (2011) recognized the growing importance of interprofessional collaboration in improving client- or patient-centred access to health care in Canada. The RNAO (2013b) described a conceptual model for developing and sustaining interprofessional health care whereby outstanding interprofessional care is a result of health care teams demonstrating expertise in six key domains: care expertise; shared power; collaborative leadership; optimizing profession, role, and scope; shared decision making; and effective group functioning (Figure 1-3).

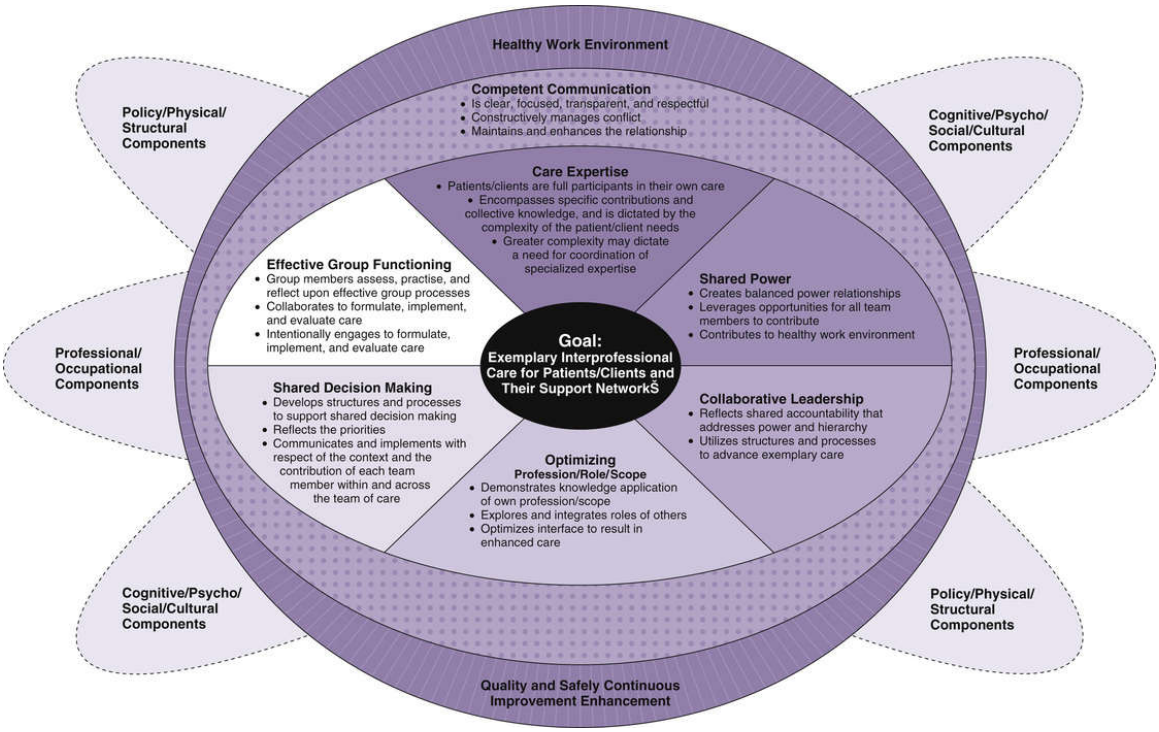

FIGURE 1-3 Conceptual model for developing and sustaining interprofessional health care. Source: Registered Nurses' Association of Ontario (2013). *Developing and sustaining interprofessional health care: Optimizing patients/clients, organizational, and system outcomes.* Toronto, Canada. Registered Nurses' Association of Ontario.

Nurses function in independent, dependent, and collaborative roles. Each province and territory has a *Nurses' Act* that determines the scope of practice for that region. These acts allow nurses to take on delegated medical responsibilities and have a wider scope of practice when working as nurse practitioners. To function effectively in these different roles, nurses must understand how the primary goals of nursing and medicine differ (Table 1-4).

TABLE 1-4

COMPARISON OF PRIMARY GOALS FOR NURSING AND MEDICINE

Nursing	Medicine
Determines responses to health problems, level of wellness, and need for assistance	Determines etiology of illness or injury
Provides physical care, emotional care, teaching, guidance, and counselling	Prescribes medical treatments; performs surgery
Implements interventions aimed at promoting health, preventing illness/complications, and assisting patients to meet their own needs	Implements interventions aimed at preventing and curing injury or illness

Source: Modified from Lewis, S. L., Dirksen, S. R., Heitkemper, M. M., et al. (2011). *Medical-surgical nursing: Assessment and management of clinical problems* (8th ed., p. 10). St. Louis: Mosby.

Communication Among Health Care Team Members.

Effective communication is a key component of fostering teamwork and coordinating care. To provide safe, effective care, everyone involved in a patient's care should understand the patient's condition and needs. Unfortunately, many issues result from a breakdown in communication. Miscommunication often occurs during transitions of care. One structured model used to improve communication is the **SBAR (situation, *b*ackground, *a*ssessment, and *r*ecommendation)** technique (see the inside back cover of this book). This technique provides a way for members of the health care team to talk about a patient's condition in a predictable, structured manner. Other ways to enhance communication during transitions include performing surgical time-outs, standardizing the change-of-shift process, and conducting interprofessional rounds to identify risks and develop a plan for delivering care.

Delegation and Assignment.

Nurses delegate nursing care and supervise other staff members who are qualified to deliver care. *Delegation* is "a formal process through which a regulated health [care] professional (delegator) who has the authority and competence to perform a procedure under one of the controlled acts delegates the performance of that procedure to another individual (delegatee)" (CRNNS/CLPNNS, 2012, p. 2). The delegation and assignment of nursing activities is a process that, when used appropriately, can result in safe, effective, and efficient patient care.

Delegation typically involves tasks and procedures that UCPs perform. The activities that UCPs perform typically include feeding and assisting

patients at mealtimes, helping stable patients ambulate, and assisting patients with bathing and hygiene. Nursing interventions that require independent nursing knowledge, skill, or judgement (e.g., initial assessment, determining nursing diagnoses, patient teaching, evaluating care) are the nurse's responsibility and cannot be delegated. Nurses need to use professional judgement to determine appropriate activities to delegate on the basis of the patient's needs. The most common delegated nursing actions occur during the implementation phase of the nursing process and are for patients who are stable with predictable outcomes. For example, the nurse might delegate measuring oral intake and urine output to a UCP, but the nurse uses nursing judgement to decide whether the intake and output are adequate. Delegation is patient-specific, and the UCP can perform the delegated task for only a particular patient.

Assignment is the "allocation of nursing care among providers in order to meet patient care needs" (Nurses Association of New Brunswick/Association of New Brunswick Licensed Practical Nurses, 2015, p. 10). Staff members can be assigned only activities that are within their scope of practice. Assignment occurs at the beginning of and throughout the shift as patient care needs change.

Whether nurses delegate or are working with staff to whom they assign tasks, they are responsible for the patient's total care during their work period. Nurses are responsible for supervising the UCP who is caring for their patient. It is important to clearly communicate what tasks must be done and provide necessary guidance. Nurses are accountable for ensuring that delegated tasks are completed in a competent manner. This supervision includes evaluation and follow-up as needed by the nurse.

Delegation is a skill that is learned and must be practised to attain proficiency in managing patient care, and it requires the use of critical thinking and professional judgement.

Informatics and Technology

Rapidly changing technologies and dramatically expanding knowledge in the fields of arts and science affect all areas of health care. In telemedicine, telehealth, and telenursing, virtual technologies are used to provide professional education, consultation, and delivery of patient services. **eHealth** refers to the use of communication and information technologies in order to support the delivery and integration of clinical care within and across settings, whereas **information and communication technologies (ICT)** are tools and applications that support the management of clinical

data, information, and knowledge (RNAO, 2012). These services are particularly helpful to health care providers who work or live in rural and remote areas.

Nursing Informatics.

Nursing informatics is a rapidly growing specialty in nursing. **Nursing informatics** refers to the integration of nursing science, computer science, and information technology to manage and communicate data, information, and knowledge in nursing practice (RNAO, 2012). Nursing is an information-intense profession. Advances in informatics and technology have changed the way nurses plan, deliver, document, and evaluate care. All nurses, regardless of their setting or role, use informatics and technology every day in practice. Informatics has changed how nurses obtain and review diagnostic information, make clinical decisions, communicate with patients and health care team members, and document and provide care.

Technology advances have increased the efficiency of nursing care, improving the work environment and the care that nurses provide. Computers and mobile devices allow nurses to document at the time they deliver care and give them quick and easy access to information, including clinical decision-making tools, patient education materials, and references. Texting, video chat, and email enhance communication among health care team members and help them deliver the right message to the right person at the right time.

Technology plays a key role in providing safe, quality patient care. Medication administration applications improve patient safety by flagging potential errors, such as look-alike and sound-alike medications and adverse drug interactions, before they can occur. Computerized provider order entry (CPOE) systems can eliminate errors caused by misreading or misinterpreting handwritten orders. Sensor technology can decrease the number of falls by patients at high risk. Care reminder systems provide cues that decrease the amount of missed nursing care.

The ability to use technology skills to communicate and access information is now an essential component of professional nursing practice. Nurses must be able to use word processing software, communicate by email and messaging, access appropriate information, and follow security and confidentiality rules. They need to demonstrate the skills to safely use patient care technologies and navigate electronic documentation systems. The CASN (2012) outlined three entry-to-practice

competencies related to nursing informatics: (a) use of relevant information and knowledge to support the delivery of evidence-informed patient care; (b) use of ICTs in accordance with professional and regulatory standards and workplace policies; and (c) use of ICTs in the delivery of patient/client care (pp. 6–10). These nursing informatics competencies are considered the minimum knowledge and skills that new graduate nurses require to practise. Throughout this book, "Informatics in Practice" boxes such as the one below offer suggestions for nurses on how to make information technology part of good nursing practice.

Informatics in Practice

Responsible Use of Social Media

A nurse wants to post pictures (or videos) of himself and his nursing colleagues from the hospital.

- Before sharing anything on social media, the nurse should ensure that the posts do not reflect negatively on the nursing profession, the workplace, himself, or his colleagues as health care providers.
- The nurse should ensure that posts do not cause a breach of confidentiality and privacy for patients, colleagues, or the workplace.
- The nurse should know and follow employer policies on using social media in the workplace.

Nurses have an obligation to ensure the privacy of their patient's health information. To do so, it is necessary to understand their agency's policies regarding the use of technology. Nurses need to know the rules regarding accessing patient records and releasing personal health information, what to do if information is accidently or intentionally released, and how to protect any passwords they use. If nurses are using social media, they must be careful not to place online any personal health information that is individually identifiable and must adhere to certain principles in order to reduce risks to members of the public (Table 1-5). They must also be guided by their professional code of conduct and standards of practice.

TABLE 1-5
6 *P*S OF SOCIAL MEDIA USE

Professional: Act professionally at all times **P**ositive: Keep posts positive **P**atient/Person-free: Keep posts patient- or person-free **P**rotect yourself: Protect your professionalism, your reputation, and yourself **P**rivacy: Keep your personal and professional life separate; respect privacy of others **P**ause before you post: Consider implications; avoid posting in haste or anger

Source: International Nurse Regulator Collaborative. (2014). Social media use: Common expectations for nurses. Retrieved from *https://www.crnbc.ca/Standards/Lists/StandardResources/INRCSocialMediaUseCommonExpectforNurses.pdf*.

Electronic Health Records.

Informatics is most widely used in **electronic health records (EHRs)**, also called *electronic medical records.* An EHR is a computerized record of patient information. It is shared among all health care team members involved in a patient's care and moves with the patient: to other providers and across care settings. The ideal EHR is a single file in which team members review and update a patient's health record, document care given, and enter patient care orders, including medications, procedures, diets, and results of diagnostic and laboratory tests. The EHR should contain a patient's medical history, diagnoses, medications, treatment plans, immunization dates, allergies, and test results.

Many agencies have adopted electronic documentation. EHRs and the Canadian Health Outcomes for Better Information and Care (C-HOBIC) project are examples of electronic collection of health care data, and they are being implemented across many parts of Canada. The EHR integrates the output of a number of information systems. Several projects are under way across Canada to develop systems that form the essential building blocks of an EHR, such as digital imaging, summaries of drug prescriptions, and laboratory test results. Provinces and territories across Canada are working together with Canada Health Infoway to accelerate the development of these systems. In the C-HOBIC project, a strategy is being developed for the collection of standardized patient outcome data related to nursing care in EHRs in Saskatchewan, Manitoba, and Ontario (C-HOBIC, 2013). This project introduces a systematic, structured language for admission and discharge assessment of patients receiving acute care, complex continuing care, long-term care, or home care. Data on the following outcomes are being collected: functional status, therapeutic

self-care (readiness for discharge), symptom management (e.g., pain, nausea, fatigue, dyspnea), safety (falls, pressure injuries), and patient satisfaction with nursing care (C-HOBIC, 2013). C-HOBIC will provide real-time information to nurses about how patients are benefitting from care, as well as collecting nursing-related outcomes that provide valuable information about preparing patients for discharge.

EHRs have the potential to reduce medical errors associated with traditional paper records and to improve clinical decision making, patient safety, and quality of care. Unfortunately, several obstacles remain in the way of fully implementing EHRs. Systems are expensive and technologically complex, and a number of resources are needed to implement and maintain them. In addition, communication is still lacking among computer systems and software applications in use. Finally, patients must be assured of their privacy and that information is accessed only by members of their care team with a right to know.

What Is Medical-Surgical Nursing?

Medical-surgical nursing is a challenging and dynamic type of nursing that involves caring for acutely ill adults experiencing complex variations in health (Canadian Association of Medical and Surgical Nurses [CAMSN], 2016). Because the scope of medical-surgical nursing is very broad, the nurse practising in this area is expected to acquire and maintain a great deal of knowledge and skill. This book provides the beginning nurse with much of the knowledge necessary to become a safe and competent practitioner.

The medical-surgical nurse is considered a leader and a key member of the interdisciplinary team (CNA, 2015b). Primary responsibilities of the medical-surgical nurse include prioritization, accountability, advocacy, organization, and coordination of evidence-informed care for multiple patients. Medical-surgical patients and their caregivers come from diverse backgrounds and often possess multiple, complex illnesses, and medical-surgical nurses therefore must be knowledgeable and well prepared. Because of the rapidly changing and complex health concerns that may affect multiple body systems of medical-surgical patients, safe and effective use of technology is an increasingly important competency required by these nurses. The effective medical-surgical nurse demonstrates adaptability and a strong commitment to ensuring the best possible patient outcomes.

Medical-surgical nurses practise in diverse environments, ranging from outpatient and primary care environments through the continuum of care to tertiary care hospitals (CNA, 2015a). As the largest group of nursing professionals in Canada (CAMSN, 2016), they utilize a broad range of evidence-informed knowledge and clinical skills to address the needs of acutely ill adults and their families. The CAMSN is a national organization that promotes excellence through best practice standards to provide high-quality, safe, and ethical care to patients across the continuum of care. Registered nurses may choose to seek recognition of their expertise in this specialty through postlicensure certification offered by the CNA.

Critical Thinking in Nursing

To provide high-quality care in clinical environments of increasing complexity and greater accountability, nurses need to develop higher level thinking and reasoning skills. The ability to engage in critical thinking is

widely regarded as a fundamental skill in nursing education and practice. According to the Foundation for Critical Thinking, **critical thinking** is the art of analyzing and evaluating thinking with a view to improving it (Paul & Elder, 2014). Table 1-6 describes the characteristics of a well-cultivated critical thinker.

TABLE 1-6

CHARACTERISTICS OF THE WELL-CULTIVATED CRITICAL THINKER

A well-cultivated critical thinker:

- Raises vital questions and problems, formulating them clearly and precisely;
- Gathers and assesses relevant information, [and by] using abstract ideas to interpret it effectively comes to well-reasoned conclusions and solutions, testing them against relevant criteria and standards;
- Thinks open-mindedly within alternative systems of thought, recognizing and assessing, as need be, their assumptions, implications, and practical consequences; and
- Communicates effectively with others in figuring out solutions to complex problems.

Source: Paul, R., & Elder, L. (2014). *The miniature guide to critical thinking: Concepts and tools* (7th ed., p. 4). Dillon Beach, CA: Foundation for Critical Thinking.

Alfaro-LeFevre's (2016) work suggests that "a synonym for critical thinking is reasoning because it implies careful, deliberate thought" (p. 6). *Critical thinking* is "an umbrella term that includes aspects of reasoning inside and outside of the clinical area" (p. 7). Critical thinking is not memorizing a list of facts or the steps of a procedure; instead, it is the ability to solve problems by making sense of information. Learning and using critical thinking is a continual process that occurs inside and outside of the clinical setting.

Clinical reasoning is the process used to examine and analyze patient care issues at the point of care (Alfaro-LeFevre, 2016). It involves understanding the medical and nursing implications of a patient's situation when decisions regarding patient care are made. Nurses use clinical reasoning when they identify a change in a patient's status, take into account the context and concerns of the patient and caregiver, and decide what to do about it.

Because of the complexity of patient care today, nurses are required to learn and implement critical thinking and clinical reasoning skills long before they obtain those skills through the experience of professional practice. Throughout this book, select boxes, case studies, and review questions promote the use of critical thinking and clinical reasoning skills.

Evidence-Informed Practice

Evidence-informed nursing is "a continuous interactive process involving the explicit, conscientious, and judicious consideration of the best available evidence to provide care" (CNA, 2010, p. 1). Basing health care decisions on evidence is essential for quality care in all domains of nursing practice. According to the CNA (2010), evidence-informed decision-making " . . . is essential to optimize outcomes for individual clients, promote healthy communities and populations, improve clinical practice, achieve cost-effective nursing care and ensure accountability and transparency in decision-making within the health-care system" (p. 1).

Four primary elements contribute to the practice of evidence-informed nursing (DiCenso, Guyatt, & Ciliska, 2005): (a) clinical state, setting, and circumstances; (b) patient preferences and actions; (c) best research evidence; and (d) health care resources (Figure 1-4). *Clinical expertise,* in which these other four components are integrated, is the nurse's "ability to use clinical skills and past experience to identify the health state of patients or populations, their risks, their preferences and actions, and the potential benefits of intervention; to communicate information to patients and their families; and to provide them with an environment they find comforting and supporting" (DiCenso et al., 2005, p. 5).

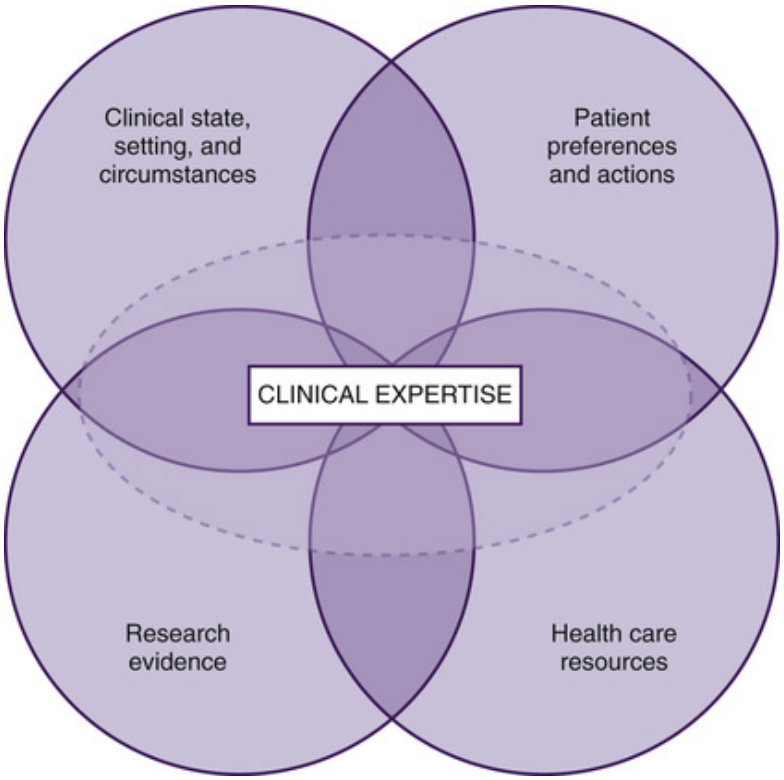

FIGURE 1-4 A model for evidence-informed clinical decisions.

Evidence-informed practice (EIP) produces better outcomes in the most effective and efficient way. Application of EIP results in more accurate diagnoses, the most effective and efficient interventions, and the most favourable patient outcomes. The most distinguishing feature of EIP is that the new scientific base for practice is built through a summary of studies on a topic. These summaries are called *evidence syntheses, systematic reviews,* or *integrative reviews,* depending on the organization that produces them. The evidence synthesis summarizes all research results into a single conclusion about the state of the science. From this point, the clinician translates the knowledge into a clinical practice guideline, implements it through individual and organizational practice changes, and evaluates it in terms of the effectiveness and efficiency of producing intended health care outcomes (Figure 1-5). Clinical practice guidelines can take the form of protocols, clinical pathways, practice guidelines, policy statements, computer-based protocols, or algorithms.

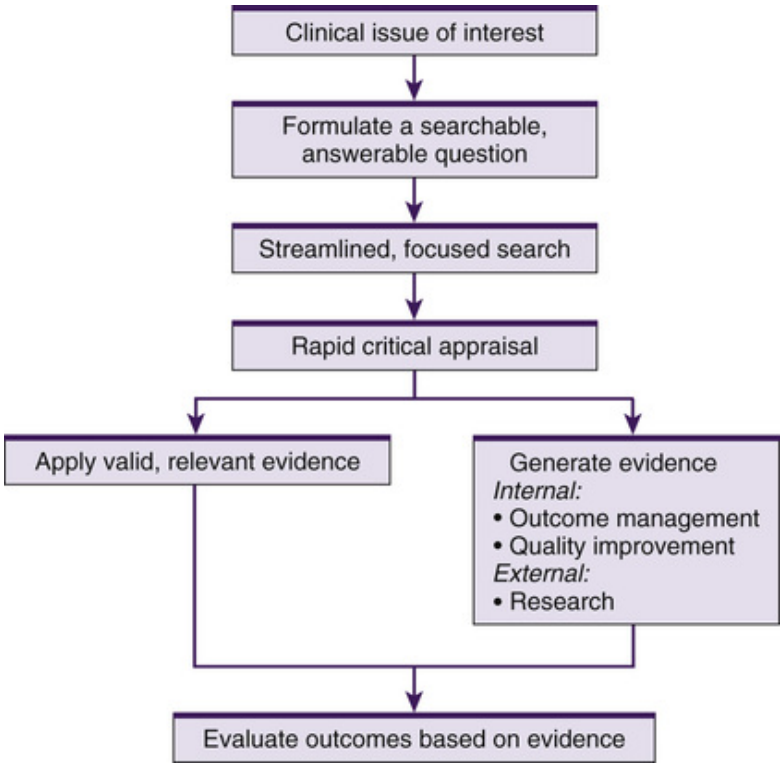

FIGURE 1-5 Process of evidence-informed practice.

Best practice guidelines are increasingly used to guide clinical practice in health care. Such guidelines are "systematically developed statements based on best available evidence to assist practitioners' and patients' decisions about appropriate health care" (RNAO, n.d.). Examples of the current best practice guidelines include *Adult Asthma Care Guidelines for Nurses: Promoting Control of Asthma* (RNAO, 2004); *The Assessment and Management of Pain* (RNAO, 2013a); *Person- and Family-Centred Care* (RNAO, 2015); and *Caring for Persons with Delirium, Dementia & Depression* (RNAO, 2005).

Throughout this book, two different types of "Evidence-Informed Practice" (EIP) boxes are available for selected topics. "Research Highlight" boxes provide answers to specific clinical questions. These boxes contain the PICOT (**p**atients/population of interest, **i**ntervention, **c**omparison or comparative group, **o**utcome[s], and **t**ime period as applicable) question (Table 1-7); critical appraisal of the syntheses of evidence or primary studies; implications for nursing practice; and the source of the evidence. "Translating Research into Practice" boxes provide an opportunity for you to practise your critical thinking skills in applying evidence to patient scenarios. Evidence can support current practice and

increase confidence that nursing care will continue to produce the desired outcome, or evidence may necessitate a change in practice.

TABLE 1-7

STEPS OF THE EVIDENCE-INFORMED PRACTICE PROCESS

1. Ask clinical questions by using the **PICOT** format: **P**atients/population of interest **I**ntervention **C**omparison or comparison group **O**utcome(s) **T**ime period (as applicable)
2. Collect the most relevant and best evidence.
3. Critically appraise and synthesize the evidence.
4. Integrate all evidence with your clinical expertise and the patient's preferences and values in making a practice decision or change.
5. Evaluate the practice decision or change.
6. Share the outcomes of the decision or change.

Steps in the Evidence-Informed Practice Process.

The six steps of the EIP process are provided in Table 1-7 and Figure 1-5.

Step 1.

Step 1 is to ask a clinical question in the PICOT format. Developing the clinical question is the most important step in the EBP process (Echevarria & Walker, 2014). A good clinical question sets the context for integrating evidence, clinical judgement, and patient preferences. In addition, the question guides the literature search for the best evidence to influence practice.

An example of a clinical question in PICOT format is "In adult patients undergoing abdominal surgery (**p**atients/population), is splinting with an elasticized abdominal binder (**i**ntervention) or a pillow (**c**omparison) more effective in reducing pain associated with ambulation (**o**utcome) on the first postoperative day (**t**ime period)?" A properly stated clinical question may not have all components of PICOT; some include only four components. The (T) timing or (C) comparison component may not be appropriate for a particular question.

Step 2.

Step 2 is to search for the best evidence in the literature. The question directs the clinician to the databases that are most appropriate. The search begins with the strongest external evidence to answer the question.

Preappraised evidence tools, such as systematic reviews and evidence-informed guidelines, are appropriate time-saving resources in the EIP process. Systematic reviews of randomized controlled trials are considered the strongest level of evidence to answer questions about interventions (i.e., cause and effect). However, a limited number of systematic reviews are available to answer the many clinical questions. In addition, systematic reviews or meta-analyses may not always provide the most appropriate answers to all clinically meaningful questions.

If the clinical question is about how a patient experiences or copes with a health problem or lifestyle change, searching for a metasynthesis of qualitative evidence may be the most appropriate approach. When research is insufficient to guide practice, evidence from opinion leaders or authorities or reports from expert committees may be all that exist. This type of evidence should not be the sole substantiation for interventions. Care based on expert opinions requires diligent, ongoing, rigorous outcome evaluation to generate stronger evidence.

Step 3.

Step 3 is to critically appraise and synthesize the data from studies found in the search. A successful critical appraisal process focuses on three essential questions: (a) Are the results of the study valid? (b) What are the results? (c) Are the findings clinically relevant to the clinician's patients? The purpose of critical appraisal is to determine not only the flaws of a study but also the value of the research to practice. To conclude what the best practice is, clinicians must determine the strength of the evidence and synthesize the findings in relation to the clinical question.

Step 4.

Step 4 involves implementing the evidence in practice. Recommendations that are based on sufficient, strong evidence (e.g., interventions with systematic reviews of well-designed randomized controlled trials) can be implemented in practice in combination with clinicians' expertise and patient preferences. Clinical judgement will influence how patient preferences and values are assessed, integrated, and entered into the decision-making process. For example, although evidence may support the effectiveness of morphine as an analgesic, its use in a patient with renal failure may not be appropriate.

Step 5.

Step 5 is to evaluate identified outcomes in the clinical setting. Outcomes must match the clinical project that has been implemented. For example, when the effectiveness of morphine for pain control is compared with that of fentanyl, evaluating the cost of each medication will not provide the required data about clinical effectiveness. Outcomes must reflect all aspects of implementation and capture the interdisciplinary contributions elicited by the EIP process.

Step 6.

Step 6 is to share the outcomes of the EIP change. If nurses performing research do not share the outcomes of EIP, then other health care providers and patients cannot benefit from what they learned from their experience. Information is shared locally through unit- or hospital-based newsletters and posters and regionally and nationally through journal publications and presentations at conferences.

Implementation of Evidence-Informed Practice.

To implement EIP, nurses continuously seek scientific evidence that supports the care that they provide. The incorporation of evidence should be balanced with clinical expertise and should take into account each patient's unique circumstances and preferences. EIP closes the gap between research and practice, resulting in care that produces more reliable and predictable outcomes than does care that is based on tradition, opinion, and a trial-and-error method. EIP provides nurses with a mechanism to manage the explosion of new literature, introduction of new technologies, concern about health care costs, and increasing emphasis on quality care and patient outcomes.

In collaboration with the First Nations and Inuit Health Branch of Health Canada, the CNA launched a Web-based portal for nurses, called **NurseONE** (see the "Resources" section at the end of this chapter). The portal provides opportunities for nurses to access libraries and information related to evidence-informed practice and clinical practice issues through a dedicated Web-based portal.

Throughout this book, two different types of EIP boxes are used to show how EIP is used in nursing practice. The "Translating Research into Practice" boxes provide initial answers to specific clinical questions. These boxes contain the clinical question, critical appraisal of the supportive evidence, implications for nursing practice, and the source of the evidence.

“Applying the Evidence” boxes provide an opportunity for nurses to practise their critical thinking skills in applying EIP to patient scenarios.

The Nursing Process

The nursing process is one strategy to assist nursing students in understanding the steps involved in providing effective nursing care. The **nursing process** is an assertive, problem-solving approach to the identification and treatment of patient health problems. It provides a framework to organize the knowledge, judgements, and actions that nurses supply in patient care (Wilkinson, 2011). Using the nursing process, the nurse can focus on the unique responses of patients to actual or potential health problems.

Phases of the Nursing Process

The nursing process consists of five phases: assessment, diagnosis, planning, implementation, and evaluation (Figure 1-6). **Assessment** involves collecting subjective and objective information about the patient. The nursing diagnosis phase involves analyzing the assessment data, drawing conclusions from the information, and labelling the human response. **Planning** consists of setting goals and expected outcomes with the patient and, when feasible, the patient's family and determining strategies for accomplishing the goals. **Implementation** involves the use of nursing interventions to activate the plan. The nurse also promotes self-care and family involvement when appropriate. **Evaluation** is an extremely important part of the nursing process that is too often not addressed sufficiently. In the evaluation phase, the nurse first determines whether the identified outcomes have been met. Then the overall accuracy of the assessment, diagnosis, and implementation phases is evaluated. If the outcomes have not been met, new approaches are considered and implemented as the process is repeated.

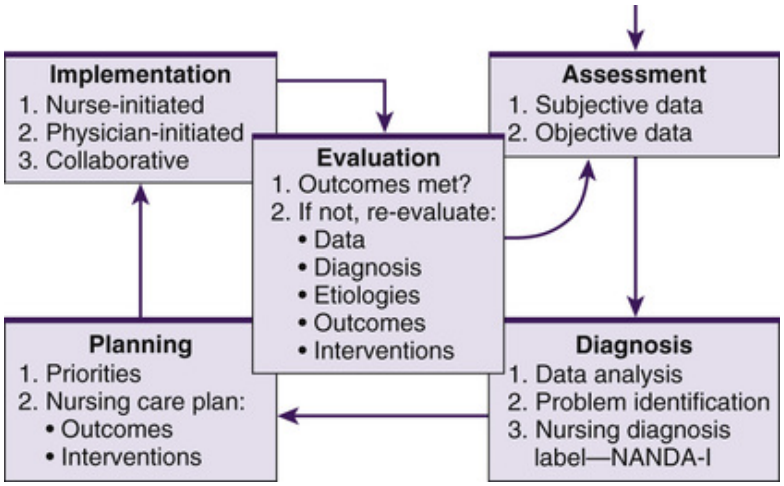

FIGURE 1-6 The nursing process.

Interrelatedness of Phases

The five phases of the nursing process do not occur in isolation from one another. For example, nurses may gather data about the wound condition (assessment) as they change the soiled dressing (implementation). There is, however, a basic order to the nursing process, which begins with assessment. Assessment provides the data on which planning is based. An evaluation of the nature of the assessment data usually follows immediately, resulting in the formulation of a diagnosis. A plan based on the nursing diagnosis then directs the implementation of nursing interventions. Evaluation continues throughout the cycle and provides feedback on the effectiveness of the plan or the need for revision. Revision may be needed in the data collection method, the diagnosis, the expected outcomes or goals, the plan, or the intervention method. Once initiated, the nursing process is not only continuous but also cyclical in nature.

Assessment Phase

Data Collection.

Sound data form the foundation for the entire nursing process. Collection of data is a prerequisite for diagnosis, planning, and intervention (Figure 1-7). Humans have needs and problems in biophysical, psychological, sociocultural, spiritual, and environmental domains. A nursing diagnosis made without supporting data pertaining to all of these dimensions can lead to incorrect conclusions and depersonalized care. For example, if a hospitalized patient does not sleep all night, a disturbed sleep pattern may

be mistakenly diagnosed, whereas, in fact, the patient may have worked nights her entire adult life, and it is normal for her to be awake at night. Information concerning her sleeping habits is necessary to provide individualized care to her by ensuring that sleep medication is not routinely administered to her at 2200 hours. The importance of person-centred assessment in the process of clinical decision making cannot be overemphasized.

FIGURE 1-7 Collection of data is a prerequisite for diagnosis, planning, and intervention. Source: bikeriderlondon/Shutterstock.

Because nursing interventions are only as sound as the data on which they are based, the database must be accurate and complete. When possible, collateral information obtained from sources such as the patient's record, other health care workers, the patient's family, and the nurse's observations should be validated with the patient. If the patient's statements seem questionable, they should be validated by a knowledgeable person.

Diagnosis Phase

Data Analysis and Problem Identification.

The diagnosis phase begins with clustering of information and, after analysis of the assessment data, ends with an evaluative judgement about a patient's health status. Analysis involves sorting through and organizing the information and determining unmet needs, as well as the strengths, of

the patient. The findings are then compared with documented norms to determine whether anything is interfering or could interfere with the patient's needs or ability to maintain his or her usual health pattern.

After a thorough analysis of all available information, one of two possible conclusions is reached: (1) the patient has no health problems that necessitate nursing intervention or (2) the patient needs nursing assistance to solve a potential or actual health problem.

Nursing Diagnosis.

The term *nursing diagnosis* has many different meanings. To some, it merely connotes the identification of a health problem. More commonly, a nursing diagnosis is viewed as the conclusion about an identified cluster of signs and symptoms. The diagnosis is generally expressed as concisely as possible according to specific guidelines.

Nursing diagnosis is the act of identifying and labelling human responses to actual or potential health problems. Throughout this book, the term *nursing diagnosis* means (1) the process of identifying actual and potential health problems and (2) the label or concise statement that describes "a clinical judgment concerning a human response to health conditions/life processes, or a susceptibility for that response, by an individual, family, group or community. . . . A nursing diagnosis provides the basis for selection of nursing interventions to achieve outcomes for which the nurse has accountability" (NANDA International [NANDA-I], 2017, p. 115). Many human responses that are identified result from a disease process. For example, a patient may have the medical diagnosis of chronic obstructive pulmonary disease (COPD). In this case, the nursing diagnosis would focus on how the COPD affects the patient's daily functioning. Examples of patient responses to COPD might be anxiety, activity intolerance, or an inability to maintain a household. Appendix A contains a comprehensive list of nursing diagnoses relevant to care of the medical-surgical patient.

Diagnostic Process.

The diagnostic process involves analysis and synthesis of the data collected during assessment of the patient. Data that indicate dysfunctional or risk patterns are clustered, and a judgement about the data is made. It is important to remember that not all conclusions resulting from data analysis lead to nursing diagnoses. Nursing diagnoses refer to health states that nurses can legally diagnose and treat. Data may also point to health problems that nurses treat collaboratively with other health

care providers. During this phase of the nursing process, the nurse identifies both nursing diagnoses and treatments that necessitate collaborative nursing intervention.

Nursing diagnostic statements are considered acceptable when written as two- or three-part statements. When written in three parts, the statement is in the PES (**p**roblem, **e**tiology, and **s**igns and symptoms) format (Carpenito-Moyet, 2012; Gordon, 2014). A two-part statement is deemed acceptable if the signs and symptoms data are easily available to other nurses caring for the patient through the nursing history or progress notes. "Risk" nursing diagnoses are also two-part statements because signs and symptoms are not relevant. Use of a three-part statement is recommended during the learning process:

Problem (P): A brief statement of the patient's potential or actual health problem (e.g., pain)

Etiology (E): A brief description of the probable cause of the problem; contributing or related factors (e.g., related to surgical incision, localized pressure, edema)

Signs and symptoms (S): A list of the objective and subjective data cluster that leads the nurse to pinpoint the problem; critical, major, or minor defining characteristics (e.g., as evidenced by verbalization of pain, isolation, withdrawal)

It is important to remember that gathering the "S" comes first in the diagnostic process, even though it is last in the PES statement format.

Identifying the Problem.

The NANDA International (NANDA-I; formerly known as the North American Nursing Diagnosis Association) classification system is one framework that is useful for formulating actual nursing diagnoses and at-risk diagnoses. Clinically relevant cues are clustered into functional health patterns on the basis of Gordon's (2014) 11 functional health patterns. Gordon's functional health patterns are health perception–health management pattern; nutritional–metabolic pattern; elimination pattern; activity–exercise pattern; sleep–rest pattern; cognitive–perceptual pattern; self-perception–self-concept pattern; role–relationship pattern; sexuality–reproductive pattern; coping–stress tolerance pattern; and value–belief pattern.

The process of making a nursing diagnosis from clustered cues begins with the recognition of dysfunctional patterns. Checking the definition of

nursing diagnoses classified according to the functional pattern helps identify the appropriate label for the problem. Before final selection of any nursing diagnosis for the patient, the nurse verifies the diagnostic statement with the defining characteristics listed with the diagnosis (Carpenito-Moyet, 2012; Gordon, 2014; NANDA-I, 2017). The nursing diagnosis deemed most accurate is based on the individual patient's data.

Etiology.

The etiology underlying a nursing diagnosis is identified in the diagnostic statement. Taking time to properly link the problem with its etiology directs the nurse to the correct interventions. Interventions to manage the problem are planned by directing nursing efforts toward the etiology. The etiology can be a pathophysiological, maturational, situational, or treatment-related factor (Carpenito-Moyet, 2012). The etiology is written after the diagnostic label. These two components are separated by the phrase "related to." For example, in Nursing Care Plan 1-1, the nursing diagnosis is *"Activity intolerance* related to *imbalance between oxygen supply/demand."* The etiology directs the nurse to select the appropriate interventions to modify the factor of fatigue. When the etiology is not included in the diagnosis, the nurse is not able to plan the correct intervention to treat the specific cause of the problem. When possible, the etiology should be validated with the patient. When the etiology is unknown, the statement reads "related to unknown etiology." When identifying "risk-for" nursing diagnoses, the specific risk factors present in the patient's situation are identified as the etiology, and the phrase "as evidenced by" is used rather than "related to".

Nursing Care Plan 1-1

Heart Failure*

NURSING DIAGNOSIS	***Activity intolerance*** related to *imbalance between oxygen supply/demand* as evidenced by *abnormal heart rate response to activity, exertional dyspnea, and fatigue.*
Expected Patient Outcomes	**Nursing Interventions and *Rationales***
• Achieves a realistic program of activity that balances physical activity with energy-conserving activities • Vital signs, O_2 saturation, and colour are within normal limits in response to activity	*Energy Management*
	• Encourage alternate rest and activity periods *to reduce cardiac workload and conserve energy.* • Provide calming diversionary activities *to promote relaxation to reduce O_2 consumption and to relieve dyspnea and fatigue.* • Monitor patient's oxygen response (e.g., pulse rate, cardiac rhythm, colour, O_2 saturation, and respiratory rate) to self-care or nursing activities *to determine level of activity that can be performed.* • Teach patient and caregiver techniques of self-care *to minimize O_2 consumption (e.g., self-monitoring and pacing techniques for performance of ADLs).*
	Activity Therapy
	• Collaborate with occupational therapist, physiotherapist, or both *to plan and monitor activity and exercise program.* • Determine patient's commitment to increasing frequency or range of activities, or both, *to provide patient with obtainable goals.*

ADLs, activities of daily living.

*The complete nursing care plan for heart failure is provided in Nursing Care Plan 37-1 in Chapter 37.

Signs and Symptoms.

Signs and symptoms are the clinical cues that, in a cluster, point to the nursing diagnosis. The signs and symptoms are often included in the diagnostic statement after the phrase "as evidenced by." The complete nursing diagnostic statement in Nursing Care Plan 1-1 is "*Activity intolerance* related to *imbalance between oxygen supply/demand* as evidenced by *abnormal heart rate response to activity, exertional dyspnea, and fatigue.*" Throughout this book, you will see nursing diagnoses listed for many diseases and patient situations. These are NANDA-I approved diagnoses and related factors, and sometimes include additional explanatory non-NANDA-I material in parentheses.

Collaborative Problems.

Collaborative problems are potential or actual complications of disease or of treatment that nurses manage together with other health care providers (Carpenito-Moyet, 2012). A look at the primary goals of nursing helps in differentiating between nursing and medical diagnoses (see Table 1-3). During the diagnosis phase of the nursing process, the nurse identifies the risks for these physiological complications in addition to nursing diagnoses. Identification of collaborative problems requires knowledge of

pathophysiology and possible complications of medical treatment. For example, collaborative problems with heart failure described in Nursing Care Plan 1-1 could include pulmonary edema, hypoxemia, dysrhythmias, cardiogenic shock, or a combination of these (Carpenito-Moyet, 2012). In the interdependent role, nurses use both physician-prescribed and nursing-prescribed interventions to prevent, detect, and manage collaborative problems.

Collaborative problem statements are usually written as "potential complication: _____" (e.g., "potential complication: pulmonary edema") without a "related to" statement. When potential complications are used in this textbook, "related to" statements have been added to increase understanding and link the potential complication to possible causes.

Planning Phase

Priority Setting.

After the nursing diagnoses and collaborative problems are identified, the nurse must determine the urgency of the identified problems. Diagnoses of the highest priority necessitate immediate intervention. Those of lower priority can be addressed later. When setting priorities, the nurse should first intervene for life-threatening problems involving airway, breathing, or circulation issues.

Maslow's (1954) hierarchy of needs also acts as a useful guide in determining priorities. These needs include the physical needs; safety, love, and belonging; esteem; and self-actualization. Lower-level needs must be satisfied before a higher level can be addressed.

Another guideline in setting priorities is to determine the patient's perception of what is important. When the patient's priorities are not congruent with the actual situation, the nurse may have to give explanations or do some teaching to help the patient understand the need to do one thing before another. Often it is more efficient to meet the need that the patient deems a priority before moving on to other priorities.

Identifying Outcomes.

After priorities are established, expected outcomes or goals for the patient are identified. *Outcomes* are simply the results of care. **Expected patient outcomes** are *goals* that articulate what is desired or expected as a result of care. The terms *goals* and *expected outcomes* are often used interchangeably: both terms describe the degree to which the patient's response, as identified in the nursing diagnosis, should be prevented or changed as a

result of nursing care. Expected outcomes should be agreed upon with the patient, if feasible, just as priorities of interventions are considered with the patient when possible. Although the ultimate goal for the patient is to maintain or attain a state of dynamic equilibrium at the highest possible level of wellness, the setting of more specific expected outcomes, both short- and long-term, is necessary for systematic evaluation of the patient's progress. Expected patient outcomes identified in the planning stage indicate which criteria are to be used in the evaluation phase of the nursing process.

The nurse identifies both long-term and short-term goals by writing specific expected patient outcomes in terms of desired, realistic, measurable patient behaviours to be accomplished by a specific date. For example, a short-term expected outcome for the patient in Nursing Care Plan 1-1 might be "The patient will maintain normal vital signs in response to activity in 2 days," whereas a long-term expected outcome might be "The patient will identify a realistic activity level to achieve or maintain by the time of discharge." These outcomes would be evaluated in 2 days and at discharge, and the care plan would be revised as necessary if the outcomes were not met. However, these statements are less than optimal because they provide no criteria by which to evaluate the patient's degree of progress from admission to discharge.

Determining Interventions.

After patient outcomes are identified, nursing interventions to accomplish the desired status of the patient should be planned. A **nursing intervention** is any treatment based on clinical judgement and knowledge that a nurse performs to enhance patient outcomes (Bulechek, Butcher, Dochterman, et al., 2013).

Sound knowledge, good judgement, and decision-making ability are necessary to effectively choose the interventions that the nurse will use (Figure 1-8). The nurse should foster the use of a research-based approach to interventions. In the absence of a nursing research base, scientific principles from the behavioural and biological sciences should guide the selection of interventions.

FIGURE 1-8 Collaboration among the patient, the family, and the nurse is necessary in setting goals and coordinating high quality care. Source: privilege/Shutterstock.com.

Implementation Phase.

Carrying out the specific, individualized plan constitutes the implementation phase of the nursing process. The nurse performs the interventions or may designate and supervise other health care workers who are qualified to intervene. Throughout the implementation phase, the nurse must evaluate the effectiveness of the methods chosen to implement the plan.

Evaluation Phase.

All phases of the nursing process must be evaluated (see Figure 1-4). Evaluation occurs after implementation of the plan but also continuously throughout the process. The nurse evaluates whether sufficient assessment data have been obtained to allow a nursing diagnosis to be made. The diagnosis is, in turn, evaluated for accuracy. For example, pain might have actually been related to a wound itself or to pressure from a constricting dressing.

Next, the nurse evaluates, with the patient when possible, whether the expected patient outcomes and interventions are realistic and achievable. If not, a new plan should be formulated. This may involve revision of expected patient outcomes and interventions. Consideration must be given to whether the plan should be maintained, modified, totally revised, or discontinued in view of the patient's status.

Nursing Care Plans

When the nurse has determined the nursing diagnoses, the outcomes, and the interventions for a patient, the plan is recorded to ensure continuity of care by other nurses and health care providers. The plan should contain specific directions for carrying out the planned interventions, including how, when, for how long, how often, where, by whom, and with what resources the activities should be performed.

Various methods and formats are used to record the nursing care plan. One of the important factors influencing a choice of care plan format has to do with the frameworks used in a particular agency. Care plans are often written on a specific form adopted by an institution, but they may also be entered electronically to organize nursing data. Every nurse who cares for the patient must have access to the plan, whether handwritten or computer generated, to provide the planned care. The care plan is part of the patient's medical record and may be used in legal proceedings. The nurse must document the patient's nursing care requirements, changes that are made as the plan is implemented, and the outcomes of the nursing interventions. Not every activity that the nurse implements with the patient will be recorded on the care plan.

Standardized care plans are sometimes used as guides for routine nursing care and as a basis for developing individualized care plans. When standardized care plans are used, they should be personalized and specific to the unique needs and problems of each patient.

Beginning in 2009, all nurses practising in Quebec were required to develop and update therapeutic nursing plans. Such plans are a compulsory and permanent part of the patient's record.

Concept Maps

A concept map is another method of recording a nursing care plan. In a concept map care plan, the nursing process is recorded in a visual diagram of patient problems and interventions that illustrates the relationships among clinical data. Nurse educators use concept mapping to teach nursing process and care planning. There are various formats for concept maps. *Conceptual care maps* blend a concept map and a nursing care plan. On a conceptual care map, assessment data used to identify the patient’s primary health concern are centrally positioned. Diagnostic testing data, treatments, and medications surround the assessment data. Positioned

below are nursing diagnoses that represent the patient's responses to the health state. Listed with each nursing diagnosis are the assessment data that support the nursing diagnosis, outcomes, nursing interventions with rationales, and evaluation. After completing the map, connections can be drawn between identified relationships and concepts. A conceptual care map creator is available online on the website for this book. For selected case studies at the end of the management chapters, related concept maps are available on the website at http://evolve.elsevier.com/Canada/Lewis/medsurg.

Clinical (Critical) Pathways

Care related to common health problems experienced by many patients is delineated with the use of clinical (critical) pathways. A **clinical (critical) pathway** directs the entire health care team in the daily care goals for select health care problems. It includes a nursing care plan, specific interventions for each day of hospitalization, and a documentation tool.

The clinical pathway organizes and sequences the caregiving process at the patient level to better achieve desired quality and cost outcomes. It is a cyclical process organized for specific case types by all related health care departments. The case types selected for clinical pathways are usually those that occur in high volume and are highly predictable, such as myocardial infarction, stroke, and angina.

The clinical pathway describes the patient care required at specific times in the treatment. A multidisciplinary approach helps the patient progress toward desired outcomes within an estimated length of stay. The exact content and format of clinical pathways vary among institutions.

Documentation

It is critical that the patient's progress be documented in a systematic way. Proper documentation enables safe and effective patient care. Patient records are also frequently used as evidence when there are legal issues related to negligence and competency. Nurses in Canada should be aware of the Canadian Nurses Protective Society. This is the agency that provides liability coverage and is a source of information and education on issues such as documentation and charting.

Many documentation methods and formats are used, depending on personal preference, agency policy, and regulatory standards. Many provinces are now moving to implement EHRs (see "Electronic Health Records" earlier in this chapter). Funding and support are available through organizations such as the Canada Health Infoway. Patient progress may be documented by nurses with the use of flow sheets; narrative notes; SOAP (**s**ubjective, **o**bjective, **a**ssessment, **p**lan) charting (described in the next section); clinical pathways; and computer-based charting. Every method or combination of methods is designed to document the assessment of patient status, the implementation of interventions, and the outcome of interventions.

Charting

There are several methods of documentation that address the nursing process. The SOAP method is a common way of evaluating and recording patient progress. Some institutions use SOAPIER notes (**s**ubjective, **o**bjective, **a**ssessment, **p**lan, **i**ntervention, **e**valuation, and **r**evision of plan). A SOAP or SOAPIER progress note is problem specific and incorporates the elements in Table 1-8. The following is the process of SOAP documentation.

TABLE 1-8

COMPONENTS OF A SOAP PROGRESS NOTE

SOAP Component	Explanation
Subjective	Information supplied by patient or knowledgeable other person
Objective	Information obtained by nurse directly by observation or measurement, from patient records, or through diagnostic studies
Assessment	Nursing diagnosis or problem according to subjective and objective data
Plan	Specific interventions related to a diagnostic or problem with consideration of diagnostic, therapeutic, and patient education needs

1. Additional subjective and objective data related to the area of concern are gathered.
2. On the basis of old and new data, the patient's progress toward the expected patient outcome and the effectiveness of each intervention are assessed.
3. On the basis of the reassessment of the situation, the initial plan is maintained, revised, or discontinued.

The following is an example of SOAP charting for the nursing diagnosis "*Risk for infection* as evidenced by *alteration in skin integrity and invasive procedure* (surgery)":

S: Wound is more painful today
O: Temperature of 39.4°C, facial grimacing in response to movement, dressing saturated with purulent drainage
A: Risk for wound infection
P: Notify surgeon, take temperature q2h, reinforce dressing.

A second method of documentation is the PIE (**p**roblem, **i**ntervention, and **e**valuation) method, which is similar to SOAP charting and is also problem oriented. It does not include assessment data because those are recorded on flow sheets.

A third documentation format is DAR (**d**ata, both subjective and objective; **a**ction or nursing intervention; and **r**esponse of the patient) progress notes. It is also called *focus charting,* and it addresses patient concerns, not just problems.

Charting by exception is another method of documentation that focuses on documenting deviations from predefined normal findings. Assessments

are standardized on flow sheets, and nurses make a narrative note only when there are exceptions to the standardized statements.

Future Challenges of Nursing

Nursing roles continually evolve as society changes and health care providers learn to integrate new knowledge and technology into current practices. Although nursing is defined in different ways, past and current definitions of nursing include commonalities of health, illness, and caring. It is important that these concepts are addressed in nursing education as greater demands are placed on the profession. Future nursing practice will continue to call for the use of reasoning, analytic thinking skills, and synthesis of rapidly expanding knowledge to assist patients in maintaining or attaining optimal health.

An increasing emphasis on leadership, accountability, courage and persistence, innovation and risk taking, and decision making is essential if nursing is to move forward. **Nursing leadership** refers not only to people holding certain positions but also to an attitude and approach in which lifelong learning and a commitment to excellence in practice are valued. In its attempt to keep pace, nursing would do well to remember what the Red Queen in *Through the Looking Glass* said to Alice: "Now here, you see, it takes all the running you can do to keep in the same place. If you want to get somewhere else, you must run at least twice as fast as that" (Carroll, 1865/1973). This appears to be the future of nursing. Nursing leaders must ask some fundamental questions about what the contribution of nurses must be for the twenty-first century. We must increasingly challenge the status quo by relying on research and the wisdom that results from asking difficult questions. Nurse leaders must have an attitude of open-mindedness while remaining grounded in values that overcome the tendency to promote self-interest.

Review Questions

The number of the question corresponds to the same-numbered learning outcome at the beginning of the chapter.

1. Which of the following is a current challenge facing the Canadian health care system?
   a. Lack of long-term funding model between provinces/territories and federal government
   b. Lack of innovation in health care
   c. Expanding knowledge and technology
   d. Health care ranking as a low-priority public health policy issue by Canadians
2. Which of the following is an example of a nursing activity that reflects the Canadian Nurses Association's definition of nursing?
   a. Establishing that the client with jaundice has hepatitis
   b. Determining the cause of hemorrhage in a postoperative client on the basis of vital signs
   c. Identifying and treating dysrhythmias that occur in a client in the coronary care unit
   d. Determining that a client with pneumonia cannot effectively cough up pulmonary secretions
3. Which of the following characteristics of health care teams are important for outstanding interprofessional care? *(Select all that apply.)*
   a. Care expertise
   b. Diverse mix of health care providers
   c. Collaborative leadership
   d. Effective group functioning
   e. Clear differentiation between roles
4. The nurse is caring for a client with diabetes who has just undergone debridement of an infected toe. Which of the following statements best demonstrates client-centred care?
   a. “Administer analgesics every 4 hr prn.”
   b. “Keep foot elevated to promote venous return.”
   c. “Elicit expectations of client and family for relief of pain, discomfort, or suffering.”

d. "Initiate the process of teaching the client and family about self-care management."

5. What are advantages of using informatics in health care delivery? *(Select all that apply.)*
   a. Reduced need for nurses in acute care
   b. Increased client anonymity and confidentiality
   c. The ability to achieve and maintain high standards of care
   d. Access to standard plans of care for many health problems
   e. Improved communication of the client's health status to the health care team
6. Which of the following actions best describes the work of medical-surgical nurses?
   a. Providing care only in acute care hospital settings
   b. Requiring certification by the Canadian Nurses Association in this specialty
   c. Addressing the needs of acutely ill adults and their families
   d. Caring primarily for perioperative clients
7. "In adults older than 60 with chronic obstructive pulmonary disease, is structured pulmonary rehabilitation more effective than classroom instruction in reducing the incidence of exacerbation?" In this question, what is the outcome of interest?
   a. Adults older than age 60
   b. Adults with chronic obstructive pulmonary disease
   c. Structured pulmonary rehabilitation
   d. Reduced incidence of exacerbation
8. The nurse identifies the nursing diagnosis of *constipation* related to *laxative abuse* for a client. What is the most appropriate expected client outcome related to this nursing diagnosis?
   a. The client will stop the use of laxatives.
   b. The client ingests adequate fluid and fibre.
   c. The client passes normal stools without aids.
   d. The client's stool is free of blood and mucus.

1. a; 2. d; 3. a, c, d; 4. c; 5. c, d, e; 6. c; 7. d; 8. c.

CHAPTER 2

Cultural Competence and Health Equity in Nursing Care

Written by, Rani H. Srivastava

LEARNING OBJECTIVES

1. Define the terms *culture, cultural competence, cultural safety, ethnocentrism, cultural imposition, world view, health literacy,* and *health equity.*
2. Identify the determinants of health and health inequities for Indigenous populations.
3. Describe the factors that lead to health inequities in culturally diverse populations.
4. Explain the links between cultural competence, patient safety, and patient- or family-centred care.
5. Describe strategies for successfully communicating with a person with limited English proficiency.
6. Examine ways that a nurse's own cultural background may influence how that nurse delivers nursing care.
7. Describe strategies for demonstrating cultural competence and promoting health equity in care encounters.
8. Identify the benefits and challenges associated with a diverse workforce.

KEY TERMS

The Need for Cultural Competence

In today's increasingly multicultural environment, nurses come in contact with individuals from many different cultures, as patients and as colleagues, during their professional careers. This diversity can be enriching as it offers unique opportunities to learn from patients, families, and each other. At the same time, differences in culture can affect the safety and quality of care.

Because of the changes in demographic and cultural compositions of Canada and other countries, all health care providers must understand the influence of culture on health beliefs, practices, and outcomes. Culture influences individual beliefs about health, illness, care, cure, and even expectations of health care providers. Understanding these differences is crucial for providing care that is safe, meaningful, and effective for patients and families.

Canadian society is an ethnocultural mosaic characterized by immigrant population, linguistic diversity, and religious diversity. According to data from the 2011 National Health Survey (NHS), foreign-born individuals represented approximately one-fifth (20.6%) of Canada's total population (Statistics Canada, 2013a). This is a slight increase from the 2006 census. Since the mid-1980s, Canadian immigration patterns have been undergoing a significant shift with regard to the countries from which people come. Before the 1970s, the majority of immigrants to Canada came from European countries such as the United Kingdom, Italy, Germany, and the Netherlands; however, the proportion of European-born immigrants has continued to decline steadily. By 2006, immigrants born in Asia (including the Middle East) made up 58% of all newcomers to Canada, and in 2011, the top three countries of origin were the Philippines, China, and India, followed by the United States, Pakistan, the United Kingdom, Iran, South Korea, Colombia, and Mexico. Although the majority of immigrants tend to settle in four provinces—Ontario, British Columbia, Quebec, and Alberta—changing demographics are evident across all of the provinces and cities (Statistics Canada, 2013a).

The shift in countries of origin for immigrants has led to increased linguistic and religious diversity, as well as increases in the proportion of newcomers who are also members of visible minorities. The term *visible minority,* as used by Statistics Canada, is defined as "persons, other than Aboriginal persons, who are non-Caucasian in race or non-white in colour" (Statistics Canada, 2013b). In 2011, 1 per 5 people identified themselves as a member of a visible minority. Of this number, approximately one-third were born in Canada, and approximately two-thirds (65%) were born outside the country and came to Canada as immigrants (Statistics Canada, 2013a).

Language diversity has also continued to increase in Canada; nearly 73% of Canadian immigrants have reported a first language other than English or French (Statistics Canada, 2013a). Nearly 200 languages have been reported as first languages, the most frequent being the Chinese languages, Tagalog, Spanish, and Punjabi (Statistics Canada, 2013a).

Another noteworthy trend is the relatively young age of the immigrant population. In 2011, the majority of individuals who had come to Canada since 2006 were between 25 and 54; approximately 20% were children aged 14 and younger; 15% were between the ages of 15 and 24 (Statistics Canada, 2013a). These trends provide insights into the potential health needs that will arise for this population in the coming years.

Although these changing demographics portend new challenges and opportunities in providing health care to a multi-ethnic population, it is important to remember that newcomer status is only one marker of cultural diversity. Indigenous people are the original inhabitants of Canada, but they are not part of the dominant Canadian cultural group. Instead, they are considered a minority group and experience many of the challenges faced by newcomers with regard to language and cultural beliefs in accessing health care (Statistics Canada, 2013b). In addition, the historical legacy of colonization and discrimination has led to social, psychological, and cultural crises in the Indigenous population that necessitate a deeper understanding of the unique challenges for this community,

including the context of colonial policies and practices both past and present (Allan & Smylie, 2015).

Individuals with identities other than Indigenous, immigrant, or visible minority status also experience threats to patient safety and quality care. These include but are not limited to people with nondominant sexual orientation, nondominant gender identity, language disability, low socioeconomic status, and mental or physical disabilities.

The need for culturally appropriate care has been highlighted by increasing evidence of health inequities in these populations and a growing recognition that a lack of cultural competence (a concept discussed in depth later in this chapter) leads to unsafe care. Cultural competence is recognized as a critical attribute for the provision of safe, effective, quality care and an entry to practice level competency for registered nurses in Canada (Canadian Nurses Association, 2010; Douglas, Rosenkoetter, Pacquiao, et al., 2014).

In a culturally diverse nation such as Canada, it is important to recognize that those who differ from the majority are not just different with regard to their values and beliefs, and how they respond in certain situations; being different from the majority or the "norm" also puts them at a disadvantage in terms of power dynamics (Srivastava, 2014). This is discussed later in the chapter.

Health Equity

As discussed in Chapter 1, health status of individuals and communities is influenced by many factors: social, economic, and political. Health equity is an important concept in the pursuit of quality care for all individuals, regardless of their background and socioeconomic status. **Health equity** is present when individuals have the opportunity to achieve their full health potential and is often described as the absence of unfair systems and policies that cause health inequalities (Canadian Medical Association [CMA], 2013). Health equity is concerned with creating equal opportunities for good health for everyone in two ways: (a) decreasing the negative effect of the social determinants of health and (b) by improving services to enhance access and reduce exclusion.

An understanding of health equity requires an understanding of two related but distinct concepts: health inequality and health inequity. **Health inequality** is a broad term that refers to differences in the health status of individuals and groups as a result of factors such as biological and genetic makeup, physical environments, actions of the health care system, and broad social and economic issues (CMA, 2013). **Health inequity** refers to health inequalities that are a result of factors that are generally considered to be *unfair* or *unjust and modifiable* (Public Health Agency of Canada, 2011).

For example, differences in health status that are based on genetics or developmental processes such as aging lead to inequalities in health but are not considered unfair. However, Canadians who live in remote or northern regions do not have the same access to nutritious foods, such as fruits and vegetables, as do other Canadians, and this lack of access to healthy foods results in poor nutrition, which in turn can affect health significantly; this is an example of heath inequity. As a result of inequities in health, groups of people who are already socially disadvantaged (because of socioeconomic status, sex, or membership in a minority racial, ethnic, or religious group) are at further disadvantage with regard to health.

Health Inequities Among Indigenous and Other Marginalized Populations

Indigenous populations in Canada experience many health inequities, as is evident from the significantly higher rates of illnesses such as tuberculosis, diabetes, and cardiovascular disease and by the higher rates of suicide and self-injury among these groups (Wasekeesikawa & Perley-Dutcher, 2013). Many factors contribute to these inequities. Living in remote or northern regions is one potential contributing factor; however, the health of Indigenous Canadians is also affected by the loss of culture, including language and connection to land; by racism and stigmatization; and by loss of connection with Indigenous identity and spirituality (Canadian Institute of Health Research [CIHR], 2015; Wasekeesikawa & Perley-Dutcher, 2013). These losses can be traced back to the history of colonization and policies resulting in cultural destruction and trauma (Allan & Smylie, 2015).

Table 2-1 provides additional examples of some social and health inequities experienced by marginalized populations.

TABLE 2-1

EXAMPLES OF HEALTH INEQUITIES EXPERIENCED BY MARGINALIZED POPULATIONS

- People who experience racial discrimination self-report poor or fair health more often than do those who do not experience it (Levy, Ansara, & Stover, 2013).
- People who reported experiencing racial discrimination were more likely to report depressive symptoms than did people who did not report experiencing racial discrimination (Levy, Ansara, & Stover, 2013).
- Smoking rates are more than two times higher among the three Indigenous groups than among the non-Indigenous population. Indigenous people were also twice as likely to be exposed to second-hand smoke in the home (Gionet & Roshanafshar, 2015).
- Suicide rates are five to seven times higher among Indigenous youth than among non-Indigenous youth. Suicide rates among Indigenous youth are among the highest in the world, at 11 times the national average (Health Canada, 2013).
- Transgendered people experience extremely high levels of depression and suicide. More than half of transgendered people in Ontario have levels of depressive symptoms consistent with clinical depression, and 43% had a history of attempting suicide (Bauer & Scheim, 2015).
- The health of immigrants begins to decline soon after arrival in Canada; "visible minority" status is a statistically significant factor in the decline of immigrant health (Nestel, 2012).

Racialization and health inequities in Toronto. Toronto: Toronto Public Health; and Nestel, S. (2012). *Colour coded health care: The impact of race and racism on Canadians' health.* Toronto: The Wellesley Institute.

Health Literacy

Another factor that can potentially compromise a person's ability to achieve health equity is health literacy. In Canada, **health literacy** is defined as the "ability to access, comprehend, evaluate and communicate information as a way to promote, maintain and improve health in a variety of settings across the life-course" (Public Health Agency of Canada, 2014). This includes being able to access and navigate the health care system. Lack of health literacy has been identified as a significant challenge across a number of population groups, including many cultural communities, and is associated with a variety of poor health outcomes (Kalich, Heinemann, & Ghahari, 2015; Paasche-Orlow, 2011). (Health literacy is discussed further in Chapter 4.)

Equity in Nursing Care

The growing evidence of health inequities across a variety of groups is challenging previous assumptions about how to provide quality health care for everyone in the context of a diverse society. Without cultural competence, patients, families, and communities are at risk for a lack of care or for receiving care that is ineffective or unsafe. A commitment to health equity and social justice, along with a focus on determinants of health, is a key principle for primary health care as well (see Chapter 6). Nurses promote health equity by adopting a social justice approach and providing services that are accessible and devoid of discrimination and prejudice, by removing unnecessary complexity in care, and by developing cross-cultural communication competencies that empower individuals and communities to make informed, effective choices (Paasche-Orlow, 2011).

The importance of health equity has been recognized internationally, and considerable work is happening at both national and provincial levels. Pathways to Health Equity for Aboriginal Peoples is an example of national effort launched by the CIHR (2015). Another example is the development of a health equity impact assessment (HEIA) tool as a decision support tool to help identify how a program, policy, or initiative will affect population groups in different ways. When unintended potential effects are recognized, mitigating strategies can be put in place to reduce the negative and maximize the positive effects (Ontario Ministry of Health and Long Term Care, 2013).

Culture as a Determinant of Health

As discussed in Chapter 1, culture is one of the 12 determinants of health identified by the Public Health Agency of Canada (2013). It is also considered one of the *social* determinants of health, which are linked to the colonial history of Canada and ongoing inequitable social and political structures and systems.

Health and illness are inextricably linked to cultural issues. Culture influences how illness is perceived and experienced, what symptoms are reported, what remedies are sought, and who is consulted in the process (Srivastava, 2007a). The effect of culture on

health is significant and pervasive and can be both positive and negative.

Fowler and Reimer-Kirkham (2012) identified several positive influences of religion and culture, including countering effects of stress and isolation, positive psychosocial and physiological effects of fellowship and community, and finding meaning in illness and suffering. As noted earlier, although loss of cultural identity and supports can produce ill health, experience from the Indigenous communities also highlights the positive relationship between supporting traditions and beliefs of a community and good health (Anderson & Olson, 2013).

Language barriers pose a major threat to patient safety and quality of care (Flores, 2014; King, Desmarais, Lindsay, et al., 2015). The resettlement process for immigrants and refugees presents inherent challenges as these individuals experience difficulties in employment, housing, and access to social support. In addition, such individuals may face health risks from a social environment in which dominant cultural values perpetuate conditions of marginalization, stigmatization, loss or devaluation of language and culture, and lack of access to culturally appropriate diet, activity, and health care services. Disruptions in traditional lifestyles can also lead to greater social exclusion and to increased use of substances such as alcohol, tobacco, and other substances. As a result of cultural differences between patients and health service providers, patients may delay seeking help, health care providers may ignore symptoms that are important to patients, and patients may not follow through with prescribed treatments.

Of importance is that although culture is regarded as a determinant of health, it should not be confused with being the *cause* of inequities; rather the inequities are rooted in the social determinants of health.

Exploring the Concepts: Definitions and Meanings

One of the greatest difficulties associated with developing cultural competence in health care has been a lack of clarity about the meaning of terms such as *culture, cultural competence,* and *cultural safety,* as well as related terms such as *diversity, ethnicity, race,* and *minority.* For example, the term *visible minority* is often used as though it refers to a single group of people, but it actually refers to a wide range of heterogeneous groups whose experiences have been historically different and who hold different positions in the economic and political systems (Nestel, 2012). Terminology related to cultural diversity is subject to multiple interpretations and continues to evolve over time.

Cultural Safety and Cultural Competence

In Canada, both *cultural safety* and *cultural competence* are concepts used to guide the provision of safe, effective, equitable, patient-centred care. Frameworks for both concepts have different origins but have many similarities with regard to key attributes and skills needed by nurses and other health care providers.

The concept of cultural safety is based on the notion of biculturalism and was initially developed in New Zealand to draw attention to the effect of colonization on the health of the indigenous Maori people. **Cultural safety** focuses on the power imbalances that lead to a disregard for health and illness beliefs of the indigenous people and to a privileging of the dominant cultural values. In Canada, the notion of cultural safety continues to be applied largely to health care for Indigenous people. It recognizes the effects of colonization, historical trauma created by forced social assimilation, and the resulting loss of cultural cohesion (Racine, 2014). The extent to which the concept of cultural safety applies to immigrant, refugee, ethnic, and other racialized populations remains unclear.

The call for "culturally competent care" in nursing can be traced back to the 1960s, when Madeleine Leininger advocated for the use of culturally based health knowledge and care to ensure appropriate and effective care for individuals and groups with differences in values, beliefs, explanatory models of illness (discussed later in this chapter), and systems of healing (Srivastava, 2007a).

Some authors view cultural safety as an extension of cultural competence on a continuum, whereby cultural competence is a process and cultural safety is the outcome; others view it as a fundamental paradigm shift that focuses on social and political power and redefines the provider–patient relationship with emphasis on self-determination. Although cultural safety has a greater focus on race relations and on historical and current government practices and policies, both frameworks articulate the need for inclusivity; respect for unique history, traditions, and beliefs of individuals and groups; communicating in culturally appropriate ways; and a recognition of the effect of the broader social determinants of health on individuals, families, and communities.

In this chapter, the term *cultural competence* is used largely because the notion of competence implies acquisition and use of specific knowledge and skills in an intentional way to ensure the provision of quality care. The fundamental tenets underlying culturally competent care are (a) the need to uncover and address one's own assumptions about people and situations; (b) the importance of purposefully seeking out similarities and differences between individuals and groups in order to be responsive to people's varying needs; (c) the importance of addressing the dynamics of difference that lead to unequal social power and social exclusion at the levels of both the individual and the broader system; and (d) promoting inclusivity and self-determination of goals for individuals and communities. These tenets form the basis of the relational approach to cultural care (Srivastava, 2008). Throughout this text, special "Culturally Competent Care" sections highlight knowledge and skills relevant to providing culturally competent health care.

"Culture" and Other Related Terms

The term **culture** is difficult to define. Although many people equate culture with ethnicity, race, country of origin, or religion, this is an erroneous oversimplification. Culture can include many dimensions, including ethnicity, language, religion, sex, socioeconomic class, professional status, age, sexual orientation, group history, and life experiences (Garneau & Pepin, 2015). Culture affects ways of perceiving, behaving in, and evaluating the world, and it serves as a guide for people's values, beliefs, and practices, including those related to health and illness. Culture is not something that belongs to particular individuals; everyone has a culture. Culture exists at the levels of the individual, group, and larger society, and with regard to achieving health equity, the culture of health care providers and the health care system matters as much as the culture of the patient (Srivastava, 2008).

Cultural values are often unconsciously developed and are responsible for many inherent biases, including perceptions of acceptable and unacceptable behaviour. Cultural beliefs and ways of being are often referred to as a **world view.** A world view is a paradigm or a set of assumptions, values, concepts, and practices that influences how people perceive, interpret, and relate to the world around them.

Culture has a number of distinguishing features (Table 2-2 highlights six key characteristics). Although individuals within a cultural group have many similarities through their shared values, beliefs, and practices, there is also much diversity within groups. Individual differences continue to exist, and each person is culturally unique.

TABLE 2-2
KEY CHARACTERISTICS OF CULTURE

Culture is…
• *Learned* through the processes of language acquisition and socialization
• *Shared* by all members of the same cultural group
• *Adapted* to specific conditions such as environmental factors
• *Dynamic* and ever-changing in relation to historical, political, and social conditions
• *Invisible* and often sensed but not seen
• *Selective,* thereby distinguishing members of one group from those of another and differentiating between groups

Source: Adapted from Srivastava, R. (2007). Culture care framework I: Overview and cultural sensitivity. In R. Srivastava (Ed.), *The healthcare professional's guide to clinical cultural competence* (pp. 53–74). Toronto: Elsevier Canada.

Ethnocentrism is a tendency of people to believe that their way of viewing and responding to the world is the most correct, most natural, and superior one. To some extent, this is a universal tendency; each person has the greatest familiarity with and a preference for his or her own way of doing things. However, the conscious or unconscious belief that a particular way is the only way or the best way for everyone is problematic and can cause a person to categorize others' beliefs as unusual, inferior, bizarre, and therefore inappropriate. Ethnocentrism can prevent people from considering alternative perspectives and from respecting others' world views.

Cultural imposition, a closely related concept, is the situation in which a person's own cultural beliefs and practices are, intentionally or unintentionally, imposed on another person or group of people. In health care, it can result in disregarding or trivializing a patient's health beliefs or practices.

Cultural practices change over time through processes such as acculturation. **Acculturation** is a multidimensional process in which individuals and groups undergo stages of adjustment, as well as changes in several domains such as language, socioeconomic status, values, and attitudes (Lopez-Class, Castro, & Ramirez, 2011). This process may be a gradual change that results in increased similarity between two cultures.

Ethnicity refers to characteristics of a group whose members share a common social, cultural, linguistic, or religious heritage and often

implies a geographical or national affiliation (Browne & Varcoe, 2014). **Race** is controversial in that it is both a biological and social construct. The term *race* is sometimes used to highlight biological differences and physical characteristics such as skin colour, bone structure, or blood group. However, the biological basis of race is frequently challenged. Children of mixed-race couples can have varying degrees of skin pigmentation and physical characteristics, and yet all the children of a mixed-race couple share similar genetic makeup and social culture. As a social construct, race has been used to denote superiority and inferiority, whereby the assigned status limits or increases opportunities and leads to assumptions about individuals and groups; thus the social meaning of race is often more important than the biological meaning (Nestel, 2012).

Such categorization or differentiation according to race is described as a process of racialization. **Racialization** is closely linked to discrimination, in which members of a particular cultural group are treated unfairly. Ethnicity and race have an intersectional relationship in that the racial diversity occurs within ethnically defined groups and vice versa, and the effect on health is often interrelated (Nestel, 2012; Veenstra, 2011).

In a large and growing body of research, racism has been linked to poor health (see Nestel, 2012). The effect of racism is multifaceted. Individuals experiencing racism may resort to high-risk behaviours, such as substance abuse, self-harm, or simply delaying seeking health care. Racism can influence physical health by causing chronic, negative emotional states such as anxiety, depression, and diminished self-esteem or identity, which, in turn, can have direct effects on biological processes such as the cardiovascular and immune systems and can increase vulnerability to infections, diabetes, high blood pressure, heart attack, stroke, depression, and aggression (Nestel, 2012). Racism also influences health indirectly through differential exposures and opportunities related to other determinants of health such as education and employment (or affects self-worth when negative messages are internalized).

In **stereotyping,** members of a specific culture, race, or ethnic group are automatically assumed to have characteristics associated with that group, without further exploration of what the individuals

—or, for that matter, what the cultural group itself—are actually like. This oversimplified approach does not take into account individual differences that exist within a culture. Stereotyping can occur with patients or health care providers. In health care, as well as in other settings, being a member of a particular ethnic group does not make the person an expert on other members of that same group. Such stereotyping can lead to false assumptions and negative attitudes that adversely affect a patient's care.

Diversity is another term that is related to culture. For some people, the term simply refers to differences or variations across individuals and social groups, whereas for others, it represents a sum of differences, usually with regard to unequal access to power, privilege, and resources. In general, in the health care context, diversity implies difference from the majority or dominant group that is assumed to be the norm (Srivastava, 2008). Diverse groups and communities, in this context, have marginalized status in society, and diversity initiatives often become synonymous with asserting human rights, freedom from discrimination, social justice, and, more recently, health equity.

Intersectionality is described as a framework for understanding how multiple social identities such as race, gender, sexual orientation, and economic status interact with each other to reflect interlocking systems of privilege and oppression. No single social identity is responsible for these systems; rather, they all interact with each other to create a new unique identity, which results in varying degrees of exclusion and disadvantage (National Collaborating Centre for Healthy Public Policy, 2015; Veenstra, 2011).

Cultural Competence

Cultural competence is a complex concept that has evolved from older terms such as *cultural sensitivity* and *cultural awareness.* Whereas cultural sensitivity and awareness refer to an appreciation of and respect for cultural differences, competence takes the concept one step further and refers to the ability to actually apply knowledge and skill appropriately in interactions with patients. **Cultural competence** is a process that involves the application of knowledge, attitudes, and skills that enhance cross-cultural communication; foster meaningful, respectful interactions with others; and, in so doing, address issues of exclusion that can affect health outcomes. Cultural competence includes valuing diversity, knowing about cultural norms and traditions of the populations being served, and accounting for these differences when care is provided (Douglas, Rosenkoetter, Pacquiao, et al., 2014; Srivastava, 2014).

The International Council of Nurses (2013) noted that nurses demonstrate cultural competence by developing self-awareness without letting it have undue influence on their treatment of patients from other backgrounds, by having knowledge and understanding of a patient's culture, by accepting and respecting cultural differences, and by adapting care to be congruent with a patient's culture. Cultural competence does not mean knowing everything about a particular culture; rather, it is an evolving process that is grounded in knowledge of a number of concepts, reflection, and action (Blanchet-Garneau & Pepin, 2015).

There are many definitions, frameworks, and models of cultural competence, each highlighting a different aspect of culture and attributes of cultural competence (Shen, 2015; Srivastava, 2007a). However, three key domains are evident across these frameworks: (a) an *affective* domain, which reflects an awareness of and sensitivity to cultural values, needs, and biases; (b) a *behavioural* domain, which reflects skills necessary to be effective in cross-cultural encounters; and (c) a *cognitive* domain, which involves cultural knowledge, as well as theory, research, and cross-cultural approaches to care.

Together, these domains can be considered the *ABCs* of cultural competence.

To fully understand the complexities of cultural competence and its relationship to health equity, however, two other domains must also be present. The *dynamics* of difference *(D)* highlights the fact that the effect of difference is based on differences in world views, as well as on the stigma and racism associated with minority group status and social power imbalances. The practice *environment (E)* consists of the context of care and the supports that may or may not be available; the goal of *equity* is assumed as well (Srivastava, 2008). Understanding and actively addressing the dynamics of difference is consistent with nursing role expectations of social justice advocacy. Working towards social justice requires understanding the effect of unequal relationships, being aware of the mechanisms of oppression and systemic bias, and the ability to identify and challenge the inequities that are based on social power.

Figure 2-1 shows the ABCDE framework for cultural competence. Table 2-3 presents examples of attributes that describe the ABC domains of cultural competence. The influence of the dynamics of difference and the environment is evident throughout the affective, behavioural, and cognitive domains and is thus not highlighted separately in the table.

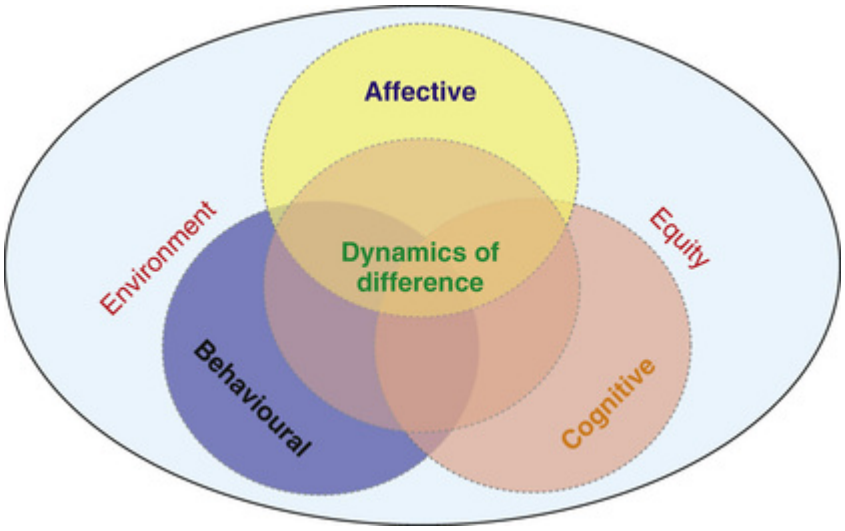

FIGURE 2-1 The ABCDEs of cultural competence. Source: Adapted from Srivastava, R. (2008). The ABC [and DE] of cultural competence in clinical care. *Ethnicity and Inequalities in Health and Social Care, 8*(11), 25–31 (p. 31).

TABLE 2-3
THE ABCS OF CULTURAL COMPETENCE

Component	Description
Affective (Awareness) Domain	
Attitude	• Humility and a recognition of the need for ongoing learning and *un*learning • Genuine curiosity and desire to learn; valuing differences • Nonjudgemental stance in encountering situations and perspectives that are different from those of self or the norm • Commitment to the goal of social justice, inclusivity, and equity
Awareness of self, others, and dynamics of difference	• Self-awareness of values, beliefs, and biases, including unconscious bias • Critical reflexivity to examine and critique own beliefs • Awareness of own social location and privilege • Awareness of challenges with cross-cultural communication • Awareness of cultural influences on information seeking, conflict, and decision making • Recognition of the historical effects of racism and discrimination in society and health care
Behavioural (Skills) Domain	
Assessment	• Ask the correct questions in the correct way (knowing what and knowing how) • Establish trust and health care provider's credibility • Elicit patient's explanatory model of illness • Assess for the effect of social determinants on current situation
Cross-cultural communication	• Determine patient's values, strengths, and goals • Adapt own communication style to address cultural nuances and differences in information processing and decision making • Provide information in ways that are consistent with patient's linguistic and health literacy needs • Become familiar with different communication styles and patterns
Collaborative decision making Empowering and promoting patient choice Advocacy across differences	• Elicit patient's values, preferences, and explanatory models of health and illness • Recognize the need for and make use of interpreters for language support • Accommodate values and preferences and negotiate approaches to obtain mutually agreed-upon goals • Review cultural conflicts as opportunities to learn from differences • Reframe situations to mitigate biases that are held by the health care provider or the patient • Promote health literacy • Support informed patient choices
Development of resources (personal and organizational) to support practice	• Identify own privilege and use it appropriately to further goals of equity • Recognize and address the dynamics of difference at patient–clinician level and at patient–health care system level • Connect patients with resources within their community to promote greater autonomy and self-management • Explore opportunities to partner with and learn from colleagues, patients, and communities that are culturally different from self or own • Seek information on different cultural groups through the internet, media, movies, and visits to cultural and community centres • Seek out the insider cultural perspectives and meanings of events and traditions • Develop relationship with service agencies that support health for specific cultural groups and communities
Cognitive (Knowledge) Domain	

Component	Description
Generic cultural knowledge	• Understand the effect of culture on health and health seeking behaviours • Understand the difference between individualistic and collectivist cultures • Recognize dimensions of care that are likely to be influenced by culture in a particular setting (e.g., end-of-life care) • Identify bio-physiological determinants of health and illness in minority groups • Identify social determinants of health: effects of race, culture, health status, employment, and so forth • Understand health disparities and health equity issues • Identify the effect of health policy on culturally diverse groups, particularly those whose members are economically disadvantaged • Understand the effect of diversity on team functioning
Specific cultural knowledge	• Develop in-depth knowledge of particular communities served, including religious and cultural beliefs and traditions; cultural strengths and resources; and health inequities particular to the group or groups, such as issues of access to health care, congruence of health care with the culture, and incidence and prevalence of major illnesses • Learn about commonly held world views and healing traditions • Identify the effect of life events such as migration, settlement, and racism • Review the care process for own clinical specialty and identify processes and treatments that are particularly susceptible to cultural differences • Do not make assumptions on the basis of cultural background; instead, use knowledge as a beginning point for further assessment and inquiry

K., Rosenkoetter, M., Pacquiao, D. F., et al. (2014). Guidelines for implementing culturally competent nursing care. *Journal of Transcultural Nursing*, *25*(2), 109–121. doi:10.1177/1043659614520998.

Affective Domain

The affective domain of cultural competence is concerned with both attitude and awareness. This domain is often seen as the first step toward achieving cultural competence. Openness, a desire to learn, valuing differences, respect for others, and developing humility are characteristic of this domain (Douglas, Rosenkoetter, Pacquiao, et al., 2014; Srivastava, 2014). This domain is characterized by acceptance of the notion of multiple world views and norms and by the recognition that no one way is universally beneficial.

Cultural awareness is a conscious learning process in which individuals become appreciative of and sensitive to their own culture, as well as the cultures of other people. Awareness can be subcategorized into three components: self-awareness, awareness of others, and awareness of the dynamics of difference (see the "Dynamics of Difference" section later in this chapter). Every person

is a cultural being; therefore, any nurse–patient interaction is affected by the cultures of both the nurse and the patient. The nurse is influenced by his or her cultural background, by the culture of the nursing profession, and by the culture of the health care setting in which the interaction occurs.

The first step in developing cultural awareness is for the nurse to examine his or her own biases toward people from different cultures. Identifying how these views may influence the care encounter is a critical step in recognizing ethnocentrism and avoiding cultural imposition. Development of self-awareness requires the nurse to engage in ongoing critical self-reflection and being amenable to feedback from other people (see the "Nurse's Self-Assessment" section later in this chapter). Awareness of other people as cultural beings is based on recognition of multiple world views and norms. Cultural differences are not issues of right or wrong; they are simply about being different.

Behavioural Domain

The behavioural domain concerns the actual application of knowledge and awareness and is also described as cultural skill. Through the intentional use of these skills, the health care provider can determine the most appropriate goals and interventions by performing a comprehensive assessment of not only patients' complaints and symptoms but also their values, beliefs, and practices. Different cultural groups have different beliefs about the causes of illness and the appropriateness of various treatments. It is important for the nurse to try to determine the patient's **explanatory model** (set of beliefs regarding what causes the disease or illness and the methods that would potentially treat the condition best). It is also important to determine how experiences and beliefs affect health-seeking behaviours. Table 2-4 lists key questions that can be used to learn about the patient's explanatory model of illness and care. These questions do not have to be asked in the order they are listed, and they can be adapted to the situation. Through these questions, nurses can identify cultural values and beliefs that are important to the patient in a given situation (College of Nurses of Ontario, 2009).

TABLE 2-4

QUESTIONS FOR DETERMINING THE PATIENT'S EXPLANATORY MODEL OF ILLNESS AND CARE

1. "What do you call the problem?"
2. "What do you think has caused the problem?"
3. "Why do you think it started when it did?"
4. "What do you think the sickness or illness does to you? How does it work?"
5. "How severe is the sickness? Will it have a long or short course?"
6. "What are the major problems or difficulties this sickness has caused in your life?"
7. "What have you done for this problem up to now?"
8. "What kind of treatment do you think you should receive?"
9. "What are the most important results you hope to achieve from the treatment?"
10. "What do you fear most about the sickness?"
11. "What do you fear most about the treatment?"
12. "Who else should be consulted or involved in your care?"

Source: From Srivastava, R. (2007). Culture care framework I: Overview and cultural sensitivity. In R. Srivastava (Ed.), *The healthcare professional's guide to clinical cultural competence* (p. 89). Toronto: Elsevier Canada. Adapted from Kleinman, A., Eisenberg, L., & Goode, B. (1978). Culture, illness, and care: Clinical lessons from anthropologic and cross cultural research. *Annals of Internal Medicine, 88,* 251–258.

The behavioural or skills domain is complex and requires competency in awareness, knowledge, and application of the generalized awareness of cultural issues to specific clinical situations.

Cross-Cultural Communication.

Communication is foundational for every aspect of the clinical encounter; therefore, cross-cultural communication is a key area in which to develop cultural skill (see Table 2-3). Cultural differences are often cited as a barrier to effective communication, leading to poor adherence to regimens, dissatisfaction with care, and adverse health outcomes (Flores, 2014; King, Desmarais, Lindsay, et al., 2015). Culturally safe communication that includes communication of cultural understanding and respect is an essential tool in forming a therapeutic relationship with the client. It is critical for establishing trust, for informed consent, for decision making, for ability to partner in care, and for self-management of chronic illnesses

(Canadian Nurses Association, 2010; International Council of Nurses, 2013).

Verbal and Nonverbal Communication.

Cultural influences on communication are evident in both verbal and nonverbal communication. Verbal communication includes not only the language or dialect but also the voice tone, volume, timing, and a person's willingness to share thoughts and feelings. Nonverbal communication includes eye contact, use of touch, body language, style of greeting, and the spatial arrangement taken up by the participants. Culture influences the ways that feelings are expressed, as well as which verbal and nonverbal expressions are appropriate in given situations.

Nonverbal communication includes silence, touch, and eye contact, and the norms vary across cultures. For example, many Indigenous people are comfortable with silence and interpret silence as essential for thinking and carefully considering a response. In these interactions, silence shows respect for the other person and demonstrates the importance of the remarks. In traditional Japanese and Chinese cultures, the speaker may stop talking and leave a period of silence for the listener to think about what has been said before continuing. In other cultures (e.g., French, Spanish, and Russian), silence may be interpreted as meaning agreement.

Although nurses are often taught to maintain direct eye contact, patients who are Asian, Arab, or Indigenous may avoid direct eye contact and consider direct eye contact disrespectful or aggressive. Other factors to consider include the role of sex, age, status, or position on what is considered to be appropriate eye contact. For example, Muslim-Arab women avoid eye contact with men other than their husbands and when in public situations in order to exhibit modesty.

The degree of physical contact and touch, across gender and age varies across cultures. In certain cultures (e.g., Muslim), health care providers may be prohibited from touching patients of the opposite sex (Marcus, 2016). Many Asians believe that touching a person's head is a sign of disrespect, especially because the head is believed to be the source of a person's strength. Observing how a patient

interacts with others and asking permission to touch before touching are appropriate ways of respecting the patient's cultural values.

Culturally Competent Care

Communication Skills

It is not sufficient for nurses to simply learn about cross-cultural communication issues; they must also develop and adapt their communication skills to connect with different cultural groups (see Table 2-3). Some groups may respond effectively to direct questions, whereas others respond more comfortably in interactions that are less direct. For example, instead of telling a person what to do, a nurse may phrase the teaching in a less directive way: "Many people who experience this illness find it helpful to do. …" Nurses must understand that when a patient says, "Yes," it can have multiple interpretations, including "Go on," "I hear you," "I understand," or "I agree." Understanding and agreement must be validated through other means.

Negotiation skills are also important in cultural competence because nurses are often required to negotiate interventions and goals that range along the gamut of mainstream and traditional ways of healing.

Providing Effective Language Support.

Providing effective language support through the use of language aids, including interpreters, is essential for patient safety. Nurses and other health care providers often feel that they can get by without interpreters by using a few words in the patient's language and actions to demonstrate meaning; however, this is a fallacy and compromises quality care. Nurses must identify encounters where linguistic support is required through trained interpreters, seek out appropriate supports and demonstrate the abilities to effectively work with interpreters (International Council of Nurses, 2013). Table 2-5 lists strategies for working effectively with interpreters, and Table 2-6 lists strategies for communicating with patients with limited proficiency in English.

TABLE 2-5
WORKING EFFECTIVELY WITH INTERPRETERS

General Considerations

• If possible, the interpreter should meet with the patient ahead of time to establish rapport before the interpreting begins.
• Allow extra time for the session.
• Use trained bilingual–bicultural interpreters instead of the patient's family or children.
• Consider personal attributes of the interpreter such as age, gender, ethnicity, and dialect that may influence communication; use the services of an agency interpreter if possible.
• Be aware of common issues such as the following:
  • Words that cannot be translated
  • Being too rushed
  • The interpreter's answering for the patient
  • Conflict between the interpreter and the patient (if this occurs, stop the session immediately)
• Verify translations to avoid misunderstandings, mistakes, and distortions.

Before the Interpretation Session
• Get to know the interpreter. • Provide an overview of the situation (patient, goals, and procedures). • Ask for concerns or issues from the interpreter's perspective. • Remind interpreter to interpret *everything.* • Ask the interpreter to share his or her cultural insights with you but to differentiate these from the interpretation itself. • Reinforce confidentiality.
During the Interpretation Session
• Face the patient directly. • Speak in the first person. • Introduce yourself, allowing the interpreter to interpret. • Describe the role of the interpreter, the interpreter service's mandate, and the purpose of the session. • Ask the interpreter to introduce himself or herself and his or her role in both languages. • Address questions to the patient, not to the interpreter. • Use simple language, and avoid jargon and technical terminology. • Speak in one- to two-sentence bursts to allow for easier translation. • Ensure that the interpreter understands what is to be translated. • Allow the interpreter to ask open-ended questions if necessary to clarify what the patient says. • Observe the patient for off-target reactions (signalling mistakes in interpretation). • Observe and evaluate what is going on before you interrupt the interpreter.
After the Interpretation Session and Follow-Up Strategies
• Consider providing written instructions as appropriate. • Ask the patient whether he or she has anything to ask or convey. • Provide information on how the patient may request an interpreter's services in the future. • Discuss the process and outcomes of the session with the interpreter.

TABLE 2-6

COMMUNICATING WITH PATIENTS WITH LIMITED ENGLISH PROFICIENCY

1. Be polite and formal.
2. Gesture to yourself and say your name, offering a handshake, nod, smile, or other greeting. If possible, greet patient in the patient's preferred language. This indicates that you are aware of and respect the patient's culture.
3. Proceed in an unhurried manner. Pay attention to any effort by the patient or family to communicate.
4. Speak in a low, moderate voice. Avoid talking loudly. Remember that there is a tendency to raise the volume and pitch of your voice when the listener appears not to understand. The listener may perceive that you are shouting or angry, or both.
5. Use simple words, such as "pain" instead of "discomfort." Avoid medical jargon, idioms, and slang. Avoid using contractions (e.g., "don't," "can't," "won't"). Use nouns repeatedly instead of pronouns. For example:
    - Do not say: "He has been taking his medicine, hasn't he?"
    - Do say: "Does Ahmad take medicine?"
6. Pantomime words and simple actions while you verbalize them.
7. Organize what you say, giving information and instructions in the proper sequence. For example:
    - Do not say: "Before you rinse the bottle, sterilize it."
    - Do say: "First, wash the bottle. Second, rinse the bottle."
8. Discuss one topic at a time. Avoid using conjunctions. For example:
    - Do not say: "Are you cold and in pain?"
    - Do say: "Are you cold [while pantomiming]? [Wait for patient's response.] Are you in pain?"
9. Validate understanding by having the patient repeat instructions, demonstrate the procedure, or act out the meaning.
10. Do not ask questions that can be answered with only "yes" or "no."
11. Summarize often, including your understanding of what the person is saying and checking whether your understanding is correct.

Source: Data from Jarvis, C., & Browne, A. J. (2014). *The interview*. In C. Jarvis, A. J. Brown, J. MacDonald-Jenkins, et al. (Eds.), *Physical examination and health assessment* (2nd Canadian ed.). Toronto: Elsevier; and from Srivastava, R. (2007). Culture care framework I: Overview and cultural sensitivity. In R. Srivastava (Ed.), *The healthcare professional's guide to clinical cultural competence* (pp. 53–74). Toronto: Elsevier Canada.

Although in-person interpretation by trained health care interpreters is considered optimal, organizations and individuals can often use technology-aided solutions such as telephone or remote interpretation. Caution is needed for using smart phones and applications such as Google Translate because they can pose risks to accuracy and thus patient safety, and such translation must be carefully validated (Flores, 2014).

Cognitive Domain

Cultural knowledge is a crucial element of cultural competence. To provide culturally competent care, nurses must identify and seek out the cultural knowledge they need (see Table 2-3). Cultural knowledge can be divided into two categories: generic cultural knowledge and specific cultural knowledge (Fung, Lo, Srivastava, et al., 2012).

Generic cultural knowledge is foundational knowledge that applies across a variety of cultural groups. The most fundamental aspect of generic cultural knowledge is understanding the effect of culture on health- and illness-related behaviours. Generic knowledge can be broken down into several broad areas that nurses should be aware of, such as variations in world views and explanatory models of illness; beliefs about care, cure, caregivers, and healing systems; family roles and relationships; migration and settlement; norms about time and personal space; and spirituality and religion. These areas are discussed in greater detail in the following section.

Specific cultural knowledge focuses on learning about the particular cultural population that the nurse is working with. Because of the number of cultural groups in Canada, a detailed discussion of specific cultural knowledge is beyond the scope of this chapter. Nurses should educate themselves (see Table 2-3) about specific cultures they encounter frequently in their practice and always be amenable to learning more as circumstances require. For example, if the nurse is working in a community with large numbers of South Asian and Chinese people, it is important to learn more about the beliefs and issues relevant to these communities. Nurses working with the Indigenous community need to acquire deeper understanding of the legacy of residential schools and the associated trauma. Other examples of specific cultural knowledge include focusing on specific health issues faced by particular populations, such as immigrant women or the transgendered community (Srivastava, 2007a). (Table 2-3 lists other attributes of this component of cultural competence.)

In addition to determining the kind of generic and specific knowledge that is needed, nurses must critically appraise how knowledge is developed and used. Culture is concerned with shared patterns, not universal truths. Therefore, cultural knowledge should

not be used to obscure individual differences. Individualized assessments are important to determine the extent to which the patient shares the beliefs and practices ascribed to the culture. Familiarity with cultural norms is helpful but should be used cautiously, inasmuch as it may lead to cultural stereotyping. It is important for nurses to reflect on how they acquired the knowledge and the extent to which the knowledge is unique to the individual, reflective of the broader cultural group, or reflective of cultural processes in general. It is also important to treat cultural knowledge as tentative hypotheses that can be verified and expanded upon by the patients and families.

Generic Cultural Knowledge

Care, Cure, Caregivers, and Healing Systems.

Cultural norms have a significant influence on how illness is understood, what remedies are deemed appropriate and desirable, and who provides the care. Whereas in some cultures patients seek professional help, others rely more on family, friends, or spiritual and religious leaders. It is important to ascertain a patient's beliefs about the cause of illness, as well as perceptions of severity, expected treatment, prognosis, and effects (see Table 2-4).

Canadian health care systems and health professions also have a cultural basis in the dominant white, Eurocentric culture. The biomedical approach to health care, although regarded as the conventional treatment in North America, is one of several philosophical and scientifically based systems of healing. Other such systems include homeopathy, traditional Chinese medicine, Indigenous medicine, and Ayurvedic medicine (a form of traditional Hindu medicine). Although it is not possible for a health care provider to have expertise in all the healing systems, familiarity with the major systems and with their basic principles can be helpful. Individuals often use multiple healing systems, and a critical part of patient assessment is knowledge of what conventional treatments, as well as other folk or herbal treatments, are being used. Nurses need to understand their role in supporting and providing complementary and alternative therapy (College of Nurses of

Ontario, 2014). Complementary and alternative therapies are further discussed in Chapter 12.

The Canadian approach to health care delivery is often team-based; different members of the team have different roles, and boundaries with regard to who does what are often very clear. In many cultures, people are used to having a single authoritative healer and may regard others as helpers (Srivastava, Srivastava, & Srivastava, 2012). Lack of familiarity with roles and mistrust can jeopardize patient safety because information may not be disclosed or shared appropriately with the health care team.

Help seeking is also influenced by system factors, some of which are presented in Table 2-7.

TABLE 2-7

CULTURAL AND SYSTEM FACTORS AFFECTING HELP SEEKING

Economic Factors
• Patients may not obtain health care because they cannot pay the costs associated with travel for health care, medications, or treatments. • Patients may lack health insurance.
Health Care System
• Patients may not make or keep appointments because of the time lag between the onset of an illness and an available appointment. • Hours of operation of health care facilities may not accommodate patients' work schedules or need to use public transportation. • Patients may be relying on friends and family for transportation, language support, or navigation within the system. • Lack of culturally sensitive health care programs and approaches may deter people from seeking health care. • Patients may not have a primary care provider and thus use emergency departments for health care. • Patients may lack knowledge about the availability of existing health care resources and may not know how to navigate the health care system.
Beliefs and Practices
• Care provided in established health care programs may not be perceived as culturally relevant. • Patients may delay seeking care because of mistrust or because of a preference for folk medicine and herbal remedies. • Dietary preferences may affect adherence to specific therapeutic diets. • Patients may stop treatment or discontinue visits for health care because the symptoms are no longer present and they thus perceive that further care is not required. • Patients may have negative associations with hospitals and extended-care facilities, such as death or abandonment. • Patients may have prior negative experience with culturally insensitive health care providers or discriminatory practices. • Patients may mistrust the dominant population and institutions.

Culturally Competent Care

Clock Time

Patient values regarding time orientation and personal space can also affect the care delivery process. Health care providers in hospitals and clinics are often frustrated because many patients show up late for appointments and seem to have no regard for appointments and schedules. In reality, this may be a result of several factors, including issues of transportation, ability to navigate the health care system, and time orientation. The value of clock time and punctuality is different across cultures. In collectivist cultures—that is, cultures in which the relationships and interconnectedness between people are valued over the needs of the individual—it is often more important to attend to a social role than to arrive on time for an appointment with a health care provider. Hence, the lack of adherence to the appointment time can be attributed to competing demands, and a lack of appreciation for punctuality and should not be interpreted as a blatant disregard or disrespect for the health care providers or the system.

Biology, Physiology, and Pharmacology.

The racial and ethnic influences on biological and physiological processes are often viewed as controversial because these influences are considered more to be social categories than scientific categories. However, clinical realities should not be ignored. Gender differences exist in the prevalence of illness, expression of illness, and response to pharmaceutical agents. The occurrence of certain diseases in different racial and ethnic populations is also different. However, it is important to note that when an illness is prevalent in a particular culture, neither the individual nor the cultural background is the cause of illness; rather, the broader determinants of health must be assessed to understand and address disparities.

Genetic predisposition also varies across racial and ethnic lines. For example, sickle cell disease is a common genetic disorder among people of African descent. By being aware of such illness incidences,

health care providers can perform a focused and thorough assessment and can avoid stereotypical assumptions (e.g., that an Indigenous patient is a "drunken Indian" when the real issue is diabetic ketoacidosis, or that a young Black man is a drug addict when really he is experiencing pain from sickle cell disease). Having knowledge of increased vulnerability can enhance clinical decision making and prevent misdiagnosis or unnecessary delays that lead to poor care.

There is increasing evidence that ethnicity influences responses to certain medications. These variations are a result of physiological and pathophysiological differences; pharmacogenetics and genetics; environmental factors such as diet, nutritional status, smoking, and alcohol use; and simultaneous use of herbal remedies (Ramamoorthy, Pacanowski, Bull, et al., 2015). Some European and African patients metabolize drugs at a slower rate, which leads to high drug levels, whereas some Japanese and Indigenous patients metabolize drugs more quickly. Differences in rates of metabolism mean that individuals from Japan, China, Thailand, and Malaysia require lower doses of drugs such as codeine than does a European person.

Differential response has also been documented for drug classifications such as antihypertensive, antipsychotic, and antianxiety agents. In general, Black persons respond better to diuretics than to beta blockers and angiotensin-converting enzyme (ACE) inhibitors; Chinese patients require lower doses of antipsychotic drugs; and Japanese patients require lower doses of antimanic agents (Lilley, Harrington, Snyder, et al., 2010). Although some drugs may have population-specific recommendations, it is important for nurses to be vigilant to variations in dosage response and side effects. For nurses working in particular specialty areas, it is important to learn about the ethnocultural variations in response to the particular classification of medications commonly taken by their clinical population.

Family Roles and Relationships.

Family structures and roles differ from one culture to another (Figure 2-2). For this reason, it is important for the nurse to

determine who should be involved in the communication and decision making related to health care. For example, individualistic cultures emphasize individual rights, goals, and needs, whereas collectivist cultures assign greater priority to the needs of the group (family or community), and there is an emphasis on interdependence rather than independence (Carteret, 2011). In countries such as Canada and the United States, people hold strong beliefs related to autonomy, and each adult individual is expected to make decisions and sign consent forms when receiving health care. In contrast, in Asian cultures, the head of the household or the eldest son is expected to make health care decisions. In collectivist cultures, including Indigenous communities, affiliation is valued over confrontation, and cooperation is preferred to competition. When the nurse encounters a family that values collectivity over individualism, conflicts may arise in how decisions are made. There may be a delay in treatment while the patient waits for significant family members to arrive before giving consent for a procedure or treatment. In other instances, the patient may make a decision that is best for the family but may have negative or adverse consequences for the patient. By being aware of such values, the nurse is better prepared to advocate for and support the patient.

FIGURE 2-2 Family roles and relationships differ from one culture to another. Source: Shutterstock.com.

Expectations regarding caregiving also vary across cultures. In Asian and Latin American cultures, caregiving is seen as a duty, and it is often deemed unacceptable to place the responsibility of care in the hands of strangers (Pharr, Francis, Terry, et al., 2014). The same expectations do not hold for European families. Thus it is important for nurses to understand and support caregiver burden from a cultural perspective.

Spirituality and Religion.

Spirituality and religion are aspects of culture that may affect a person's beliefs and decisions about health and illness. *Spirituality* commonly refers to a person's efforts to find purpose, meaning, and a sense of belonging (Camp, 2011; Taylor, 2012). *Religion* is a more formal and organized system of beliefs, including belief in or worship of God, and involves prayer and one or more rituals. Religion is based on beliefs about life, death, good and evil, and pain and suffering. Religious and spiritual beliefs have been shown to positively influence health outcomes, particularly in the care of patients with mental health and addiction issues (Camp, 2011). It is important for health care providers to understand the role of

religion, spirituality, and culture in health and illness. For some ethnocultural groups, culture, spirituality, and religion are inseparable. For example, the Indigenous culture and way of life are entwined with the religious and spiritual beliefs, and these extend to health and wellness. Similarly, Hinduism is as much a way of life as it is a religion and is also associated with a healing system that may influence perceptions of care and cure (Srivastava, Srivastava, & Srivastava, 2012). Many people differentiate between spirituality and religion and may identify with being spiritual but may not be religious.

Nurses can use many interventions to meet a patient's spiritual and religious needs. These interventions include use of prayer, scriptures, listening, and referral. Attention to spirituality is an important aspect of holistic care throughout the life span; however, it can take on increasing significance in end-of-life care, inasmuch as this is often a time when patients reaffirm their beliefs.

It is also important for nurses to be aware of their own assumptions about spirituality and religion and how they may differ from patients. Not all religions have the same end goals and may, in fact, vary greatly in their central theological questions and objectives (Fowler, 2012). Concepts such as "sin" and "heaven" may be central to Christian theological understanding but are not central concerns in religions such as Buddhism and Hinduism. Even the relationship between the mind, body, and spirit varies among religions (Srivastava, Srivastava, & Srivastava, 2012). It is therefore important to ascertain what religion and spirituality means to particular individuals and groups, how it may affect health and wellness, and the nurses' role in offering support.

Migration and Settlement.

Understanding the influence of migration and resettlement processes on health is another area of generic cultural knowledge. Research indicates that new immigrants tend to be in better overall health than the general resident population. This finding, known as the *healthy immigrant effect*, is not surprising inasmuch as immigrants are screened before being granted admittance to Canada. However, this advantage does not last, and even after 20 years in the country, the

health of immigrants, as determined by age-standardized mortality rates, is generally poorer than those of the Canadian-born population (Pottie, Greenway, Feightner, et al., 2011). In a systematic review, Vang, Sigouin, Flenon, and colleagues (2015) noted that the healthy immigrant effect is linked to immigrants' duration of residence in the country and appears to be strongest during adulthood but less so during childhood, adolescence, and late life.

Recent immigrants are at risk for health problems for many reasons. The settlement process is associated with many losses and can cause physical stress and mental distress. New immigrants often experience challenges in areas of the social determinants such as employment, housing, social support, and access to services. They are also at risk for social exclusion through underemployment, workplace stress, and unemployment. Older immigrants are especially affected by changes in role, social position, and potentially social isolation in a new country. Factors such as fatigue, stress, and racism—and, for refugees, premigratory circumstances—can result in serious physical and psychological trauma. Many newcomers face difficulties in accessing the health care system because of a lack of familiarity with the system, limited language proficiency, transportation difficulties, or inability to take time away from other responsibilities related to work and family (Kalich, Heinemann, & Ghahari, 2015). However, not all differences in access are limited by socioeconomic and language difficulties. Roberts (2012) pointed out that immigrant women access health care differently than men, on the basis of their desire to seek health care versus medical care and their use of family and community-based networks as guides.

Dynamics of Difference

In the ABCDE framework, *dynamics of difference* is not a distinctly separate domain; rather, it is evident across the ABC domains. The dynamics of difference must be understood at two levels: (a) the nurse–patient level, and (b) the patient–health care system level (Srivastava, 2014). Power differences exist in all nurse–patient relationships; however, these can be magnified, often through unconscious bias, when clinicians and clients belong to different

cultural groups. To ensure that clients' rights and autonomy are respected, it is important for health care providers to be aware of their own biases and to be vigilant for processes that can be marginalizing. At the system level, understanding the dynamics of difference means understanding the effect of systematic oppression and institutional racism.

Understanding the effect of colonization and other social determinants of health (including historical trauma, racism, discrimination, and culturally destructive processes such as residential schools for Indigenous communities) helps shape awareness of how differences matter, and which differences matter more than others in particular contexts (Allan & Smylie, 2015). Demonstrating cultural competence means understanding and navigating power dynamics at both levels. Specific actions to address the dynamics of difference are outlined throughout Table 2-3.

Critical self-reflection and attention to the dynamics of difference, as well as cultural similarities and differences between the patient's culture and that of the health care provider, are essential for providing care that is truly patient centred (Douglas, Rosenkoetter, Pacquiao, et al., 2014; Srivastava, 2014).

Environment and Equity

In the ABCDE framework, *environment* and *equity* do not refer to a separate domain; rather, they refer to the importance of the context of care and the goal of equity. *Environment* highlights the importance of understanding, developing, and utilizing resources at the individual and organizational levels for ongoing learning, consultation, and referral (Fung, Lo, Srivastava, et al., 2012; Douglas et al., 2014). Examples of such resources include colleagues who can share experience and expertise in cross-cultural care; language support aids such as interpreters or telephonic services; information and education about the people and communities served; and access to spiritual and faith leaders.

Understanding the Difference Between Equity and Equality

Equity refers to the goal of health equity or quality care for all. Health care providers need to embrace the concept of health equity and understand the difference between equity and equality. The concept of equality refers to sameness in *process* (e.g., everyone gets the same treatment). That of equity, on the other hand, focuses on sameness in *outcomes.* To achieve equality in outcomes, people need to be treated differently—according to their needs.

Imagine three people of different heights trying to see over a 4-ft (122-cm) fence to watch a ball game. Kyle is an adult, 6 ft (183 cm) in height; Larry is a teenager, 4 ft (122 cm) in height; and Michael is a child who is 2.5 ft (76 cm) in height. As a way of providing support for onlookers, the park provides 12-inch crates on which people can stand on to see over the fence.

In a system in which equality is the driving principle, each person gets one crate to stand on. As a result, Kyle, who is able to see over the fence with no difficulty, is even taller; Larry, who is able to see if he stood on tip-toe, can now stand on the crate and see the game more comfortably. But Michael, even with the crate, still reaches 6 inches (15 cm) below the top of the fence and therefore is still not able to see the game. The outcome is not much different than before the crates were provided, except for some benefit to Larry. The return on investment of crates is minimal, and the crate for both Kyle and Michael is a wasted resource.

In a system in which equity is the driving force, the resource of the three crates is distributed according to need. Kyle does not receive a crate to stand on, Larry gets one crate, and Michael gets two crates. The outcome is that all three individuals are able to see over the fence comfortably (Figure 2-3).

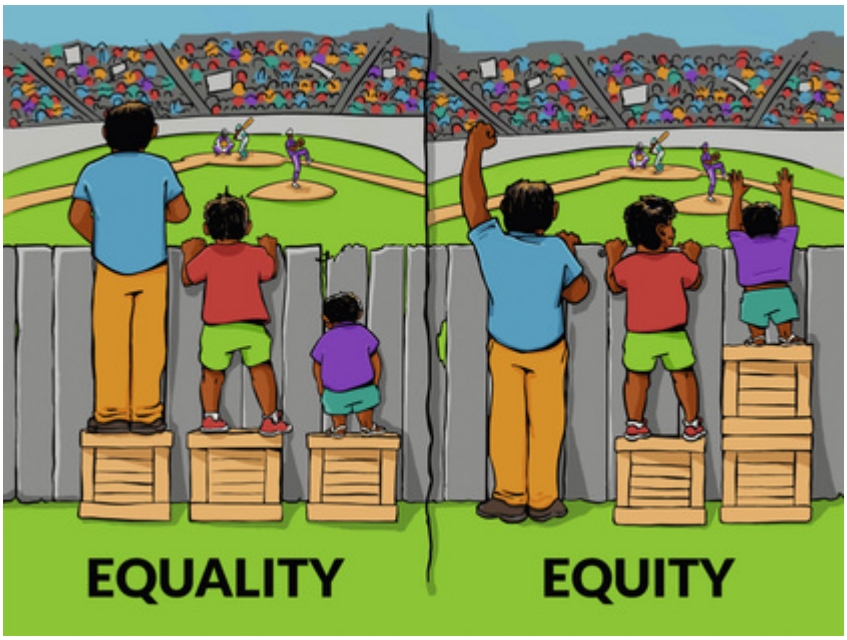

FIGURE 2-3 Illustration of the difference between equity and equality. Source: Interaction Institute for Social Change/Artist: Angus Maguire. *interactioninstitute.org*, *madewithangus.com*.

In the first scenario of resource distribution according to the principle of equality, everyone is assumed to be in the same situation and to have the same needs. This is simply not true. Differences in race, gender, income, and other factors means individuals vary in the strengths and needs they bring to every interaction. When these are recognized, interventions can be targeted on the basis of need. The result is optimal outcome with minimal waste.

Nurse's Self-Assessment

Developing an understanding of one's own culture through reflection and self-assessment is a crucial first step toward cultural competence in clinical care. Evidence indicates that health care providers' attitudes, whether they are conscious of them or not, have a significant influence on their interactions with other people (Browne & Varcoe, 2014; Srivastava, 2007b). Self-awareness includes being aware of one's motivation and the value that one places on cultural competence. Is the motivation purely to avoid problems for the health care provider, or is there genuine desire to learn from differences and achieve equity in health for everyone? In the interest of striving for the latter, nurses must recognize both conscious and unconscious bias that may exist at the personal, interpersonal, or organizational level. Many tools are available to assist in this process (Registered Nurses' Association of Ontario, 2007). For example, Harvard University researchers have developed the Implicit Association Test (IAT) (see the Resources at the end of this chapter), a measure of attitudes and beliefs that people may not even know exist within themselves (Banaji & Greenwald, 2013).

Culturally Competent Patient Assessment

A cultural assessment should be a fundamental part of all patient assessments. Conducting a cultural assessment means asking key questions with regard to language, diet, religion, and acculturation and eliciting the patient's explanatory model of health and illness (see Table 2-4).

A patient assessment achieves cultural competence not only through the questions that are asked but also through the use of cultural knowledge and skill to determine when and how to explore particular issues. It is critical to build trust by adopting an approach that conveys respect, a nonjudgemental attitude, and genuine curiosity to understand the patient perspective. Many health care processes require close physical contact, discussions of an intimate nature, or both; thus personal boundaries can be particularly significant with regard to a patient's disclosures and cooperation with activities. Issues concerning personal space and gender often surface during activities involving physical assessment and personal care. Health care providers must use sensitivity in talking with patients to find approaches that best fit the patients' health care needs and personal preferences.

Table 2-8 summarizes nursing actions that are part of a culturally competent health assessment.

TABLE 2-8
CULTURALLY COMPETENT HEALTH ASSESSMENT

- Become aware of your own values, beliefs, and biases.
- Develop humility and a critical awareness that your own expertise is probably ethnocentric.
- Know that racism, heterosexism, classism, sexism, genderism, ageism, ableism, and so forth, are taught, not innate, and that the unlearning process is ongoing.
- Perceive patients/consumers as experts of their own realities.
- Work to build trust.
- Communicate in ways that are nonjudgemental and show respect for differences.
- Use open-ended questions to understand patients' priorities and perceptions.
- Pay attention to the economic and social contexts of patients' and families' lives.
- Inquire about health beliefs, practices, and help-seeking behaviours.
- Inquire about the role of religion and spirituality in health and illness.
- Identify sources of support cultural support (friends, family, community).
- Advocate with and for patients, and learn how to be an ally across diversity and oppression.
- Challenge discrimination, marginalization, and oppression.
- Assist patients in becoming informed, knowledgeable, and empowered.
- Embrace learning as an ongoing process.

Bridging Cultural Distances: The LEARN Model

Key characteristics of cultural competence are the ability to effectively apply the ABCDEs of cultural competence: cultural awareness, knowledge, and skills in clinical situations; the ability to keep in mind the dynamics of difference; supports available through the practice environment; and the goal of equity. Throughout this chapter, strategies that can be used to bridge gaps and differences across cultures have been discussed. One model useful for summarizing this discussion is the LEARN (**l**isten, **e**xplain, **a**cknowledge, **r**ecommend, and **n**egotiate) model (Table 2-9) which offers simple but comprehensive guidelines for cross-cultural health care.

TABLE 2-9
LEARN MODEL FOR CROSS-CULTURAL CARE

Listen with sympathy and understanding to the patient's perception of the problem.
Explain your perception of the problem.
Acknowledge and discuss the differences and similarities.
Recommend treatment.
Negotiate agreement.

Source: Berlin, E. A., & Fowkes, W. C., Jr. (1983). A teaching framework for cross-cultural health care—Application in family practice in cross-cultural medicine. *The Western Journal of Medicine, 12*(139), 93–98.

The LEARN model enables the nurse to reveal and acknowledge patients' values and perspectives and practice in a professional manner by sharing his or her expertise. By listening first, the nurse is less likely to give the impression of being hurried or too busy and will be able to tailor explanations in ways that are relevant for the patient.

Working in Diverse Teams

Interactions between patients and health care providers are not the only situations in which cross-cultural issues and challenges can arise. The increasing diversity in society also affects the makeup of the health care team (Figure 2-4).

FIGURE 2-4 Nurses working together in a multicultural health environment. Source: Sean Locke Photography/Shutterstock.com.

In general, workforce diversity is viewed as a positive attribute and a valuable resource to support the development of cultural competence and the provision of culturally relevant care. A diverse working team creates opportunities for cultural encounters and interactions that can result in greater cultural understanding and better delivery of care; however, diversity in the workforce has challenges. Although culturally diverse groups have more potential to generate a greater variety of ideas and other resources than do culturally homogeneous groups, racially and ethnically mixed groups actually experience more conflict and miscommunication than do homogeneous groups. When health care providers from different cultures and countries work together as members of the

health care team, opportunities for miscommunication and conflict naturally arise (Adeniran, Bhattacharya, & Srivastava, 2015; Premji & Etowa, 2014).

The cultural origins of miscommunication and conflict in the workplace are often interconnected with cultural beliefs, values, and etiquette. Examples of such origins are the meaning, purpose, and value of work; family obligations; time orientation; gender roles and sexual orientation; and historical rivalries among groups. Cultural misunderstandings can lead to tensions within the working team, miscommunication, and wrongful assumptions, all of which result in work stress and poor outcomes for patients. These challenges can be minimized through the same principles of respect, empathy, and learning from difference that apply to nurse–patient interactions.

Even though there is a strong belief that culturally competent care necessitates a diverse workforce, workforce diversity does not necessarily result in cultural competence. Development and demonstration of cultural competence requires intentional work as discussed throughout the chapter and outlined in Table 2-3.

Conclusion

The need for cultural competence is a fundamental issue of health care quality and patient safety, and achieving it requires a commitment to principles of inclusiveness and equity. Developing cultural competence (see Table 2-3) is a journey in which nurses can begin with generic knowledge and, with time and experience, acquire additional knowledge specific to populations and aspects of care. It is important for the nurse to combine the use of this information and knowledge with critical reflection and critical thinking. This approach adds both depth and breadth to the nurse's clinical competence and ability to provide patient-centred care.

Case Study

Communication

Source: szifei/Shutterstock.com

Patient Profile

Mrs. Jagwant is a 45-year-old woman who is admitted to the hospital for investigation of a tumour. She is accompanied by her husband. Dr. Stuart, the attending physician, explains to the couple that the prognosis is excellent and the treatment involves radiation. She plans to schedule the first treatment the following week.

Mr. and Mrs. Jagwant have been in Canada for approximately 3 years, and both speak English, albeit with an accent. There have

been no difficulties in communicating in English with either Mr. or Mrs. Jagwant, although Mr. Jagwant tends to do most of the talking. While Dr. Stuart is explaining the diagnosis, they listen intently, nod periodically, and do not raise any questions or objections to the plan. Dr. Stuart assumes that the patient is in agreement with her plan.

Discussion Questions

1. Do you agree with Dr. Stuart's assessment?
2. What factors may be influencing the couple's silence?
3. What actions could be taken by the nurse who is present for this discussion or the doctor that reflect cultural competence?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. Which of the following is an example of forcing one's own cultural beliefs and practices on another person?
   a. Stereotyping
   b. Ethnocentrism
   c. Cultural relativity
   d. Cultural imposition
2. Which of the following is true about inequities between Indigenous health and the health of the general population? *(Select all that apply.)*
   a. They result from lifestyle choices.
   b. They result from differences in living conditions, such as housing and education.
   c. They result from conflict between systems of Indigenous medicine and Western health care concepts.
   d. They result from bias and discrimination from the mainstream system.
3. Which of the following is true about health inequity?
   a. Health inequities are caused largely by cultural factors compounded by social disadvantage.
   b. Health inequities are largely caused by different beliefs, practices, and lifestyles associated with the cultural communities.
   c. Health inequities can be reduced by improving services to enhance access and reduce exclusion.
   d. In a country in which access to health care is universal, health inequities are largely issues of health care quality.
4. Which of the following *most* accurately describes cultural factors that may affect health?

a. Diabetes and cancer rates differ by cultural and ethnic groups.
b. Most clients find that religious rituals help them during times of illness.
c. There is limited ethnic variation in physiological responses to medications.
d. Silence during a nurse–client interaction usually means that the client understands the instructions.

5. In communications with a client who speaks a language different from the nurse's, which of the following interventions is important?
a. Have a family member translate.
b. Use a trained medical interpreter.
c. Use specific medical terminology so that there will be no mistakes in the information communicated.
d. Focus on the translation rather than the nonverbal communication.

6. Why is it important for the nurse to develop cultural self-awareness? *(Select all that apply.)*
a. This enables the nurse to clearly articulate the nurse's own values to the client.
b. This enables the nurse to prevent ethnocentrism.
c. This enables the nurse to prevent cultural imposition.
d. This enables the nurse to challenge his or her own assumptions and stereotypes.

7. Which of the following strategies are appropriate for demonstrating cultural competence in clinical care? *(Select all that apply.)*
a. Explaining to the client and family how the Canadian health care system works
b. Exploring economic and social factors affecting the client and family
c. Pairing the client with a provider from the client's own cultural community

d. Exploring the client's explanatory model of illness

8. How does a diverse workforce influence a nurse's ability to provide care?
   a. It facilitates matching clients with health care providers of the same ethnicity.
   b. It exposes the nurse to different values, beliefs, and world views.
   c. It leads to greater creativity and innovation and to the development of appropriate interventions for diverse clients.
   d. It meets mandated objectives of the federal and provincial governments.

1. d; 2. c, d; 3. c; 4. a; 5. b; 6. c, d; 7. b, d; 8. b.

CHAPTER 3

Health History and Physical Examination

Written by, Jennifer Saylor

Adapted by, Mary Ann Fegan

LEARNING OBJECTIVES

1. Explain the purpose, components, and techniques of a patient's health history and physical examination.
2. Obtain a nursing history with the use of a common health history format.
3. Select appropriate techniques of inspection, palpation, percussion, and auscultation for physical examination of a patient.
4. Differentiate among comprehensive, focused, and emergency types of assessment in terms of indications, purposes, and components.

KEY TERMS

auscultation, p. 42
database, p. 37
general survey statement, p. 41
inspection, p. 41
nursing history, p. 37

objective data, p. 37

palpation, p. 42

percussion, p. 42

physical examination, p. 41

subjective data, p. 37

During the assessment phase of the nursing process, the nurse documents a patient's health history and performs a physical examination. The findings of this assessment (a) contribute to a database that identifies the patient's current and past health status and (b) provide a baseline against which future changes can be evaluated. The purpose of the nursing assessment is to enable the nurse to make clinical judgements or nursing diagnoses about the patient's health status (Jarvis, Browne, MacDonald-Jenkins, et al., 2014). Assessment is the first step of the nursing process, but it is performed continuously throughout the nursing process to validate nursing diagnoses, evaluate nursing interventions, and determine whether patient outcomes and goals have been met.

Data Collection

In the broadest sense, the **database** is all the health information about a patient. This includes the data from the nursing history and physical examination, the data from the medical history and physical examination, results of laboratory and diagnostic tests, and information contributed by other health care providers.

The focus of nursing care is the diagnosis and treatment of human responses to actual or potential health problems or life processes. The information obtained from the **nursing history** and physical examination is used to determine the patient's strengths and responses to a health problem. For example, for a patient with a diagnosis of diabetes, the patient's responses may include anxiety or a lack of knowledge about self-management of the condition. The patient may also experience the physical response of fluid volume deficit because of the abnormal fluid loss caused by hyperglycemia. These human responses to the condition of diabetes are diagnosed and treated by nurses. During the nursing history interview and physical examination, the nurse obtains and records the data to support the identification of nursing diagnoses (Figure 3-1).

FIGURE 3-1 Obtaining a nursing history is an important role of the nurse. Source: Monkey Business Images/Shutterstock.com.

The purpose of the health history is to collect both subjective and objective data. **Subjective data,** also known as *symptoms,* are collected in an interview with the patient or caregiver, or both, during the nursing history. This type of data includes information that can be described or verified only by the patient or caregiver. It is what the person tells the nurse either spontaneously or in response to a direct question.

Objective data, also known as *signs,* are data that can be observed and measured. The nurse obtains this type of data by using inspection, palpation, percussion, and auscultation during the physical examination. Objective data are also acquired by diagnostic testing. Patients often provide subjective data while the nurse is performing the physical examination. The nurse also observes objective signs while interviewing the patient. All findings related to a specific problem, whether subjective or objective, are known as *clinical manifestations* of that problem.

Interviewing Considerations

The purpose of the patient interview is to obtain a complete health history (e.g., subjective data) about the patient's past and present health status. Effective communication is a key factor in the

interview process. Creating a climate of trust and respect is crucial for establishing a therapeutic relationship, as is the nurse's ability to engage in reflective practice. This ability includes the required capacities of self-awareness, self-knowledge, empathy, and awareness of boundaries and limits of the professional role (Registered Nurses' Association of Ontario, 2006). The nurse needs to communicate acceptance of the patient as an individual by using an open, responsive, nonjudgemental approach. Nurses communicate not only through language but also in their manner of dress, gestures, and body language. Modes of communication are learned through one's culture and influence: not only the words, gestures, and posture one uses but also the nature of information that is shared with others (see Chapter 2 for discussion on culture).

In addition to understanding the principles of effective communication, the nurse must develop a personal style of relating to patients. Although no single style fits all people, the wording of questions can increase the probability of eliciting the needed information. Asking questions, particularly those related to sensitive areas such as sexual functioning and economic status, becomes easier with training and experience.

The amount of time needed to complete a nursing history may vary with the format used and the experience of the nurse. The nursing history may be completed in one or several sessions, depending on the setting and the patient. For example, several short sessions might be needed for an older adult patient with a low energy level to allow time for the patient to provide the needed information. The nurse must also make a judgement about the amount of information collected on initial contact with the patient. In interviews with patients with chronic disease, patients in pain, and patients in emergency situations, the nurse should ask only questions that are pertinent to a specific problem. The nurse can complete the health history interview at a more appropriate time.

Before beginning the nursing history, the nurse should explain to the patient that the purpose of a detailed history is to collect information that will provide a health profile for comprehensive health care, including health promotion. This detailed information is collected during the patient's entry into the health care system, and

subsequently, only updates are needed. The nurse should explain that personal and social data are needed to individualize the plan of care. This explanation is necessary because the patient may not be accustomed to sharing personal information and may need to know the purpose of such questioning. The nurse should assure the patient that all information will be kept confidential. The Canadian Nurses Association (CNA) requires that nurses protect the confidentiality of all information obtained in the context of the professional relationship and practise within the bounds of relevant laws governing privacy and confidentiality of personal health information. The CNA *Code of Ethics for Registered Nurses* provides helpful guidelines for ensuring confidentiality in nursing practice (CNA, 2017). To obtain factual, easily categorized information, a direct interview technique can be used. Closed-ended questions such as, "Have you had surgery before?" that require brief, specific responses are used. When asking sensitive personal and social questions, the nurse can communicate the acceptance or normality of behaviours by prefacing questions with phrases such as "most people" or "frequently." For example, stating, "Many people taking antihypertensive drugs have concerns about sexual functioning; do you have any you would like to discuss?" shows the patient that a particular situation may not be unique to that patient.

Another method of putting the patient at ease is to word the question so that an affirmative answer appears expected. An example of this technique is to ask, "What do you like to drink at a party?" instead of "Do you drink?" "How often do you drink alcohol?" is another way of obtaining information related to alcohol intake. These questions are open ended, encouraging the patient to discuss the issue in the patient's own words and at his or her own pace (Wilson & Giddens, 2013).

The nurse must judge the reliability of the patient as a historian. An older adult may give a false impression about her or his mental status because of a prolonged response time or visual and hearing impairment. The complexity and long duration of health problems may make it difficult for an older adult or a chronically ill younger patient to be an accurate historian.

It is important for the nurse to determine the patient's priority concerns and expectations because the nurse's priorities may be different from the patient's. For example, the nurse's priority may be to complete the health history, whereas the patient is interested only in relief from symptoms. Until the patient's priority need is met, the nurse will probably be unsuccessful in obtaining complete and accurate data.

Teamwork and Collaboration

Ongoing data collection is expected of all members of the health care team. In acute care settings, the initial (admission) nursing assessment must be completed by a registered nurse (RN) and within the timeframe determined by the employer. Table 3-1 shows the roles of various nursing personnel in data assessment and collection.

TABLE 3-1

DATA ASSESSMENT AND COLLECTION: ROLES OF NURSING PERSONNEL

Role of Registered Nurse (RN)
• On admission, complete a comprehensive assessment (see Table 3-4). • Document patient's health history by interviewing patient, caregiver, or both. • Perform physical examination, using inspection, palpation, percussion, and auscultation as appropriate. • Document findings from the health history and physical examination in the patient's record. • Organize patient data into functional health patterns, if appropriate. • Develop and prioritize nursing diagnoses and collaborative problems for the patient. • Throughout patient's hospitalization, perform focused assessments that are based on patient's history or clinical manifestations (see Table 3-6).
Role of Registered Practical Nurse (RPN)
• Collect and document specific patient data as delegated by the RN (after the RN has developed the plan of care on the basis of findings of the admission assessment). • Perform focused assessment that is based on patient's history or clinical manifestations, or as instructed by the RN (see Table 3-6).
Role of Personal Support Worker (PSW)
• Report patient's subjective complaints to RN or RPN. • Perform activities of daily living, personal care, transferring patient in and out of bed as delegated by RN or RPN.

Data Organization

Assessment data must be systematically obtained and organized so that the nurse can readily analyze and make judgements about the patient's health status and any health problems. Information about the patient in various health care settings can be gathered in numerous approaches and formats. The format used in this chapter for obtaining a nursing history includes the following sequence of categories, similar to those outlined by Jarvis, Browne, MacDonald-Jenkins, and colleagues (2014). These assessment data provide a generic database for all health care practitioners:

1. Biographical data
2. Reason for seeking care
3. Current health status or history of current illness
4. Past medical history
5. Family medical history
6. Functional assessment
7. Review of systems

Culturally Competent Care

Assessment

The process of obtaining a health history and performing a physical examination is an intimate experience for the nurse and the patient. As noted earlier in the chapter, a person's culture influences patterns of communication and what information is shared with others. During the interview and physical examination, the nurse must be sensitive to issues of eye contact, space, modesty, and touching, as discussed in Chapter 2. Knowing the cultural norms related to male–female relationships is especially important during the physical examination. To avoid violating any culturally based practices, the nurse can ask the patient about cultural values. The nurse should determine whether the patient would like to have someone else present during the history taking or physical examination or would prefer someone of the same gender to perform the history taking and physical examination (Jarvis, Browne, MacDonald-Jenkins, et al., 2014).

Nursing History: Subjective Data

Biographical Data

The nurse records the patient's name, address, contact information, age, birthdate, marital status, ethnocultural background, primary language, and current occupation. Advance care directives can be documented among these data (see Chapter 13). Also important to include here is the source of history: who is providing the information, how reliable the informant seems, and any special circumstances, such as the use of an interpreter (Jarvis, Browne, MacDonald-Jenkins, et al., 2014).

Reason for Seeking Care

The reason for seeking care is a brief statement in the patient's own words describing the reason for the visit. This statement is documented in quotation marks to indicate the patient's exact words (e.g., “My head has been aching for 3 days”; “My child has a fever and has been vomiting since last evening”).

Current Health or History of Current Illness

This section is a chronological record of the reason for seeking care, beginning with the first time the symptom appeared until now. Symptoms experienced by the patient are not observed, so the symptom must be explored. Table 3-2 shows a mnemonic (PQRSTU) to help remember the areas to explore if a symptom is reported. The information that is obtained may help determine the cause of the symptom. A common symptom assessed is pain (see Chapter 10). For example, if a patient states that he has “pain in his leg at times,” the nurse would assess and record the data with the use of PQRSTU:

TABLE 3-2

INVESTIGATION OF PATIENT-REPORTED SYMPTOM

Factor	Questions for Patient and Caregiver	Record
Precipitating and **p**alliative	Were there any events that came before the symptom? What makes it better? Worse? What have you done for the symptom? Did this help?	Influence of physical and emotional activities Patient's attempts to alleviate (or treat) the symptom
Quality	Tell me what the symptom feels like (e.g., aching, dull, pressure, burning, stabbing).	Patient's own words (e.g., "Like a pinch or stabbing feeling")
Radiation	Where do you feel the symptom? Does it move to other areas?	Region of the body Local or radiating, superficial or deep
Severity	On a scale of 0–10, with 0 meaning no pain and 10 being the worst pain you could imagine, what number would you give your symptom?	Pain rating number (e.g., 5/10)
Timing	When did the symptom start? Any particular time of day, week, month, or year? Has the symptom changed over time? Where are you and what are you doing when the symptom occurs?	Time of onset, duration, periodicity, and frequency Course of symptoms Where patient is and what patient is doing when the symptom occurs
Understanding	Understand the patient's perception of the problem: What do you think it means?	Patient's own words about what the problem means to him or her

Has right midcalf pain that usually occurs at work when climbing stairs after lunch (P). Pain is alleviated by stopping and resting for 2 to 3 minutes. Patient thinks this pain is a "muscle cramp" and states he has been "eating a banana every day for extra potassium" but "it hasn't helped" (U, P). Pain is described as "stabbing" and is nonradiating (Q, R). Pain is so severe (rating 9 on 0–10 scale) that patient cannot continue activity (S). Onset is abrupt, occurring once or twice daily. It last occurred yesterday while he was cutting the lawn (T).

Past Health History

The past health history provides information about the patient's prior state of health. The patient is asked specifically about major childhood and adult illnesses, injuries, hospitalizations, and surgeries. This documentation should include questions about any infectious diseases such as human immunodeficiency virus (HIV) infection, hepatitis, methicillin-resistant *Staphylococcus aureus* (MRSA) infection, and vancomycin-resistant enterococcal (VRE) infection. Specific questions are more effective than simple questions of whether the patient has had any illness or health problems in the past. For example, the question "Do you have a history of diabetes?" elicits better information than does "Do you have any chronic health problems?"

Medications.

The nurse obtains specific details related to past and current medications, including prescription and illicit drugs, over-the-counter drugs, vitamins, herbs, and dietary supplements. Patients frequently do not consider herbs and dietary supplements as drugs. It is important to ask specifically about their use because they can interact adversely with existing or newly prescribed medications (see Chapter 12, Table 12-7). Older adult and chronically ill patients should be questioned about medication routines; for these patients, polypharmacy, changes in absorption, distribution, metabolism, and elimination of and reaction to drugs can pose serious potential problems (Touhy, Jett, Boscart, et al., 2011).

Allergies.

The patient's history of allergies to drugs, latex, contrast media, food, and the environment (e.g., pollen) should be explored. Documentation should include a detailed description of any and every allergic reaction reported by the patient.

Surgery or Other Treatments.

All surgeries, along with the date of the event, the reason for the surgery, and the outcome should be recorded. Possible outcomes

include complete resolution of the problem and residual effects. The nurse should ask about and record any blood products that the patient has received.

Family History

The nurse should ask about the health of family members, as well as the ages at and cause of death of blood relatives, such as parents, siblings, and grandparents. Common questions include those about any family history of heart disease, high blood pressure, stroke, diabetes, blood disorders, cancer, sickle cell disease, arthritis, allergies, obesity, alcoholism, mental health issues or illness, seizure disorder, kidney disease, and tuberculosis (Jarvis, Browne, MacDonald-Jenkins, et al., 2014). A genogram or family tree will help the nurse accurately document this information.

Functional Health Assessment

The nurse assesses the patient's functional health to identify positive, dysfunctional, and potential dysfunctional patterns. Dysfunctional health patterns result in nursing diagnoses, and potential dysfunctional patterns identify risk conditions for problems. Gordon's (2014) functional health pattern framework for assessment can assist the nurse in differentiating between areas for independent nursing intervention and areas necessitating collaboration or referral. The nurse may identify patients with effective health function who express a desire for a higher level of wellness.

It is also important to consider the social determinants of health to ensure a complete and relevant health history assessment. The nurse should explore the patient's living conditions by asking about employment; working conditions; well-being; health and social services received; and ability to obtain quality education, food, and housing, among other factors (Mikkonen & Raphael, 2010).

Health Perception–Health Management.

Assessment of the patient's health perception and health management focuses on the patient's perceived level of health and

well-being and on personal practices for maintaining health. The patient is asked to describe his or her personal health and any concerns about it. The patient's opinions of the effectiveness of health maintenance practices can be explored with questions about what helps and what hinders his or her well-being. The patient should be asked to rate his or her health as excellent, good, fair, or poor. When possible, this information is best recorded in the patient's own words. Asking about the type of health care providers that the patient uses is important. For example, if the patient is Indigenous Canadian, a traditional healer may be considered the primary health care provider. If the patient is of Chinese origin, a Chinese healer who practices traditional Chinese medicine may be the primary health care provider.

The purpose of questions for this pattern is also to identify risk factors with regard to family history (e.g., cardiac disease, cancer, genetic disorders), history of personal health habits (e.g., tobacco, alcohol, drug use), and history of exposure to environmental hazards (e.g., asbestos). If the patient is hospitalized, the nurse should ask about the expectations for this experience. The patient can be asked to describe his or her understanding of the current health problem, including its onset, course, and treatment. These questions elicit information about a patient's knowledge of the health problem and ability to use appropriate resources to manage the problem.

Nutrition–Metabolic.

The nurse must assess the patient's processes of ingestion, digestion, absorption, and metabolism. A 24-hour dietary recall should be obtained from the patient to evaluate the quantity and quality of foods and fluids consumed. If a problem is identified, the nurse may ask the patient to keep a 3-day food diary for a more careful analysis of dietary intake. The effect of psychological factors such as depression, anxiety, stress, and self-concept on nutrition should be assessed. In addition, socioeconomic and cultural factors such as food budget, who prepares the meals, and food preferences are also determined. To determine whether the patient's present condition

has interfered with eating and appetite the nurse can explore any symptoms of nausea, intestinal gas, or pain. Food allergies should be differentiated from food intolerances, such as lactose or gluten intolerance.

Elimination.

To assess bowel, bladder, and skin function, the nurse should ask the patient about the frequency of bowel and bladder activity, including laxative and diuretic use. The skin is assessed again in the elimination pattern in terms of its excretory function.

Activity–Exercise.

The nurse assesses the patient's usual pattern of exercise, work activity, leisure, and recreation. The patient should be questioned about his or her ability to perform activities of daily living and any specific problems noted.

Sleep–Rest.

It is important for the nurse to describe the patient's perception of his or her pattern of sleep, rest, and relaxation in a 24-hour period. This information can be elicited by the question "Do you feel rested when you wake up?"

Cognitive–Perceptual.

Assessment of this area involves a description of all of the senses and cognitive functions. In addition, pain is assessed as a sensory perception in this pattern. (See Chapter 10 for details on pain assessment.) The patient should be asked about any sensory deficits that affect the ability to perform activities of daily living. Ways in which the patient compensates for any sensory–perceptual problems should be recorded. To plan for patient teaching, the nurse can ask the patient how he or she communicates best and what he or she understands about the illness and treatment plan. (See Chapter 4 for details on patient teaching.)

Self-Perception–Self-Concept.

The nurse should explore the patient's self-concept, which is crucial for determining the way the person interacts with others. Included are attitudes about self, perception of personal abilities, body image, and general sense of worth. The nurse should ask the patient for a self-description and about how his or her health condition affects self-concept. A patient's expressions of helplessness or loss of control frequently reflect an inability to care for himself or herself.

Role–Relationship.

The nurse should explore the patient's roles and relationships, including major responsibilities. The patient should be asked to describe family, social, and work roles and relationships and to rate his or her performance of the expected behaviours related to these. The nurse should determine whether patterns in these roles and relationships are satisfactory or whether strain is evident. The nurse should note the patient's feelings about how the current condition affects his or her roles and relationships. It is important to assess whether the patient has access to family and friends who can help out when needed.

Sexuality–Reproductive.

The nurse evaluates the patient's satisfaction or dissatisfaction with personal sexuality and reproductive issues. Assessing these aspects is important because many illnesses, surgical procedures, and drugs affect sexual function. A patient's sexual and reproductive concerns may be expressed and teaching needs may be identified through information obtained in this assessment.

The interview should be appropriate to the sex, age, and developmental stage of the patient. Obtaining information related to sexuality may be difficult for the nurse. However, it is important to document a health history and screen for sexual function and dysfunction in a nonjudgemental way and to provide information as appropriate or to refer the patient to a more experienced health care provider.

Coping–Stress Tolerance.

The nurse should describe the patient's general coping pattern and the effectiveness of the coping mechanisms. Assessment of this pattern involves analyzing the specific stressors or problems that confront the patient, the patient's perception of the stressors, and the patient's response to the stressors. The nurse should document any major losses or stressors experienced by the patient in the previous year. Strategies used by the patient to deal with stressors and relieve tension should be noted. Individuals and groups that make up the patient's social support networks should be recorded and explored to help assess the level of support available to the patient.

Value–Belief.

The nurse should describe the values, goals, and beliefs (including spiritual) that guide health-related choices. The patient's ethnic background and the effects of culture and beliefs on health practices should be documented. The patient's wishes about continuation of religious or spiritual practices and the use of religious articles should be noted and respected.

Physical Examination: Objective Data

General Survey

After the nursing history, the nurse makes a **general survey statement.** This reflects a general impression of a patient, including behavioural observations. This initial survey begins with the nurse's first encounter with the patient and continues during the health history interview.

Although the nurse may include other data that seem pertinent, the major areas included in the general survey statement are (a) body features, (b) mental state, (c) speech, (d) body movements, (e) obvious physical signs, (f) nutritional status, and (g) behaviour. Vital signs, height, and weight or body mass index (calculated from height and weight [kg/m^2]), or both, may be included. The following is a sample of a general survey statement:

Mrs. H. is a 34-year-old Italian woman, BP 130/84, P 88, R 18. Alert but anxious. Speech rapid with trailing thoughts. Wringing hands and shuffling feet during interview. Skin flushed, hands clammy. Overweight relative to height (body mass index, 28.3 kg/m^2). Sits with eyes downcast and shoulders slumped and avoids eye contact.

Physical Examination

The **physical examination** is the systematic assessment of a patient's physical status. Throughout the physical examination, the nurse explores any positive findings, using the same criteria as those used during the investigation of a symptom in the nursing history (see Table 3-2). A *positive finding* indicates that the patient has or had the particular problem or sign under discussion (e.g., if the patient with jaundice has an enlarged liver, it is a positive finding). Relevant information about this problem should then be gathered.

Negative findings may also be significant. A *negative finding* is the absence of a sign or symptom usually associated with a problem. For

example, peripheral edema is common with advanced liver disease. If edema is not present in a patient with advanced liver disease, this should be specifically documented as “no peripheral edema.”

Techniques.

Four major techniques are used in performing the physical examination: inspection, palpation, percussion, and auscultation. The techniques are usually performed in this sequence, except for the abdominal examination (inspection, auscultation, percussion, and palpation). Performing palpation and percussion of the abdomen before auscultation can alter bowel sounds and produce false findings. Not every assessment area requires the use of all four assessment techniques (e.g., for the musculo-skeletal system, only inspection and palpation are required).

Inspection.

Inspection is the visual examination of a part or region of the body to assess normal conditions or deviations. Inspection is more than just looking. This technique is deliberate, systematic, and focused. The nurse must compare what is seen with the known, generally visible characteristics of the body part being inspected. For example, most 30-year-old men have hair on their legs. Absence of hair may indicate a vascular problem and signals the need for further investigation, or it may be normal for a patient of a particular ethnicity (e.g., First Nations men have little body hair).

Palpation.

Palpation is the examination of the body through the use of touch. Using light and deep palpation can yield information about masses, pulsations, organ enlargement, tenderness or pain, swelling, muscular spasm or rigidity, elasticity, vibration of voice sounds, crepitus, moisture, and texture. Different parts of the hand are more sensitive for specific assessments. For example, the palmar surface (base of fingers) should be used to feel vibrations; the dorsa (back) of the hands and fingers, to assess skin temperature; and tips of the

fingers, to palpate the abdomen (Jarvis, Browne, MacDonald-Jenkins, et al., 2014) (Figure 3-2).

FIGURE 3-2 Palpation is the examination of the body using touch. Source: Jarvis, C. (2012). *Physical examination and health assessment* (6th ed.). St Louis: Saunders.

Percussion.

Percussion is a technique of tapping the body directly or indirectly with the fingertips to produce a sound and vibration to obtain information about the underlying area (Figure 3-3). The sounds and the vibrations are specific to the underlying structures. A change from an expected sound may indicate a problem. For example, dullness in the right lower quadrant instead of the normal tympany should be explored. (Specific percussion sounds of various body parts and regions are discussed in the appropriate assessment chapters.)

FIGURE 3-3 Percussion technique: tapping the interphalangeal joint. Only the middle finger of the nondominant hand should be in contact with the skin surface. Normal percussion sounds for lung tissue are *resonant;* for air-filled viscus (e.g., intestines), *tympany;* for dense organs (e.g., liver), *dull;* and for areas with no air present (e.g., bone, muscle), *flat.* Source: Modified from Seidel, H.M., Ball, J.W., Dains, J.E., et al. (2011). *Mosby's guide to physical examination* (7th ed.). St. Louis: Saunders.

Auscultation.

Auscultation is listening to sounds produced by the body to assess normal conditions and deviations from normal. This technique is particularly useful in evaluating sounds from the heart, lungs, abdomen, and vascular system. The bell of the stethoscope is more sensitive to low-pitched sounds (e.g., heart murmurs). The diaphragm of the stethoscope is more sensitive to high-pitched sounds (e.g., bowel sounds). Some stethoscopes have only a diaphragm, designed to transmit low- and high-pitched sounds. To listen for low-pitched sounds, the examiner holds the diaphragm lightly on the patient's skin. For high-pitched sounds, the examiner presses the diaphragm firmly on the skin (Jarvis, Browne, MacDonald-Jenkins, et al., 2014; Figure 3-4). (Specific auscultatory sounds and techniques are discussed in the appropriate assessment chapters.)

FIGURE 3-4 Auscultation is listening to sounds produced by the body to assess normal conditions and deviations from normal. Source: Courtesy Linda Bucher, RN, PhD, CEN, CNE, Staff Nurse, Virtua Memorial Hospital, Mt. Holly, NJ.

Equipment.

The nurse should collect the equipment needed for the physical examination before beginning (Table 3-3). This saves the time and energy for the nurse and the patient. (The uses of specific equipment are discussed in the appropriate assessment chapters.)

TABLE 3-3
EQUIPMENT FOR PHYSICAL EXAMINATION*

• Alcohol swabs • Blood pressure cuff • Cotton balls • Examining table or bed • Eye chart (e.g., Snellen eye chart) • Paper cup with water • Patient gown • Pocket flashlight • Reflex hammer • Stethoscope (with bell and diaphragm or a dual-purpose diaphragm; 38- to 46-cm tubing) • Tongue blades • Watch (with second hand or digital)

*These are examples of commonly used equipment; other equipment may be used, depending on the situation.

Organization of the Examination.

The physical examination should be performed systematically and efficiently. Explanations should be given to the patient as the examination proceeds, and the patient's comfort, safety, and privacy should be considered. By being confident and self-assured, considerate, and unhurried, the nurse will help reduce any anxiety the patient may be feeling about the examination (Jarvis, Browne, MacDonald-Jenkins, et al., 2014). Following the same sequence every time helps ensure that the nurse does not forget a procedure, a step in the sequence, or a portion of the body. Table 3-4 presents an outline of a comprehensive and organized physical examination. Adaptations of the physical examination often are useful for older adult patients, who may have age-related problems such as decreased mobility, limited energy, and perceptual changes.

TABLE 3-4
OUTLINE FOR PHYSICAL EXAMINATION

1. General Survey
Observe general state of health (patient is seated): • Body features • Mental state and level of orientation • Speech • Body movements • Physical appearance • Nutritional status • Behaviour
2. Vital Signs
Record vital signs: • Blood pressure—both arms for comparison • Apical/radial pulse • Respiration • Temperature • Oxygen saturation • Height and weight; calculation of body mass index (BMI)
3. Integument
Inspect and palpate skin for the following: • Colour • Integrity (e.g., lesions, breakdown, lacerations) • Scars, tattoos, piercings • Bruises, rash • Edema • Moisture • Texture • Temperature • Turgor • Vascularity Inspect and palpate nails for the following: • Colour • Lesions • Size • Shape • Angle • Capillary refill time
4. Head and Neck
Inspect and palpate head for the following: • Shape and symmetry of skull • Masses • Tenderness • Condition of hair and scalp • Temporal arteries • Temporo-mandibular joint • Sensory (cranial nerve V; light touch, pain) • Motor (cranial nerve VII; showing teeth, pursing lips, raising eyebrows) • Facial expression (cranial nerve VII; looking up, wrinkling forehead) • Strength (cranial nerve XI; raising shoulders against resistance) Inspect and palpate (occasionally auscultate) neck for the following: • Skin (vascularity and visible pulsations) • Symmetry

- Pulses and bruits (carotid)
- Midline structure (trachea, thyroid gland, cartilage)
- Lymph nodes (preauricular, postauricular, occipital, mandibular, tonsillar, submental, anterior and posterior cervical, infraclavicular, supraclavicular)

Test visual acuity. Inspect and palpate eyes/eyebrows for the following:

- Position and movement of eyelids (cranial nerve VII)
- Visual fields (cranial nerve II)
- Extraocular movements (cranial nerves III, IV, VI)
- Cornea, sclera, conjunctiva
- Pupillary response (cranial nerve III)
- Retinal (red) reflex*

Inspect and palpate nose and sinuses for the following:

- External nose: shape, blockage
- Internal nose: patency of nasal passages, shape, turbinates or polyps, discharge
- Frontal and maxillary sinuses

Inspect and palpate ears for the following:

- Placement
- Pinna
- Auditory acuity (whispered voice, ticking watch) (cranial nerve VIII)
- Mastoid process
- Auditory canal
- Tympanic membrane

Inspect and palpate mouth for the following:

- Lips (symmetry, lesions, colour)
- Buccal mucosa (Stensen's and Wharton's ducts)
- Teeth (absence, state of repair, colour)
- Gums (colour, receding from teeth)
- Tongue for strength (cranial nerve XII; asymmetry, ability to stick out tongue, ability to move tongue side to side, fasciculations)
- Palates
- Tonsils and pillars
- Uvular elevation (cranial nerve IX)
- Posterior pharynx
- Gag reflex (cranial nerves IX and X)
- Jaw strength (cranial nerve V)
- Moisture
- Colour
- Floor of mouth

5. Extremities

Observe size and shape, symmetry and deformity, involuntary movements. Inspect and palpate arms, fingers, wrists, elbows, and shoulders for the following:

- Strength
- Range of motion
- Joint pain
- Swelling
- Pulses (radial, brachial)
- Sensation (light tough, pain, temperature)
- Test reflexes: triceps, biceps, brachioradialis

Inspect and palpate legs for the following:

- Strength
- Range of motion
- Joint pain
- Swelling, edema
- Hair distribution
- Sensation (light touch, pain, temperature)
- Pulses (dorsalis pedis, posterior tibialis)
- Test reflexes: patellar, Achilles, plantar

6. Posterior Thorax
• Inspect for muscular development, scoliosis, respiratory movement, approximation of AP diameter. • Palpate for symmetry of respiratory movement, tenderness of CVA, spinous processes, tumours or swelling, tactile fremitus • Percuss for pulmonary resonance • Auscultate for breath sounds • Auscultate for egophony, bronchophony, and whispered pectoriloquy
7. Anterior Thorax
• Assess breasts for configuration, symmetry, dimpling of skin • Assess nipples for rash, direction, inversion, retraction • Inspect for apical impulse, other precordial pulsations • Palpate the apical impulse and the precordium for thrills, lifts, heaves, tenderness • Inspect neck for venous distension, pulsations, waves • Palpate lymph nodes in the subclavian, axillary, and brachial areas • Palpate breasts • Auscultate for rate and rhythm, character of S_1 and S_2 in the aortic, pulmonic, Erb point, tricuspid, and mitral areas; bruits at carotid, epigastrium
8. Abdomen
• Inspect for scars, shape, symmetry, bulging, muscular position and condition of umbilicus, movements (respiratory, pulsations, presence of peristaltic waves) • Auscultate for peristalsis (e.g., bowel sounds), bruits • Percuss and then palpate to confirm positive findings: check liver (size, tenderness), spleen, kidney (size, tenderness), urinary bladder (distension) • Palpate femoral pulses, inguinofemoral nodes, and abdominal aorta
9. Neurological
Observe motor status. • Gait • Toe walk • Heel walk • Drift Observe coordination. • Finger to nose • Romberg sign • Heel to opposite shin Observe the following: • Proprioception (position sense of great toe)
10. Genitalia*
Male External Genitalia
• Inspect penis, noting hair distribution, prepuce, glans, urethral meatus, scars, ulcers, eruptions, structural alterations, discharge • Inspect epidermis of perineum, rectum • Inspect skin of scrotum; palpate for descended testes, masses, pain
Female External Genitalia
• Inspect hair distribution; mons pubis, labia (minora and majora); urethral meatus; Bartholin's, urethral, and Skene's glands (may also be palpated, if indicated); introitus; any discharge • Assess for presence of cystocele, prolapse • Inspect perineum, rectum

*Additional techniques can be performed by qualified nurses in specialized settings. A retinal reflex (red reflex) examination would be performed with the eye examination. Speculum and bimanual examination of women and the prostate gland examination of men would be performed after inspection of genitalia. For examination of the genitalia, a second person may have to be present in the room.

AP, anteroposterior; *CVA,* costovertebral angle; S_1 and S_2, first and second heart sounds.

Recording Physical Examination.

At the conclusion of the examination, the nurse records the normal and abnormal findings in the patient's record. Table 3-5 provides an example of how to record the findings of a physical examination of a healthy adult. See Chapter 7, Table 7-2, and the age-related assessment findings in each assessment chapter for helpful references in recording age-related assessment differences.

TABLE 3-5

HOW TO RECORD FINDINGS OF A NORMAL PHYSICAL EXAMINATION OF A HEALTHY ADULT

Example
Patient's Name _____ Age _____
General Status
Well-nourished, well-hydrated, well-developed White [woman or man] in NAD, appears stated age, speech clear and evenly paced; is alert and oriented × 3; cooperative, calm
Skin
Clear $\bar{s}$ lesions, warm and dry, trunk warmer than extremities, turgor returns quickly, no ↑ vascularity, no varicose veins
Nails
Well-groomed, round 160-degree angle $\bar{s}$ lesions, nail beds pink, nails flexible
Hair
Thick, brown, shiny, normal [male or female] distribution
Head
Normocephalic, sinuses nontender
Eyes
Visual fields intact on gross confrontation VA: Right eye 20/20 Left eye 20/20 Both eyes 20/20 $\bar{s}$ glasses EOM: Intact on all gazes $\bar{s}$ ptosis, nystagmus Pupils: PERRLA, negative cover and uncover test results
Ears
Pinnae intact, in proper alignment; external canal patent; small amount of cerumen present; TMs intact; pearly-grey LMs, LR visible, not bulging; whisper heard at 90 cm (3 ft)
Nose
Patent bilaterally; turbinates pink, no swelling
Mouth
Moist and pink, soft and hard palates intact, uvula rises midline on “ahh,” 24 teeth present and in good repair
Throat
Tonsils surgically removed, no redness
Tongue
Moist, pink, size appropriate for mouth
Neck
Supple, $\bar{s}$ masses, $\bar{s}$ bruits, lymph nodes nonpalpable and nontender Thyroid: Palpable, smooth, not enlarged ROM: Full, intact, strong Trachea: Midline, nontender
Breasts
Soft, nonpendulous, $\bar{s}$ venous pattern, $\bar{s}$ dimpling, puckering Nipples: $\bar{s}$ inversion, point in same direction, areola dark and symmetrical, no discharge, no masses, nontender
Axilla

Hair present, shaved, no lesions, nontender

Thorax and Lungs

AP < transverse diameter, resp rate 18, reg rhythm, no ↑ in tactile fremitus, no tenderness, lungs resonant throughout, diaphragmatic excursion 4 cm bilaterally, chest expansion symmetrical, lung fields clear throughout

Heart

Rate 82, reg rate and rhythm; no lifts, heaves
Apical impulse: 5th ICS at MCL; no palpable thrills; S_1, S_2 louder, softer in appropriate locations; no S_3, S_4; no murmurs, rubs, clicks
Carotid, femoral, pedal, and radial pulses present; equal, 2+ bilaterally

Abdomen

No pulsations visible; rounded, active bowel sounds; no bruits or CVA tenderness; no palpable masses

Liver

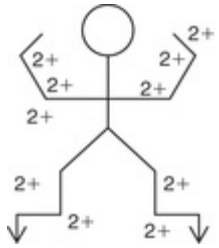
Lower border percussed at costal margin, smooth, nontender; approx 9-cm span

Spleen

Nonpalpable, nontender

Neurological System

Cranial nerves I-XII intact
Motor (drift, toe stand) intact
Coord (FN, Romberg) intact
Reflexes: See diagram



Grading Scale
0 No response
1+ Diminished
2+ Normal
3+ Increased
4+ Hyperactive
Sensation (touch, vibration, proprioception) intact

Musculo-Skeletal System

Well developed, no muscle wasting; $\bar{S}$ crepitus, nodules, swelling
ROM: Full, intact, and equal bilaterally; no scoliosis
Strength: Equal, strong bilaterally 5/5
Gait: Walks erect 60-cm steps, arms swinging at side $\bar{S}$ staggering

Female Genitalia*

External genitalia: No swelling, redness, tenderness in BUS; normal hair distribution, no cysts
Vagina: No lesions, discharge, bulging; pink
Cervix: Os closed; pink, no lesions, erosions, nontender
Uterus: Small, firm, nontender
Adnexa: No enlargement; nontender
Rectovaginal: Sphincter intact; confirms above findings

Male Genitalia

Normal male hair distribution, negative inguinal hernia
Penis: Urethral opening patent; no redness, swelling, discharge; no lesions, structural alterations
Scrotum: Testes descended; no redness, masses, tenderness

Rectal*: No lesions, redness; sphincter intact; prostate small, nontender
Psychological Status
Affect appropriate Orientation: Oriented ×3 Mood: Pleasant, appropriate Thought content: Intelligent, coherent Memory: Remote and recent intact Signature _____

*These data would be obtained from an examination of the genitalia if the nurse has the appropriate training.

AP, anteroposterior; *BUS,* Bartholin's gland, urethral meatus, Skene's duct; *coord,* coordination; *CVA,* costovertebral angle; *EOM,* extraocular movements; *FN,* finger to nose; *ICS,* intercostal space; *LMs,* landmarks; *LR,* light reflex; *MCL,* midclavicular line; *NAD,* no acute distress; *PERRLA,* pupils equal, round, reactive to light and accommodation; *reg,* regular; *resp,* respiration; *oriented ×3,* oriented to person, place, and time; *ROM,* range of motion; $\bar{s}$, without; S_1, S_2, S_3, and S_4, heart sounds; *TM,* tympanic membrane; *VA,* visual acuity.

Types of Assessment

Various types of assessment are used to obtain information about a patient. These approaches can be divided into three types: comprehensive, focused, and emergency (Table 3-6). The nurse must decide what type of assessment to perform according to the clinical situation. Sometimes the health care employer provides guidelines, and other times it is a nursing judgement.

TABLE 3-6
TYPES OF ASSESSMENT FOR VARIOUS SITUATIONS

The following describes types of assessment that the nurse may use in various situations.		
Description	**When and Where Performed**	**Where to Find in Book**
Comprehensive		
• Detailed assessment of all body systems (head-to-toe assessment)	• Onset of care in primary or ambulatory care setting • On admission to hospital, rehabilitation, or long-term care setting • On initial home care visit	• Assessment chapters for each body system • Outline for physical examination (see Table 3-4) • Findings for normal physical examination (see Table 3-5)
Focused		
• Abbreviated assessment that focuses on one or more body systems that are the focus of care • Includes an assessment related to a specific problem (e.g., pneumonia, specific abnormal laboratory findings) • Includes monitoring for signs and symptoms of new problems	• In the emergency department for non–life-threatening situations • Throughout hospital admission: at beginning of a shift and as needed throughout shift • Revisit in ambulatory care setting or home care setting	• "Focused Assessment" boxes in each assessment chapter • Tables on nursing assessment of specific diseases throughout book
Emergency		
• Limited to assessing life-threatening conditions (e.g., inhalation injuries, anaphylaxis, myocardial infarction, shock, stroke) • Conducted to ensure survival. Assessment focuses on elements in the primary survey (e.g., airway, breathing, circulation disability) • After lifesaving interventions are initiated, brief systematic assessment performed to identify any and all other injuries or problems	• Performed in any setting when signs or symptoms of a life-threatening condition appear (e.g., emergency department, critical care unit, surgical setting, ambulatory care setting, home setting)	• Chapter 71, Tables 71-3 and 71-5 • Emergency management tables throughout the book and listed in Table 71-1

Comprehensive Assessment

A *comprehensive assessment* includes detailed documentation of the health history and a physical examination of all body systems. This

is typically performed on the patient's admission to the hospital or at the onset of care in a primary care setting.

Focused Assessment

A *focused assessment* is an abbreviated health history and examination. It is used to evaluate the status of previously identified problems and monitor for signs and symptoms of new problems. It can be performed when a specific problem (e.g., pneumonia) is identified. The patient's clinical manifestations should alert the nurse to the appropriate focused assessment. For example, abdominal pain indicates the need for a focused assessment of the abdomen. Some patients require a focused assessment of more than one body system. A complaint of headache may indicate the need to perform musculoskeletal, neurological, and head and neck examinations. Assessment chapters throughout the text include "Focused Assessment" boxes.

Emergency Assessment

In an emergency or a critical care situation, an *emergency assessment* may be performed. This involves a rapid documentation of the history and rapid examination of a patient while vital functions are maintained.

Using Assessment Approaches

Assessment in a hospital inpatient setting, particularly in acute care, is markedly different from assessment in other settings. Focused assessment of hospitalized patients is frequent and performed by many different people. Such a team approach mandates a high degree of consistency among different health care providers.

While providing ongoing care for a patient, the nurse constantly refines her or his mental image of the patient. With experience, the nurse will derive a mental image of a patient's status from a few very basic details, such as "85-year-old Black woman admitted for COPD [chronic obstructive pulmonary disease] exacerbation." The nurse's view of her becomes clearer as a more complete verbal report is received, such as length of stay, laboratory results, physical findings,

and vital signs. Next, the nurse performs her or his own assessment, using a focused approach. During this assessment, the nurse confirms or revises the findings that were read in the medical record and received from other health care providers.

The process does not end once the nurse has completed her or his first assessment of a patient during rounds. The nurse will have to continue to gather information about her or his patients throughout the shift. Everything that the nurse learned previously about each patient is considered in with regard to new information. For example, while the nurse is performing a respiratory assessment on a patient with COPD, crackles are heard in the lungs. This finding should lead the nurse to perform a cardiovascular assessment because cardiac problems (e.g., heart failure) can also cause crackles. As the nurse gains experience, the importance of new findings will be more obvious.

Table 3-7 shows how the nurse can perform different types of assessments on the basis of a patient's progress through a given hospitalization. When a patient arrives at the emergency department with a life-threatening condition, the nurse performs an emergency assessment on the basis of the elements of a primary survey (e.g., airway, breathing, circulation, disability; see Chapter 71, Table 71-3). Once the patient is stabilized, the nurse can begin a focused assessment of the respiratory and related body systems. Once the patient is admitted, a comprehensive assessment of all body systems, whether they are involved in the current clinical problem or not, is performed.

TABLE 3-7
CLINICAL APPLICATION FOR TYPES OF ASSESSMENT

The following is an example of how various types of assessment would be used for a patient progressing from the emergency department to a clinical unit of a hospital.	
Timeline	**Type of Assessment**
Emergency Department	
Patient arrives in acute respiratory distress.	Emergency assessment (see Table 71-3)
Problem is identified, critical interventions are performed, and patient's condition is stabilized.	Focused assessment of the respiratory and related body systems (e.g., cardiovascular); comprehensive assessment of all body systems may begin
Clinical Unit	
Patient is admitted to a monitored clinical unit.	Complete comprehensive assessment of all body systems within proper timeframe
At beginning of each shift, patient is reassessed per orders and more frequently as determined by the nurse.	Focused assessment of respiratory system and other related body systems per agency protocol; focused assessment of one or more appropriate body systems if new symptoms are reported.

Problem Identification and Nursing Diagnoses

After completing the history and physical examination, the nurse analyzes the data and develops a list of nursing diagnoses and collaborative problems. See Chapter 1 for a description of the nursing process, including the identification of nursing diagnoses and collaborative problems.

Review Questions

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. The patient's health history and physical examination findings enable the nurse with information to primarily take which action?
   a. Diagnose a medical problem.
   b. Investigate the client's signs and symptoms.
   c. Classify subjective and objective client data.
   d. Identify nursing diagnoses and collaborative problems.
2. If a patient is concerned that his illness is threatening his job security, in which functional health pattern would the nurse place this information?
   a. Role–relationship
   b. Cognitive–perceptual
   c. Coping–stress tolerance
   d. Health perception–health management
3. The nurse is preparing to examine a client's abdomen. Number the proper order of the steps in the assessment of the abdomen, with 1 = the first technique and 4 = the last technique.
   ___ Inspection
   ___ Palpation
   ___ Percussion
   ___ Auscultation
4. Which situation would require the nurse to perform a focused assessment? *(Select all that apply.)*
   a. A client denies a current health problem.
   b. A client reports a new symptom during rounds.
   c. A previously identified problem needs reassessment.
   d. A baseline health maintenance examination is required.
   e. An emergency problem is identified during physical examination.

1. d; 2. a; 3. 1, 4, 3, 2; 4. b, c.

CHAPTER 4

Patient and Caregiver Teaching

Written by:, Linda Bucher

Adapted by:, Verna C. Pangman

LEARNING OBJECTIVES

1. Prioritize four specific goals of patient and caregiver teaching.
2. Examine teaching implications of adult learning principles.
3. Analyze specific competencies that enhance the nurse's effectiveness as a teacher.
4. Formulate strategies to manage the challenges to the nurse's teaching effectiveness.
5. Examine the intended role of the family in patient teaching.
6. Explain the basic steps in the teaching–learning process.
7. Relate physical, psychological, and sociocultural characteristics of the patient to the teaching–learning process.
8. Describe the components of a correctly written learning outcome.
9. Appraise advantages, disadvantages, and uses of various teaching strategies.
10. Examine common methods of short- and long-term evaluation.

KEY TERMS

andragogy, p. 49

Role of Patient and Caregiver Teaching

Teaching patients and caregivers (any family member or significant other) is a dynamic and interactive process. It is one of the most major and challenging roles that nurses face in the current health care system. Constraints on staff time and resources, coupled with the shortened average length of inpatient hospitalizations, can affect the nurse's ability to engage in patient education. Inadequate patient teaching frequently results in devastating consequences for the patient and caregiver. Conversely, teaching patients about promoting, maintaining, and restoring their health is a required nursing skill that most often results in a positive outcome, enhancing the patient's quality of life.

Nurses engage in patient education to help patients and their caregivers focus on optimizing their health and to enable them to cope with acute and chronic health problems. Specifically, teaching goals include (a) maintenance of health, (b) health promotion and prevention of disease, (c) management of illness, and (d) appropriate selection and use of treatment and resources. Furthermore, these goals facilitate maintaining a high level of wellness that is meaningful and relevant for the patient throughout the lifespan. Effective teaching can assist people to make informed decisions about their lifestyle, health practices, and treatment choices. For patients who have acute health problems, quality teaching can prevent complications and promote recovery. For patients with chronic illnesses, increased knowledge can promote self-care and independence.

Patient education can occur wherever nurses practice. Teaching situations include the community, schools, industry, ambulatory care centres, hospitals, long-term care facilities, and homes.

Family conferences are held mainly in hospitals and long-term care settings. These conferences provide opportunities for patients and their caregivers, along with members of the interdisciplinary health care team, to identify needs for information and assistance

with health care matters (Fineberg, Kawashima, & Asch, 2011). In fact, the involvement of the caregiver is considered one of the key variables influencing patient outcomes (Bastable, Gramet, Jacobs, et al., 2011). In family conferences, the nurse uses knowledge and skills to teach the patient and caregiver about the availability of resources and about strategies to promote health, as well as to assess additional care needs.

The teaching episodes expected from nurses are not complex. For example, teaching a patient to cough effectively and to breathe deeply after surgery can help the patient prevent atelectasis. However, when a patient has specific learning needs concerning management of a health problem or the strategies of health promotion, a teaching plan should be developed and implemented with the patient.

A **teaching plan** is a learner-centred approach for action to achieve the goals and learning outcomes agreed upon by the patient and nurse. The nurse, in cooperation with the patient, chooses activities and experiences to facilitate learning to improve the health of the patient. It then becomes necessary to evaluate the extent to which outcomes were attained (Billings & Halstead, 2016). This chapter describes the steps involved in providing patient and caregiver education and discusses factors that contribute to successful educational experiences.

Teaching–Learning Process

Teaching is much more than the simple intent of imparting information. **Teaching** is a process of deliberately planning experiences and sharing knowledge to meet learner outcomes in the cognitive, affective, and psychomotor domains. As well as being planned, teaching always endeavours to incorporate incidental experiences. Effective teaching can be conducted with a combination of methods such as simulation, use of printed materials, and assistive technology (computers) to influence the patient's knowledge and behaviour (Bastable, Gramet, Jacobs, et al., 2011). Learning is much more than listening to instruction. According to Kozier, Erb, Berman, and colleagues (2014), **learning** is a cognitive ability that is reflected by a change in behaviour (knowledge, attitudes, or skills or a combination of these) that can be observed and measured. A vital aspect of the nursing role is to understand which factors promote learning and what motivates the learner to learn (Bastable, Gramet, Jacobs, et al., 2011).

In patient education, the teaching–learning process involves the patient, the nurse, and the caregiver or social support system. The interdisciplinary team may also partake and can demonstrate accountability and responsibility for patient education on the basis of solid principles of teaching and learning.

Adult Learners

Adult Learning Principles.

Through educational research and theoretical development pertaining specifically to adults, investigators have identified specific principles and characteristics that differentiate learning by adults from learning by children. These concepts provide a foundation for the effective teaching of adults. Many of the theories of adult learning have arisen from the work of Knowles (1990), who identified seven principles of **andragogy** (adult learning) that are deemed essential for the nurse to consider when teaching adults.

These principles and their implications for patient teaching are presented in Table 4-1.

TABLE 4-1

PRINCIPLES OF ADULT EDUCATION APPLIED TO PATIENT TEACHING

Principle	Teaching Implications for the Nurse
Adults are independent learners.	• The teacher is a facilitator who directs the patient to resources but is not the source of all information. • Patients expect to make decisions about their own lives and learning experiences and to take responsibility for those decisions. • Respect for the patient's independence can be reflected in statements such as "What do you think you need to learn about this topic?"
Readiness to learn arises from life's changes.	• Patients see life processes as problems to be solved. • Readiness and motivation to learn are high when new tasks are faced. • Crises in health are "teachable moments."
Past experiences are resources for learning.	• Patients have had many life experiences and have engaged in informal learning for years. • Motivation is increased when patients believe that they already know something about the subject from past experiences. • Identifying past knowledge and experiences can familiarize patients with a new situation and increase their confidence.
Adults learn best when the topic is of immediate value.	• Patients need to apply learning immediately. • Long-term goals may have little appeal. • Short-term, realistic goals should be encouraged. • Education should be focused on information that the patient views as being needed right now.
Adults approach learning as problem solving.	• Patients seek out various resources for specific learning to help them deal with a problem. • Information that is not relevant to the problem is not readily learned. • When the patient does not recognize relevancy, explanations for the need to learn something should be offered. • Teaching should target the specific problem or circumstance.
Adults see themselves as doers.	• Patients learn better by doing. • Demonstrations, computer activities, and practice of skills should be offered when appropriate.
Adults resist learning when conditions are incongruent with their self-concepts.	• Patients do not learn when they are treated as children and told what they must do. • Patients need control and self-direction to maintain their sense of self-worth.

Determinants of Learning.

Because of the combined effects of health care trends and population demographics, the nurse must carefully assess all of the determinants of learning for the patient for whom the nurse has teaching responsibility. The three determinants of learning that require learning assessments are identified in Table 4-2.

TABLE 4-2

DETERMINANTS OF LEARNING

• The needs of the learner. Assist learner to identify, clarify, and prioritize his or her needs and interests. • The state of readiness to learn. Seize the moment when the learner demonstrates an interest in learning the material necessary to maintain optimal health. • The preferred learning style for processing knowledge and information. Assess the various teaching techniques and the teaching–learning conditions under which these learners are most likely to perceive, process, store, and recall health-related material.

Source: From Bastable, S. B. (2008). *Essentials of patient education.* Sudbury, MA: Jones & Bartlett.

Motivation of Adult Learners.

One important factor that is strongly associated with motivation is *emotional readiness* (Bastable, 2008). When a nurse is teaching an adult, it is important to identify what that adult values so that motivation can be enhanced. If the adult perceives a need for information to enhance health or avoid illness or if the adult believes that a behaviour change has health value, motivation to learn is increased. Humans seek out experiences that stimulate their desire and effort to learn. Therefore, learning activities must be stimulating to maintain a desire to reach a goal. *Motivational interviewing* has been shown to promote behaviour change in patients in various health care settings. It is a counselling approach that serves many goals, such as increasing rapport, helping patients feel understood, reducing the likelihood of resistance to change, and allowing patients to explore their inner thoughts and motivation. This approach supports self-efficacy in patients, meaning that patients' confidence in their ability to change is acknowledged as critical to successful change efforts (Lundahl, Kunz, Brownell, et al., 2010). (See

Chapter 11 for more information regarding motivational interviewing.)

When a change in health-related behaviours is recommended, patients and their families may progress through a series of steps before they are willing, or able, to accept the need for and make the change. Six stages of change have been identified in the transtheoretical model of health behaviour change developed by Prochaska and Velicer (1997). The **stages of behavioural change** and their implications for patient teaching are described in Table 4-3. It is important to note that an individual's progress through these stages occurs at his or her own pace and that progression through the stages is often nonlinear and cyclic. Therefore, it is reasonable to expect the patient to experience periods of relapse, whereby the process must be restarted—sometimes repeatedly. Accurate assessment of the patient's stage of change helps the nurse guide the patient through one stage and on to the next.

TABLE 4-3
STAGES OF CHANGE IN THE TRANSTHEORETICAL MODEL

Stage	Patient Behaviour	Nursing Implications
1. Precontemplation	Is not considering a change; is not ready to learn	Provide support and increase awareness of condition; describe benefits of change and risks of not changing
2. Contemplation	Thinks about a change; may verbalize recognition of need to change; says, "I know I should" but identifies barriers	Introduce what is involved in changing the behaviour; reinforce the stated need to change
3. Preparation	Starts planning the change, gathers information, sets a date to initiate change, shares decision to change with others	Reinforce the positive outcomes of change, provide information and encouragement, develop a plan, help set priorities, and identify sources of support
4. Action	Begins to change behaviour through practice; is tentative and may experience relapses	Reinforce behaviour with reward, encourage self-reward, discuss choices to help minimize relapses and regain focus, and help patient plan how to deal with potential relapses
5. Maintenance	Practises the behaviour regularly; is able to sustain the change	Continue to reinforce behaviour; provide additional education on the need to maintain change
6. Termination	Change has become part of lifestyle; behaviour is no longer considered a change	Evaluate effectiveness of the new behaviour; no further intervention is needed

Nurse as Teacher

Required Competencies

Knowledge of Subject Matter.

The scope of nursing practice is extensive, and its settings are diverse. Although it is impossible to be expert in all areas, the nurse can develop confidence as a teacher by acquiring knowledge of the matter that is to be taught. For example, if a nurse is teaching a patient about the management of hypertension, the nurse must be able to explain what hypertension is, why it is important to treat the disease, and what the patient needs to know about exercise, diet, and the effects of medication, both expected and untoward. The nurse should be able to teach the patient to use blood pressure equipment

to monitor the blood pressure and to identify situations that should be reported to health care providers. In addition, the nurse should provide the patient with sources of additional information such as brochures, appropriate websites, and support organizations (e.g., Canadian Heart and Stroke Foundation).

It is not unusual for the patient to ask questions that the nurse may not be able to answer. If unsure of the response, the nurse should inform the patient of this, seek additional information to answer the question, and then return to the patient to provide the response.

Communication Skills.

Patient education is an interactive and dynamic process. Through effective communication skills, a nurse can establish a valuable partnership among the nurse himself or herself, the patient, and the caregiver. In such a partnership, a nurse can provide a highly supportive environment conducive to the empowerment of the patient and caregivers (Hain & Sandy, 2013).

Empowerment has become increasingly important in the education of patients and caregivers. Empowerment focuses on the individual's capacity to make decisions about his or her health and the level of control he or she has related to health (McAllister, Dunn, Payne, et al., 2012).

Specifically, nurses can help patients identify their own internal strengths and self-care abilities, both of which can be called upon to address health care issues. Nurses can address the need for caregivers to support the rights of patients and ensure that patients have access to the resources necessary to achieve optimal health.

During the teaching process, the nurse should use basic therapeutic communication skills and strategies to support, educate, and empower patients to cope effectively with health-related issues (Arnold & Boggs, 2016). These basic communication skills encompass both verbal and nonverbal components, and they are described in Chapter 3 in the section “Interviewing Considerations.” The value of effective communication skills is to promote safe and empathic ways for patients to explore their illness experience. Terms that convey respect for culture, spiritual beliefs, and the educational

level of the patient and also that of the caregiver are essential. In communication, the use of medical jargon is unnecessary and can be omitted (Arnold & Boggs, 2016). To provide positive nonverbal messages, the nurse must sit in an open, relaxed position facing the patient, with his or her eyes level with those of the patient (Figure 4-1).

FIGURE 4-1 Open, relaxed positioning of the patient and nurse at the same eye level promotes communication in teaching and learning. Source: Monkey Business Images/Shutterstock.com.

It is important for the nurse to develop the art of active listening. This means paying attention to what is said, as well as observing the patient's nonverbal cues. The nurse concentrates on the patient as a communicator of vital information and does not interrupt the patient. Nodding in response to the patient's statements and rephrasing and verbally reflecting what the patient is saying help clarify communication. Allowing time for listening without appearing hurried requires thoughtful organization and planning on the part of the nurse. Listening attentively and red-flagging issues allow the nurse to obtain important information needed for the assessment phase of the teaching process.

Empathy.

Empathy can be defined as the quality to enter into the world of another so as not to judge, sympathize, or correct but to establish mutual understanding. Empathy means putting aside one's own concerns for a moment and adopting the patient's viewpoint. With regard to patient teaching, empathy means assessing the patient's needs before implementing a teaching plan. For example, a nurse working in a rural outpatient clinic is asked to teach a patient with newly diagnosed diabetes the symptoms of hypoglycemia. The nurse enters the room and finds the patient sitting very still, with gaze fixed and mouth slightly ajar. The empathic approach to this situation may include sitting in a chair next to the patient and discussing the feelings that the patient is experiencing before starting the discussion on the complications of diabetes.

Challenges to Nurse–Teacher Effectiveness.

The perceived lack of time is a major challenge that detracts from the effectiveness of the teaching effort. When time is limited, the nurse should inform the patient at the beginning of the interaction how much time can be devoted to the session. To make the most of limited time, the nurse and patient must set priorities for the patient's learning so that important teaching can be accomplished during any contact with the patient or caregiver.

Disagreement between the nurse and patient with regard to the expectations of teaching may also be a challenge. The nurse must accept the fact that some patients or caregivers may not be willing to discuss the health problem or its implications. The patient or caregiver may be in denial or hold ideas and values that conflict with those of conventional health care. Although the nurse may face hostility or resentment, he or she must respect the patient's response to the health problem.

Another important challenge for the nurse who is attempting to provide patient education is the current health care system. Decreased length of hospitalization has resulted in the discharge of patients into the community with only the basic elements of educational plans established. At the same time, health care is

offering increasingly complex treatment options. This situation results in greater educational needs of the patient and caregiver. Furthermore, patients and caregivers face greater difficulty using resources as the complexity of the health care system increases. Strategies that can be used to address these challenges are presented in Table 4-4.

TABLE 4-4

SUGGESTED APPROACHES TO OVERCOMING CHALLENGES TO NURSE–TEACHER EFFECTIVENESS

Challenge	Approaches
Lack of time	Preplan. Set realistic goals. Use time with patient efficiently, and use all possible opportunities for teaching, such as when bathing the patient or changing a dressing. Break teaching and practice sessions into small blocks of time. Advocate for time for patient teaching. Carefully document what was taught and the time spent teaching in order to emphasize that it is a primary role of nursing and that it takes time.
Lack of knowledge	Broaden knowledge base. Read, study, and ask questions. Screen teaching materials, participate in other teaching sessions, observe more experienced nurse–teachers, and attend classes.
Incongruent goals	Establish agreed-upon, written goals. Develop a plan, and discuss it with the patient before teaching begins. Revise expectations based on patient's needs.
Diverse patient needs	Ensure teaching methods address the learner needs (i.e., challenges with communication, education level of patient).
Powerlessness, frustration	Recognize personal reaction to stress. Develop a support system. Rely on friends and family for positive encouragement. Network with other nurses, health care providers, and community leaders to change the situation. Become proactive in legislative processes affecting health care delivery.

Caregiver and Holistic Support

Support provided by the caregiver is important to a patient's sense of physical, psychological, and spiritual well-being. It is important that nurses focus on the caregiver dynamics and interactional patterns (Wright & Leahey, 2013). For example, caregivers who live with chronic disease develop expertise in managing symptoms and adjust their lifestyles and environments. When they meet with nurses, caregivers often bring a wealth of information and personal experience to the encounter. The nurse can initiate conversations about the care and support of the patient and discover that caregivers provide diagnoses, advice, remedies, and support to their family members in both sickness and health. One particularly

important nursing strategy is that of commending the caregiver for being supportive to the patient (Wright & Leahey, 2013).

To develop a successful teaching plan, the nurse must view the patient's needs within the context of the caregiver's needs. For example, the nurse may teach a patient with right-sided paresis (weakness) self-feeding techniques with the use of special implements, but at a home visit, the nurse finds the patient being fed by the spouse. On questioning, the spouse reveals that it is too difficult to watch the patient struggle with feeding and that it is easier to feed the patient. This is an example of a situation in which both the patient and the spouse need additional teaching about the goals of self-care. Such situations represent opportunities for home care and community health nurses to partner with acute care nurses by evaluating the teaching that is performed in the hospital and providing ongoing patient teaching in the community.

Process of Patient Teaching

Patient teaching is a distinct and definable activity that includes strategies that help patients and caregivers make informed decisions about the patient's health (Epstein, 2013). These decisions can facilitate proper care for illnesses and the implementation of health-promotion interventions to aid in recovery. In fact, participation in patient education helps patients and caregivers obtain the information and education they want and need (Canadian Partnership Against Cancer, 2012).

Many different approaches are used in the process of patient education. However, the approach used most frequently by nurses is actually a parallel of the nursing process. Both the **teaching process** and the nursing process involve development of a plan that includes assessment, diagnosis, the setting of patient outcomes or objectives, intervention, and evaluation. The teaching process, like the nursing process, may not always flow in sequential order, but the steps serve as checkpoints that the teaching–learning process has been considered.

The Situated Clinical Decision-Making framework by Gillespie and Paterson (2009) has been adapted specifically for educative nursing practice. This tool encourages the nurse to develop toward becoming an expert educator in working with patients and caregivers in nursing practice (Paterson & Young, 2015). This framework focuses on the important concepts of respect, reflection, and collaboration. Central to the framework are knowing the patient, understanding the individual's past experiences in relation to health and illness, and understanding his or her preferences, supports, and resources when making important clinical decisions (Gillespie & Paterson, 2009). Another central component is caring, which provides the interpersonal context in which educative nursing practice occurs with the patient and caregivers (Paterson & Young, 2015).

Assessment

During the general nursing assessment, the nurse gathers data that determine whether the patient has learning needs that teaching can meet. For example, what does the patient know about the health problem, and how does he or she perceive the current problem? If a learning need is identified, a more refined assessment of need is made, and that problem is addressed with an appropriate teaching process (Billings & Hallstead, 2016). The general nursing assessment also identifies many variables that affect the teaching–learning process, such as the patient's physical and mental state of health and sociocultural characteristics. Caregivers may be included in the assessment, and that information can be used to determine their abilities to care for the patient at home. According to Levine (2011), *caregiver assessment* refers to a systematic process of gathering information that not only describes a caregiver situation but identifies the particular issues, needs, resources, and strengths of the family caregiver.

The assessment that is performed for the purpose of developing a teaching plan includes particularly the physical, psychological, spiritual, and sociocultural characteristics that affect learning, as well as the patient's characteristics that influence the teaching–learning process. Key questions addressing each of these areas are included in Table 4-5.

TABLE 4-5

ASSESSMENT OF CHARACTERISTICS THAT AFFECT PATIENT TEACHING: CHARACTERISTICS AND KEY QUESTIONS

Physical
• What is the patient's age and sex? • Is the patient acutely ill? • Is the patient fatigued? In pain? • What is the primary diagnosis? • Are there other medical problems? • What is the patient's hearing ability? Visual ability? Motor ability? • What medications does the patient take? Do they affect learning? • What is the physical environment in which the teaching will take place: the hospital classroom? The patient's room?
Psychological
• What is the patient's current mental status? • Does the patient appear anxious, afraid, depressed, or defensive? • Is the patient in a state of denial? • What is the patient's level of self-efficacy? • Is the "timing to teach" appropriate?
Sociocultural
• Is the patient employed? • What is the patient's current or past occupation? • How does the patient describe his or her financial status? • What is the patient's living arrangement? • Does the patient have family or close friends? • What are the patient's beliefs regarding his or her illness or treatment? • What is the patient's cultural–ethnic identity? • Is proposed teaching consistent with the patient's cultural values? • Has the patient's primary language been assessed for teaching purposes?
Educational
• What is the literacy level of the patient? • What does the patient already know? • What does the patient think is most important to learn first? • What prior learning experiences establish a frame of reference for current learning needs? • What is the patient's level of motivation? • What has the patient's health care provider told the patient about the health problem? • Is the patient ready to change behaviour or learn? • Can the patient identify behaviours and habits that would make the problem better or worse? • How does the patient learn best: through reading? Listening? Physical activities? • In what kind of environment does the patient learn best: in a formal classroom? In an informal setting, such as home or office? Alone or among peers? • In what way can the family be involved in patient education?

Physical Characteristics.

The age of the patient is an important factor to consider in the teaching plan. The patient's experiences, rate of learning, and ability to retain information are affected by age. Challenges to effective

learning such as sensory impairments (e.g., hearing or vision loss) decrease sensory input and can alter learning. For the patient with impaired vision, magnifying glasses and bright lighting may help with reading teaching materials. Hearing loss can be compensated for with hearing aids or teaching techniques that involve more visual stimuli. Central nervous system (CNS) function may be affected by disorders of the nervous system, such as stroke and head trauma, but also by other diseases, such as renal disease, hepatic impairment, and cardiovascular failure. Patients with alterations in CNS function have difficulty learning and may require information to be presented in small amounts and with frequent repetitions. Manual dexterity is needed to perform procedures such as self-administered injections or blood pressure monitoring. Problems performing manual procedures might be resolved with the use of adaptive equipment.

Pain, fatigue, and certain medications influence the patient's ability to learn. Nobody can learn effectively when in severe pain. When the patient is experiencing pain, the nurse should provide only brief explanations and follow up with more detailed instruction when the pain has been managed. A fatigued or weakened patient cannot learn effectively because of the inability to concentrate. Such inability can be caused by sleep disruption, which is common during hospitalization, frequently resulting in patients who are exhausted at the time of discharge. Also, many chemotherapeutic drugs cause nausea, vomiting, and headaches that affect the patient's ability to assimilate new information. The nurse must adjust the teaching plan to accommodate these factors by setting high-priority goals that are based on needs and are realistic. Teaching methods should also be adjusted to accommodate for any limitations that arise in the patient's ability to learn.

Psychological Characteristics.

Psychological factors have a major influence on the patient's ability to learn. Anxiety and depression are common reactions to illness. Although mild anxiety increases the learner's perceptual and learning abilities, moderate and severe anxiety limit learning. For example, the patient with newly diagnosed diabetes who is

depressed about the diagnosis may not listen or respond to instructions about blood glucose testing. Engaging with the patient in a discussion about these concerns or referring the patient to an appropriate support group may enable the patient to learn that management of diabetes is possible.

Patients also respond to the stress of illness with a variety of defence mechanisms, such as denial, rationalization, and even humour. A patient who denies having cancer is not receptive to information related to treatment options. A patient using rationalization may imagine any number of reasons for avoiding change or for rejecting instruction; for example, a patient with cardiovascular disease who does not want to change dietary habits may relate stories of persons who have eaten bacon and eggs every morning for years and lived to be 100 years of age. Humour is used by some patients to filter reality or decrease anxiety. For example, it is not uncommon for patients to assign a name or a characteristic to an intestinal stoma. The nurse must determine when a patient is using humour excessively to avoid facing reality. A nursing diagnosis for this situation could be *ineffective coping* related to *insufficent sense of control.* Humour can be important and useful in the teaching process as well but should focus only on a situation or an idea, not on personal characteristics. It is also important to note that while some patients respond well to humour, others do not.

One important psychological determinant of successful adoption of new behaviours is the patient's sense of self-efficacy. The term **self-efficacy** refers to an individual's sense of confidence in his or her ability to perform a set of actions. In fact, the greater a person's confidence, the more likely he or she is to initiate and persist in that particular activity. Self-efficacy is the mediator between knowledge and action (Williams, Kessler, & Williams, 2015). Appropriate teachings by the nurse will provide the patient with the knowledge and skill to cope with upcoming problems, which in turn will decrease the patient's anxiety. Self-efficacy is strongly related to outcomes of illness management.

The nurse should proceed from simple to more complex content to establish a positive experience of success. Both role play, to rehearse new behaviours, and peer learning are teaching strategies that can

increase feelings of self-efficacy in patients, caregivers, and family members.

Sociocultural Characteristics.

Sociocultural characteristics influence a patient's perception of health, illness, health care, life, and death. Social elements include the patient's lifestyle, status within a family, occupation, income, education, housing arrangement, and living location. Cultural elements include dietary and sleep patterns, exercise, sexuality, language, values, and beliefs. The patient and family may value the presence of an interpreter who can decrease the embarrassment of miscommunication.

Socioeconomic Factors.

Knowing the patient's current or past occupation may assist the nurse in determining what vocabulary to use during teaching. For example, an auto mechanic might understand the volume overload associated with heart failure through the metaphor of an engine flooding. An engineer may bring the principles of physics associated with gravity and pressures to bear when discussing vascular problems. This technique of teaching requires creativity but can promote a patient's understanding of pathophysiological processes.

Literacy and Health Literacy.

Health literacy is the individual's capacity to read, comprehend, and act on health information. A health-literate patient, therefore, has the capacity to acquire, process, and use health information (Spreos, 2011). Health literacy is critical to Canadians' capacity to manage their health (Mitic & Rootman, 2012). As the health care environment has become more complex, individuals with limited literacy have been shown to experience greater difficulty understanding and acting on health information. In essence, adults with low-level literacy scores do not possess the basic skills required to function within the twenty-first century health care system (Toronto & Weatherford, 2015). Even patients with high general health literacy

can exhibit low health literacy in the presence of complicated health information (Rootman & Gordon-El-Bihbety, 2008).

Knowing whether a patient has poor health literacy skills is critical. Such knowledge enables the nurse to match verbal instructions and the readability level of materials to the health literacy skills of the patient (Spreos, 2011). Printed educational materials are used extensively for the purpose of teaching patients and caregivers. Depending on the patient's health literacy, nonprint teaching materials, such as videotapes, audiotapes, demonstrations, models, pictograms, and other visual aids, may provide patients with information concerning diagnosis, prognosis, treatment, and health-promotion strategies in terms that are understandable. The use of health informatics strategies, such as telehealth, can improve access to health teaching for patients and caregivers in rural or underserviced areas. Virtual education forums are being used extensively as they allow individuals across Canada online access to professionally led educational presentations about how to live well with a particular illness, such as osteoporosis (Osteoporosis Canada, 2017).

Nurses must structure their approach to health care education so that expectations are consistent with the needs of patients. The nurse must be a facilitator of learning by assisting patients and caregivers to access, use, and evaluate the wide range of available information. Nurses can empower their patients through the creative and efficient use of information technology. Therefore, they must remain up to date with new technology-based tools and learn how and when to use technology in their practice, while also being cognizant that each patient, family, and community is a unique entity with specific needs that are met within the context of the relationship (Cullen & Wagner, 2015). For instance, nurses can provide email consultation and clinical information available on the Internet. Through technology, patients can become enlightened and empowered to take more active roles in their own health care.

According to the Organisation for Economic Co-operation and Development (OECD; 2008) and Statistics Canada and OECD (2005), five levels of literacy have been identified. People with Level 1 literacy had very poor skills; for example, they were unable to

determine the correct dose of medication from information on the package. People with Level 2 literacy required material to be simple and clearly laid out, and only tasks that were not overly complex could be included in the material. People at this level could read but had poor test results. They may have had everyday literacy-related coping skills but were unable to meet new demands, such as learning new job skills. People with Level 3 literacy had the minimum skills necessary for everyday life in a complex society, such as graduation from high school and acceptance to a postsecondary institution. People at this level were able to integrate several sources of information and solve more complex problems. People with Levels 4 and 5 literacy had higher-order skills in information processing. The majority of results are found in Table 4-6.

TABLE 4-6
SKILL LEVELS AND DISTRIBUTION WITHIN CANADA

- Notable variations in scores exist across provinces and territories, in all three domains (literacy, numeracy, and PS-TRE).
- Literacy and numeracy scores are highest at ages 24 to 34 and are lower among older age groups.
- Individuals aged 16 to 34 are found to be most proficient in PS-TRE. Despite higher levels of proficiency in PR-TRE among youth (16 to 24), 9% display proficiency at the lowest level in PS-TRE.
- Men have higher numeracy skills than women across the entire PIAAC age spectrum while, in general, both genders display similar proficiencies in literacy and PS-TRE.
- Higher education is associated with greater literacy and PS-TRE skills.
- The employed population displays greater information-processing skills than the unemployed and not-in-the-labour-force populations.
- Literacy and numeracy skills of unemployed and not-in-the-labour-force populations are similar. However, not being in the labour force is associated with lower PS-TRE skills compared to the unemployed population.
- Information-processing skills of Indigenous populations, immigrants, and official-language minority populations vary considerably across provinces and territories.

PIAAC, Programme for the International Assessment of Adult Competencies; *PS-TRE*, problem solving in technology-rich environments.

Source: Adapted from Statistics Canada. (2013). *Skills in Canada: First results from the Programme for the International Assessment of Adult Competencies (PIAAC)* (Catalogue no. 89-555-X). Retrieved from *http://www.statcan.gc.ca*.

The two most commonly used health literacy tools in health care settings are the Rapid Estimate of Adult Literacy in Medicine (REALM) and the Test of Functional Health Literacy in Adults

(TOFHLA; Altin, Finke, Kautz-Freimuth, et al., 2014). The REALM is a test of an individual's ability to recognize and pronounce words, whereas the TOFHLA is a measure of the ability to read, comprehend text, and perform computations involving health-related tasks. The two tests were modelled after general functional literacy measures and provide estimates of literacy ability when applied to health care contexts. However, recent publications suggest that neither is able to measure the full breadth of health literacy (Pleasant, McKinney, & Rikard, 2011; Kirk, Grzywacz, Arcury, et al., 2012).

Newer instruments have been developed for health care providers, including the Newest Vital Sign (NVS) (Stagliano & Wallace, 2013). As a screening tool, NVS identifies patients at risk for low health literacy. The test result provides information about the patient that allows health care providers to adapt their communication practices in an effort to achieve better health outcomes. Another tool is the Brief Health Literacy Screen (BHLS), which is a brief self-report health literacy assessment tool that addresses not only written health literacy but also verbal health literacy and the ability of patients to remember health information and instructions provided by a health care provider (Sand-Jecklin & Coyle, 2014).

Housing Arrangements and Living Location.

The patient should be asked about living arrangements that can affect the teaching–learning process. Whether the patient lives alone, with friends, or with caregivers is a determinant of who else is included in the teaching process. If the patient lives in another city or a rural area, at a distance from the site of teaching, the nurse might be expected to make arrangements for continued teaching in the patient's area. Similarly, the nurse may have to modify instructions if the patient does not have access to electricity, a phone, or a computer.

Culturally Competent Care

Understanding how to provide culturally competent patient care is important for nurses in today's society (Douglas, Pierce, Rosenkoetter, et al., 2011). *Cultural competence* is a dynamic learning process that requires nurses to apply knowledge, skills, attitudes, or personal attributes to maximize respectful relationships with diverse populations of patients, their caregivers, and co-workers (Canadian Nurses Association [CNA], 2010).

A conflict between the patient's cultural beliefs and values and the behaviours promoted by teaching can affect the teaching–learning process. For example, a patient who views being overweight as a sign of financial success may have difficulty accepting the need for diet and exercise unless the importance of blood pressure control is understood.

As part of the assessment process, patients could be asked to describe their beliefs regarding health and illness. The nurse must determine the patient's use of cultural remedies and traditional healers and, for teaching to be effective, incorporate cultural health practices into the teaching plan. In addition, it is important to know who has authority in the patient's culture. Whether this is a community leader, a spiritual leader, or a traditional healer, the patient may defer to the authority's decision making. In this case, the nurse could, if feasible, attempt to work with the decision makers in the patient's cultural group.

Learner Characteristics.

Finally, the nurse should assess patient characteristics that are directly related to the development of the teaching plan. These factors include the patient's learning needs, readiness to learn, and learning style.

Learning Needs.

Learning needs are the new knowledge and skills that an individual must acquire to be able to meet an objective or a goal. The

assessment of learning needs should first be used to determine what the patient already knows, whether the patient has misinformation, and whether the patient has any history of experiences with health problems. The learning needs of patients with chronic illnesses are different from those of patients with newly diagnosed health problems. The nurse then identifies the information, the behaviours, or the skills known to improve patient outcomes that should be included in the teaching plan.

What a patient should learn about managing an illness or what behaviours should be changed to promote health may seem obvious to the nurse. However, there is often a significant difference between what health care providers think is important for patients to learn and what patients want to know.

To individualize learning needs for a particular patient, the nurse may give the patient a list of the recommended topics and ask the patient to number the topics in order of importance. Another method includes writing each topic in question format on a single card and asking the patient to sort the cards in priority. For example, the questions on the cards for a patient with Parkinson's disease might include “When is the most important time to take my medications?” and “What can I do to help with the freezing when I walk?” By allowing a patient to prioritize his or her own learning needs, the nurse can address the patient's most important needs first. When life-threatening complications are a factor, the nurse can encourage the patient to prioritize learning this information by explaining why the item is a “need-to-know” topic.

Readiness to Learn.

Before implementing the teaching plan, the nurse should determine which stage of change the patient is in (see Table 4-3). If the patient is only in the precontemplation stage, the nurse may just provide support and increase the patient's awareness of the problem until the patient is ready to consider a change in behaviour. When the patient leaves the hospital, continuity of care is important; that is, hospital and community nurses should be aware of a transition phase for a patient as adjustment to the community continues. They can share information about the patient's learning stage by means of nurse-to-

nurse discharge summaries, continue to evaluate the patient's readiness to learn, and implement the teaching plan as the patient progresses through the stages of change.

Learning Style.

Each person has a distinct style of learning, as individual as his or her personality. **Learning style** is the way in which each individual understands and responds to a learning situation (Billings & Hallstead, 2016). The three major learning styles are (a) visual (usually reading), (b) auditory (listening), and (c) physical or kinesthetic (doing things). People often use more than one learning style. To assess a patient's learning style, the nurse might ask how the patient learns best, whether reading or listening is the preferred method to gain information, and how the patient has learned in the past. Adult learners require a variety of approaches to learning, and nurses must be creative in their delivery of health information. However, if a patient identifies a specific learning style, the nurse should use that method whenever possible. In addition to learning styles, it is valuable to know the patient's world views and how the individual perceives his or her health and illness. Further information on world views can be found in the discussions on culture in Chapter 2 and on chronic illness in Chapter 5.

Diagnosis

From the assessment, the nurse obtains information about what the patient knows, believes, and is able to do, and then compares this information with what the patient wants to know, needs to know, and needs to be able to do. Identifying the gap between the known and unknown helps determine the nursing diagnosis. With teaching, a strength can be validated or a deficiency can be corrected. An example of a desirable outcome that could facilitate validation of a patient's strength is *developing a dietary regimen.* A common nursing diagnosis for learning needs is *deficient knowledge.*

Planning

After the assessment and identification of the nursing diagnosis, the next steps in the education process include setting goals, determining learning outcomes, and planning the learning experience. Together, the patient and nurse should prioritize the patient's learning needs and agree upon the goals and learning outcomes. If the physical or psychological condition of the patient begins to interfere with his or her participation, the patient's caregiver can then assist the nurse in the planning phase.

It is important to write attainable goals and clear learning outcomes. Goals are broad, clear, and general statements of what the patient *wants to accomplish*. **Learning outcomes** are the *achieved* results of what was learned (Billings & Halstead, 2016)—the competencies and the knowledge that the patient has achieved and can demonstrate successfully after the teaching–learning has occurred. For example, the patient who is diabetic will be able to demonstrate how to give an insulin injection to himself or herself safely and with precision.

Table 4-7 shows a sample teaching plan that could be adapted to address any patient's learning needs.

TABLE 4-7
SAMPLE TEACHING PLAN

Purpose To provide patient with information necessary to correctly change a colostomy appliance					
Goal The patient will be able to affix accurately and independently a colostomy appliance to a stoma.					
Learning Outcomes	**Content Outline**	**Method of Instruction**	**Time Allotted**	**Resources**	**Method of Evaluation**
After a 25-min. teaching session, the patient will be able to do the following:					
1. Demonstrate, in order, the steps required to prepare and affix correctly the colostomy appliance (cognitive)	List of the steps Description of the various items required	1 : 1 instruction	4 min.	Description of equipment	Post-testing • Verbal • Written • Other
2. In the presence of the nurse, accurately measure and affix the colostomy appliance to the stoma (psychomotor)	Technique as per hospital policy and procedure Procedure for measuring stoma and affixing the appliance	Demonstration and return demonstration	13 min.	All equipment required; e.g., colostomy appliance, measuring grid, adhesive paste (Stomahesive), stoma model	Observation of return demonstration
3. Express to the nurse any feelings of discomfort regarding the ostomy and its care (affective)	Discuss common concerns Explore patient's feelings	Discussion	8 min.	Video of patient vignettes Handouts	Question and answer

Selecting Teaching Strategies.

Selection of a particular strategy is determined by at least three factors: (a) patient characteristics (e.g., age, educational background, degree of illness, culture, learning style); (b) subject matter; and (c) available resources. Some teaching strategies that can be employed to achieve learning objectives follow. Each has advantages and disadvantages that render it more or less suitable to a particular patient and learning situation (Figure 4-2).

FIGURE 4-2 Effective teaching with a variety of materials.

Patient Workshop.

In the patient workshop, the lecture format is an efficient, versatile, and economical teaching strategy that can be used when time is limited or when a group of patients and family members can benefit from acquiring some core information. The nurse presents a series of related ideas or facts to one person or to a group. It is important to remember that the average adult learner can remember five to seven points at a time. Disadvantages of the lecture format are that it often has negative "school learning" connotations and that the extent of individual learning is difficult to evaluate. The lecture–discussion can overcome some of the disadvantages of the lecture alone. With this strategy, the nurse presents specific information by using the lecture technique and follows up with a discussion, during which patients and their caregivers ask questions and exchange points of view with the nurse. This strategy assists the patient in becoming an active participant in the learning process and creates a more informal give-and-take learning environment. Some patients may be reluctant to actively engage in discussions.

Discussion.

The purpose of discussion may be to exchange points of view concerning a topic or to arrive at a decision or conclusion. The nurse can discuss content with an individual or with a group, keeping the specific learning objectives in mind and clarifying information as needed. Participants' questions help the nurse identify and correct inaccurate information. This strategy is a good choice when the patient or patients have previous experience with a subject and have information to share, such as about smoking cessation or convalescence after coronary artery bypass surgery. The discussion allows the patient or caregivers to participate actively and to apply their own experiences and observations to the learning process.

Group Teaching.

There are two main types of group teaching. In the first, the nurse acts as a **facilitator**, helping the group to share insights about a common problem. As facilitator, the nurse participates by keeping information moving among all group members. The nurse may introduce the patient to an existing group or may recruit a group of patients with similar problems, such as women who have multiple sclerosis.

A second kind of group teaching involves peer teaching. **Peer teaching** is teaching that is conducted within the setting of groups of peers, such as a self-help or support group. In a peer-teaching setting, the participants learn from one another without the additional input of an instructor. A support group is a self-help organization that can provide continuing information, shared experiences, acceptance, understanding, and useful suggestions about a problem or concern. Patients with health issues such as cancer, alcoholism, Parkinson's disease, compulsive overeating, diabetes, or heart disease frequently find benefit from peer-teaching situations. The nurse should actively look for opportunities to refer a patient or caregiver to a support group. This action should be taken in addition to, not instead of, the nurse's planned teaching sessions.

Demonstration–Return Demonstration.

The demonstration–return demonstration is a strategy commonly used by nurses. The purpose is to show the patient how to perform a motor skill–based task, such as a dressing change, injection, or blood pressure measurement (Figure 4-3). The focus is on the correct procedure and its application. The nurse presents the demonstration in an informal manner, defines and explains unfamiliar terms, and watches the patient for signs of confusion or uncertainty. The nurse clarifies and repeats as necessary. Then the patient returns the demonstration with the nurse as observer. The entire process should require no more than 15 to 20 minutes. Achieving motor skills requires practice, so the patient must practise the procedure between teaching sessions.

FIGURE 4-3 Careful teaching using demonstration–return demonstration has been shown to increase the probability of successful learning by the patient. Source: Courtesy Linda Bucher, RN, PhD, CEN, CNE, Staff Nurse, Virtua Memorial Hospital, Mount Holly, NJ.

Role Play.

Role play is another strategy that the nurse might employ, depending on teaching objectives. This format is most often used

when patients need to examine their attitudes and behaviours; understand the viewpoints and attitudes of others; or practise carrying out thoughts, ideas, or decisions. The nurse provides information and clear instructions to role players and observers and provides time for feedback and evaluation. Role-playing requires maturity, confidence, and flexibility on the part of the participants. It is important to remember that patients sometimes may feel uncomfortable and inhibited with this method; however, initial discomfort can usually be overcome with patience and support. Role-playing takes time, which must be factored into the teaching plan. An example of the use of role-playing is that of a wife who needs to rehearse how to talk with her husband about his need to quit smoking. In this case, practising the discussion with the nurse ahead of time is often a helpful strategy.

Use of Audiovisual Materials.

Audiovisual materials, including DVDs, computer-based programs, charts, podcasts, or simple transparencies, are commonly used to supplement other teaching strategies. This strategy can enhance the presentation of information because it promotes learning through both visual and auditory stimulation. To use this strategy effectively, the nurse must preview and evaluate the teaching materials for accuracy, completeness, and appropriateness to the learning objectives before showing them to the patient and family. CDs are relatively easy to use and are usually inexpensive. The use of audiovisual materials can be extremely beneficial, particularly when teaching content that is largely visual, such as the steps and processes of procedures (dressing changes, injections, hemodialysis). Computer-based programs designed for interactive learning of specific health information are widely available.

Use of the Internet.

The Internet is widely used by patients for self-education. Many patients use their own computers or those available at public libraries to access health information on the Internet. The Internet also offers established educational programs designed for specific learners. However, the use of the Internet as a source of information

is problematic. It offers a large number of high-quality health resources and poses seemingly unlimited opportunities to inform, teach, and connect health care providers with patients; at the same time, much Internet-borne information is incomplete, misleading, or inaccurate.

The nurse is challenged by several factors when using the Internet as a teaching tool. The nurse must have adequate computer competency to review and evaluate information and programs available on the Internet. Personal computer competency is especially necessary to teach patients and caregivers who are unfamiliar with computers, especially older adults, how to access information. All patients who use the Internet must be taught how to identify reliable and accurate information. The nurse should encourage patients to use sites established by the government, universities, or reputable medical or health-related associations (e.g., the Canadian Medical Association, Canadian Diabetes Association, Canadian Heart and Stroke Foundation, and Public Health Agency of Canada). The list of resources at the end of this chapter includes select reliable patient-education websites for the nurse to review and refer for patient use.

Use of Printed Materials.

Printed materials are most often used in combination with other teaching strategies presented in this section. For instance, after a lecture on the physiological effects of smoking, the nurse might distribute a pamphlet from the Canadian Cancer Society that reviews and reinforces the topic. For another patient, the nurse might select a book or magazine article written by a woman who has had a mastectomy and suggest that the patient read this material to prepare for future teaching sessions. Written materials are always recommended for patients whose preferred learning style is reading.

Written resources must be appropriate for the reading level of the patient. Before written materials are used with patients, the nurse should evaluate the readability level if it is not indicated on the materials. If patients are to understand and benefit from all offered education materials, then information must be selected, revised, or

redesigned so that even those patients at the lowest literacy level can comprehend it.

Major resources for acquiring relevant printed materials include the hospital or care facility library, the pharmacy, the public library, government agencies, universities, volunteer organizations, websites, and research centres. Written materials, including computer-based programs, should be reviewed by the nurse before being used. In addition to reading level, the following criteria for review are suggested: (a) accuracy, (b) completeness, (c) suitability to meet specific learning goals, (d) inclusion of pictures and diagrams to stimulate interest, (e) focus on one main idea or concept per pamphlet or program, (f) inclusion of information the patient would like to know, and (g) gender and culture sensitivity of the material (Bastable, 2008).

Games and Simulation.

A game provides a framework for inserting content to create learning activities. Frameworks are easily adaptable to a wide variety of content and learning outcomes for patients. Typically, a game requires rules for player moves and termination criteria so that winners can be determined. Simulation games have been shown to enhance educational experience so that games provide more than a mere review of content. Debriefing, an important aspect of the learning process, occurs after the game in the form of a discussion focused on concepts, generalizations, and the applications of topics covered in the game. This end process assists learners to recognize that learning has occurred within the fun experience of the game (Jaffe, 2013).

Implementation

During the implementation phase, the nurse uses the planned strategies to present information and demonstrations. Verbal and nonverbal communication skills, active listening, and empathy are incorporated into the process.

In implementing the teaching plan, the nurse should remember the principles of adult learning and the determinants of learning.

Reinforcement and reward are important. Techniques to enhance the teaching process with adults are presented in Table 4-8.

TABLE 4-8
TECHNIQUES TO ENHANCE PATIENT LEARNING

- Keep the physical environment relaxed and nonthreatening.
- Maintain a respectful, warm, and enthusiastic attitude.
- Let the patient's expressed needs direct what information is provided.
- Focus on "must-know" information; "nice-to-know" information can be added if time allows.
- Involve the patient and family in the process; emphasize active participation.
- Be aware of and take into consideration the patient's previous experiences.
- Emphasize the relevancy of the information to the patient's lifestyle, and suggest how it may provide an immediate solution to a problem.
- Individualize the teaching plan, even if standardized plans are used.
- Emphasize helping the patient to learn, rather than simply transmitting subject matter.
- Review written materials with the patient.
- Ask frequently for feedback.
- Affirm progress with rewards valued by the patient to reinforce desired behaviours.

Evaluation

Evaluation is the final step in the learning process. It is a measure of the degree to which the patient has mastered the learning objectives. The nurse monitors the performance level of the patient so that changes can be made as needed. The nurse might find that the patient has already achieved the goals. However, if certain goals are not reached, the nurse should reassess the patient and alter the teaching plan. If the patient has developed new needs, the nurse then plans new goals, content, and strategies accordingly.

For example, an older man with diabetes mellitus enters the hospital with a blood glucose level of 30.5 mmol/L. When the nurse observes the patient preparing his insulin injection, she notices that he incorrectly fills the syringe with 20 units of insulin and 20 units of air, instead of 40 units of insulin. After correcting the dosage and questioning the patient, the nurse concludes that the patient could not accurately see the markings on the syringe and may have been administering insufficient insulin to himself for a long time. The patient may require special equipment and new teaching on how to use it so he can administer the insulin safely and accurately.

Evaluation techniques may be short-term or long-term. Short-term evaluation techniques are used to evaluate quickly the patient's mastery of a concept, skill, or behaviour change; short-term evaluation can be accomplished in the following ways:

1. *Observe the patient directly.* "Let me see how you administer your injection." Through observation, the nurse determines whether the patient has mastered the task, whether further instruction is needed, or whether the patient is ready for new or additional content.
2. *Observe verbal and nonverbal cues.* If the patient asks the nurse to repeat instructions, asks questions, shakes his or her head, loses eye contact, or otherwise expresses doubt about understanding, the patient may be indicating that further instruction is needed or that an alternative approach should be taken.
3. *Ask direct questions.* "What are the major food groups?" "How often must you change your dressing?" "What should you do if you develop chest pain after returning home?" Open-ended questions almost always provide more information about the patient's understanding than do questions that call for only a "yes" or "no" answer.
4. *Use a written measurement tool, graded for accuracy.* Paper-and-pencil tests can actually increase anxiety in patients. Many adults "freeze" or "go blank" when given a test or asked to write something that will be graded. Assess the patient's comfort and learning style before using a written method of evaluation.
5. *Talk with a member of the patient's family or support system.* "Is he eating regularly?" "How is he handling the walker?" "When is she taking her medications?" Because the nurse cannot observe the patient 24 hours a day, the nurse should receive information from other people who have contact with the patient.
6. *Seek the patient's self-evaluation of progress.* By seeking out a patient's opinion, the nurse is allowing the patient to provide input into the evaluation process. Long-term evaluation

necessitates follow-up by the nurse, outpatient clinic, or outside health care organization. The nurse should set up a schedule of visits for the patient before the patient leaves the hospital or clinic or refer the patient to the proper agencies. The nurse keeps written documentation of follow-up telephone calls or emails to urge the patient to maintain the follow-up schedule. The patient's caregivers should be familiar with the follow-up plan so that everyone is involved in the patient's long-term progress.

Continuity of Educational Care

The nurse is responsible for communicating with the health care providers involved in the patient's long-term follow-up. To ensure continuity, the nurse should telephone, visit, or email these providers and supply them with the patient's education plan. This information needs to be charted and routinely updated in the patient's medical record.

Documentation of the Educational Process

Documentation is an essential component of the entire teaching–learning transaction. The nurse records everything, from the assessment through short- and long-term plans for evaluation. As mentioned, copies of the documentation should be forwarded to the organization or health care provider providing long-term follow-up. The teaching objectives, the content, the strategies, and the evaluation results should be written clearly and completely because many members of the health care team will use these records in different places and for various reasons.

The Standardized Teaching Plan

Standardized teaching plans are often included in care maps and clinical pathways, and they have become an accepted method of developing a teaching plan. Standardized teaching plans contain the widely accepted knowledge and skills that a patient and caregivers need with regard to a specific health problem or procedure.

However, the nurse should always individualize these plans to meet the patient's specific needs.

Case Study

Example of the Teaching Process

Source: Nadino/Shutterstock.com.

Mrs. Emily Crowe is admitted to the hospital for preliminary testing and preparation for a hysterectomy. The nurse is aware that a patient undergoing a hysterectomy is often deeply concerned about her self-concept as a woman. The nurse also knows that such patients need to express their feelings in an atmosphere of support and understanding. Therefore, the nurse has sought to listen attentively and ask questions carefully in order to assess the patient's feelings about and knowledge of the surgical procedure she is about to undergo. The nurse has asked open-ended questions, such as, “How do you feel about having the surgery?” and “What concerns do you have about undergoing a hysterectomy?” By establishing both a climate of trust and a counselling relationship, the nurse has completed the assessment that follows.

Biophysical Dimension

Age 44, female, high school English teacher and coach of girls' high school basketball team; good general health. Height and weight proportional and average for age. Patient reports that she jogs five evenings a week. No sensory impairment; vision, hearing, and reaction time seem normal.

Psychological Dimension

Patient appears mildly anxious about surgery and seems worried about her husband's acceptance of her sexuality. She is also worried about missing work and leaving her classes to a substitute teacher. She states that she does not “let physical problems get me down” and that she dislikes “pills and hospitals.” She states that she is used to “teaching” and not “being taught,” and she tries to dominate any conversation or input from the nurse.

Sociocultural Dimension

Married with one child (son), age 23. Mother had a mastectomy at age 51; father healthy. Two younger sisters; both experienced difficult pregnancies but are otherwise healthy. Patient describes caregiver communication as very good. She describes her lifestyle as work oriented and says that her friends are primarily teaching colleagues. She places a high priority on work and family.

Learning Style

Responds well to formal lectures. Enjoys reading and group discussions.

Determining Learning Outcomes

After a brief period of rest and adjustment to the unfamiliar hospital environment, Mrs. Crowe states that she would like to learn more about the details of the upcoming planned surgical procedure. Together, Mrs. Crowe and the nurse identify the following objectives:

After the teaching session, I (Mrs. Crowe) will be able to do the following:

1. Describe the surgical procedure (hysterectomy) to the nurse.
2. Express to the nurse and my husband my feelings about maintaining an active and fulfilling sex life.
3. Complete arrangements with my family and school principal for convalescence and return to normal activities.

4. List the general recovery experiences that are expected, and prioritize circumstances under which to seek medical advice.
5. Discuss “old wives' tales” regarding hysterectomy and verbalize concerns regarding undergoing the hysterectomy.
6. Identify ways to avoid constipation, weight gain, and potential periods of depression during the recovery period.
7. Propose ways to return comfortably to baseline sexual activities.

Discussion Questions

1. What factors might impede Mrs. Crowe from learning?
2. What teaching strategies might be the most effective for Mrs. Crowe?
3. What observations will inform the nurse that the teaching session was effective for Mrs. Crowe? (Consider verbal and nonverbal behaviours.)
4. How can the learning be reinforced?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. A nurse in a clinic is teaching the client, a middle-aged Italian woman, about methods to relieve her symptoms of menopause. Which of the following is the best goal of this teaching episode?
   a. To prevent early onset of disease
   b. To maintain health promotion
   c. To alter the client's cultural belief regarding the use of herbs
   d. To provide information for selection and use of treatment options
2. What should the nurse do when planning experiences with consideration of adult learning principles?
   a. Present material in an efficient lecture format
   b. Recognize that adults enjoy learning regardless of the relevance to their personal lives
   c. Provide opportunities for the client to learn from other adults with similar experiences
   d. Postpone practice of new skills until the client can independently practise the skill at home
3. Which of the following skills is necessary for the nurse in the role of teacher?
   a. Determining when clients are too distressed physically or psychologically to learn
   b. Assuring the client that the nurse understands what is necessary for the client to learn
   c. Developing standardized teaching plans for use with all clients
   d. Presenting information in medical language to increase the client's vocabulary and understanding of pathophysiology
4. When the nurse is feeling stressed about the limited time available for client teaching, which of the following strategies would be most beneficial? *(Select all that apply)*

a. Setting realistic goals that have high priority for the client
b. Referring the client to a nurse–educator in private practice for teaching
c. Observing more experienced nurse–teachers to learn how to teach faster and more efficiently
d. Providing reading materials for the client instead of discussing information the client needs to learn
e. Rescheduling the client for a later date

5. Which of the following is the best reason the nurse would choose to include family members in client teaching?
   a. They provide most of the care for clients.
   b. Clients have been shown to have better outcomes when caregivers are involved.
   c. The client may be too ill or too stressed by the situation to understand teaching.
   d. Family members might feel rejected and unimportant if they are not included in the teaching.

6. Which step of the teaching process is involved when the nurse, the client, and the client's family decide together what strategies would be best to meet the learning objectives?
   a. Planning
   b. Evaluation
   c. Assessment
   d. Implementation

7. A nurse is spending time with a client who is undergoing a diagnostic procedure. Which of the following comments by the client best indicates a teachable moment?
   a. “I have to email a friend in a few moments.”
   b. “How long will this procedure take?”
   c. “I have had this procedure before.”
   d. “I'm trying not to think about it.”

8. Which of the following is an example of a correctly worded learning outcome?
   a. The client will lose 11.5 kg in 6 weeks.
   b. The client should understand the implications of the condition.
   c. The client will read two pamphlets on the subject of breast self-examination.
   d. The client's spouse demonstrates to the nurse how to correctly change a colostomy bag before discharge.
9. What are the benefits of role play as a teaching strategy? *(Select all that apply)*
   a. Encourages self-reflection
   b. Increased self-efficacy of the client
   c. Rehearses new behaviours
   d. Increases self-efficacy of caregivers
10. Which of these approaches would best provide short-term evaluation of teaching effectiveness?
   a. Observing the client and asking direct questions
   b. Monitoring the client for 3 to 6 months after the teaching
   c. Monitoring for the behaviour change for up to 6 weeks after discharge
   d. Asking the client what he or she found helpful about the teaching experience

1. d; 2. c; 3. a; 4. a, e; 5. b; 6. a; 7. b; 8. d; 9. b, c, d; 10. a.

CHAPTER 5

Chronic Illness

Written by, Jane Tyerman

LEARNING OBJECTIVES

1. Describe the impact of chronic illness in Canada.
2. Define and describe acute and chronic illness and the relationships between these concepts.
3. Identify key factors contributing to the development of chronic illness.
4. Differentiate between chronic illness and disability.
5. Discuss the psychosocial implications of living with a chronic illness.
6. Describe the ways in which chronic illness may affect family members or significant others.
7. Discuss key conceptual models of chronic illness.
8. Describe the role of self-management in chronic illness.
9. Identify emerging models of providing care to individuals with chronic illness.

Chronic disease is a leading cause of preventable death and disability as it accounts for approximately two-thirds of deaths globally (World Health Organization [WHO], 2014b). **Chronic illness** refers to health problems that persist over extended periods and that are often (but not always) associated with participation and activity limitations (disability). Chronic illnesses demand a complex response from patients and families over an extended time period. This response also involves coordinated inputs from a wide range of health care providers, as well as access to essential treatments (Clark, Gong, & Kaciroti, 2014). Care for people with chronic illness is ideally embedded within a health care system that promotes patient empowerment.

Unfortunately, the Canadian health care system is still largely built around an acute, episodic model of care that is unable to address the needs of those with chronic health problems. The current mismatch between the episodic care orientation of the existing health care system and the needs of people living in the community with chronic illnesses has led to a host

of well-documented failures in care provision. These failures include high rates of hospital readmissions; medical errors; underdiagnosis of conditions; inconsistent monitoring of chronic conditions; lack of patient-centredness; insufficient health education; duplication of resources; inappropriate omission of resources; and preventable injuries (Bodenheimer & Berry-Millett, 2009). Innovative models of providing care for people with chronic illness, such as virtual wards, are currently being evaluated in Canada and hold promise for improving care in the future (Canadian Agency for Drugs and Technology, 2011).

Because we need to organize the vast amount of knowledge about the medical-surgical nursing care of people within a cohesive framework, most textbooks are organized along the lines of body systems and common medical diagnoses. It is critical to recognize, however, that medical diagnosis alone does not predict service needs, length of hospitalization, level of care, or functional outcomes and tells us nothing about the person experiencing the condition or how this person will respond to nursing care. In providing truly holistic and comprehensive care, nurses assume a perspective that includes behavioural, psychosocial, and environmental factors. Understanding the illness experience allows for the implementation of effective interventions specific to the needs of the individual, family, or group (Henly, Wyman, & Findorff, 2011). This chapter seeks to situate the information contained in the remainder of this textbook within such a framework.

The Epidemiology of Chronic Diseases

Noncommunicable diseases (NCDs) accounted for well over half (68%) of the world's 56 million deaths in 2012, with more than 40% resulting in the premature death of adults under the age of 70 years (WHO, 2014). Chronic heart disease, lung diseases, cancer, and diabetes ranked highest among NCDs, with cardiovascular diseases (37%) being responsible for the highest proportion of global deaths in 2012, followed by cancers (27%), chronic respiratory diseases (8%), and diabetes (4%) (WHO, 2014) (Figure 5-1).

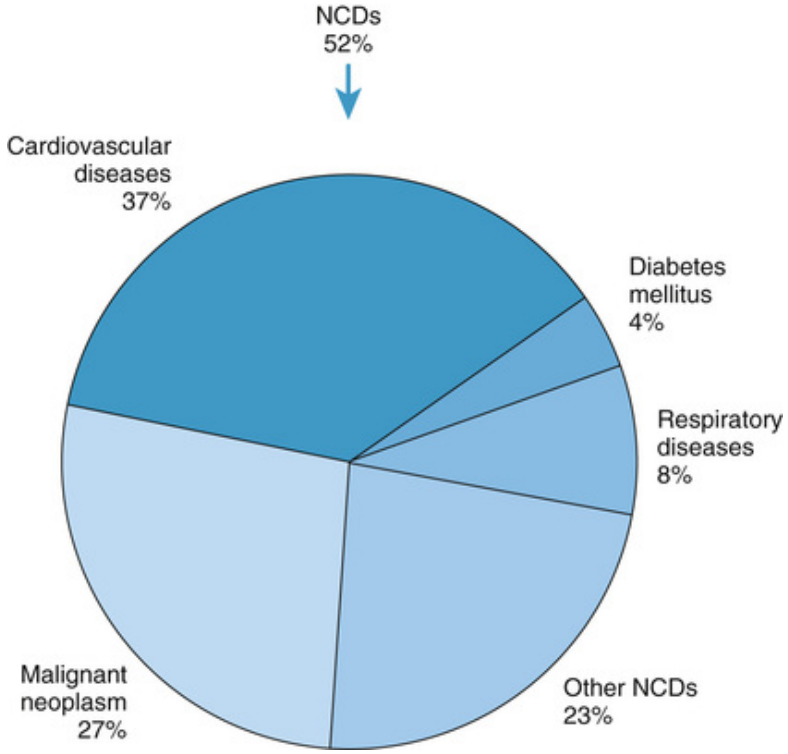

FIGURE 5-1 Main causes of global deaths younger than age 70 years for 2012. Source: Reprinted from *Global Status Report on Noncommunicable Diseases 2014,* WHO, Page No. 10, Copyright 2014.

In Canada, chronic illnesses also make a substantial contribution to morbidity and mortality. Approximately 50% of Canadians over age 20 are living with at least one chronic condition, and 14.8% of Canadians report having two ormore chronic conditions (Public Health Agency of Canada [PHAC], 2015). One in four Canadian adults is obese, and approximately 1

in 10 children in Canada is obese, a condition that could lead to the development of chronic disease in adulthood (PHAC, 2015). Canada's aging population, along with the rising rates of some risk factors for chronic diseases, is driving the chronic disease challenge. About two-thirds of deaths in Canada each year result from chronic diseases. Table 5-1 illustrates how chronic illnesses affect Canadians.

TABLE 5-1
CHRONIC ILLNESS IN CANADA

Cancer
• About 2 in 5 Canadians will develop cancer in their lifetime; mortality rate is 1 in 4. • 196 900 people are diagnosed with cancer each year. • 78 000 Canadians die each year due to cancer.
Diabetes
• About 1 in 16 Canadians (6.2%) is living with diabetes, and it is estimated that an additional 0.9% of the population (nearly 300 000) remain undiagnosed. • The prevalence of diabetes increased by 21% from 2002 to 2007. • Among adults 20 years and older, mortality rates for those with diabetes (deaths usually due to a complication of diabetes, like cardiovascular disease) were twice as high as for those without diabetes.
Cardiovascular Diseases
• 1.6 million Canadians have heart disease or are living with the effects of a stroke. • In 2007, cardiovascular diseases were responsible for about 70 000 deaths. • Death rates have decreased since the late 1960s, probably due to lower smoking rates and improved treatment.
Chronic Respiratory Diseases
• Over 3 million Canadians live with a chronic respiratory disease. • Tobacco remains the most important preventable risk factor for chronic respiratory diseases.

Of concern is the fact that chronic diseases and related risk factors are significantly higher among Canada's Indigenous peoples when compared to the national average. For example, the prevalence of diabetes among First Nations adults living on reserves is 19.7%, compared to 5.2% among the general Canadian population, and human immunodeficiency virus (HIV) infection is 2.8 times higher in Indigenous persons (Health Canada, 2010). The most common chronic conditions in First Nations adults are asthma, diabetes, heart disease, and high blood pressure (Health Canada, 2010).

Morbidity refers to the rates of disease in a population, whereas **mortality** refers to the rates of deaths. Musculo-skeletal conditions such as arthritis and osteoporosis are the most prevalent and costly chronic

conditions in Canada. In 2008, heart disease and stroke were the underlying causes of death for as many as one in three Canadians (Statistics Canada, 2011), with stroke being the leading cause of death (PHAC, 2011). In 2015, an estimated 200 000 new cases of cancer and 78 000 deaths occurred in Canada, with cancer surpassing cardiovascular disease (heart and cerebro-vascular) as the leading cause of death in Canada (Canadian Cancer Society's Advisory Committee on Cancer Statistics, 2015). Lung, prostate, breast, and colorectal cancer, the four most common cancer types in Canada, account for over 50% of all new cancer cases (Canadian Cancer Society's Advisory Committee on Cancer Statistics, 2015). Lung cancer has the highest mortality rate, causing more cancer deaths than the other three cancer types combined.

Health, Acute Illness, and Chronic Illness

Health and illness may be viewed along a continuum upon which individuals journey throughout life. **Health**, according to the WHO (2014a), is "a state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity." The state of health is dependent upon complex interactions between multiple social and economic factors, the physical environment, and individual behaviour. These factors are referred to as *determinants of health*.

Disease is a condition that a practitioner views from a pathophysiological model (Lubkin & Larsen, 2013). **Illness**, conversely, is the human experience of symptoms and suffering. This term refers to how the disease is perceived, lived with, and responded to by individuals and their families (Lubkin & Larsen, 2013). Nursing practice must be informed by both knowledge of disease and understanding of the illness experience.

Table 5-2 compares the characteristics of acute and chronic illness. **Acute illness** is typically characterized by a sudden onset, with signs and symptoms related to the disease process itself. **Signs** are typically objective manifestations of a condition, whereas **symptoms** refer to the subjective reports of the patient. Acute illness ends in a relatively short time, sometimes in recovery and sometimes in death (Lubkin & Larsen, 2013). Chronic illness often continues indefinitely. Strauss, Corbin, Fagerhaugh, and colleagues (1984) viewed chronic illness as an experience of problems that may change but do not go away. The onset of a chronic illness may be sudden, or it may develop insidiously over a long period. Some chronic illnesses are characterized by exacerbations and remissions, whereas other chronic illnesses cause persistent symptoms throughout their course.

TABLE 5-2
CHARACTERISTICS OF ACUTE AND CHRONIC ILLNESSES

Description	Characteristics
Acute Illness	
Disease that has a rapid onset and short duration *Examples:* colds, influenza, acute gastro-enteritis	• Usually self-limiting • Responds readily to treatment • Complications infrequent • After illness, return to previous level of functioning
Chronic Illness	
Disease that is prolonged, does not resolve spontaneously, and is rarely cured completely	• Permanent impairments or deviations from normal • Irreversible pathological changes • Residual disability • Special rehabilitation required • Need for long-term medical or nursing management or both

Chronic (or noncommunicable) illnesses are typically characterized as having an uncertain etiology, multiple risk factors, long latency, prolonged duration, and a noninfectious origin and can be associated with impairments or functional disability. Cardiovascular disease, diabetes, arthritis and other musculo-skeletal diseases, cancers, chronic lung diseases, and chronic neurological disorders (including depression) are conditions recognized by the Centers for Disease Control and Prevention (2011a) as chronic illnesses.

Acute and chronic illnesses can occur in an individual simultaneously. The acute illness may have a profound impact on a person with a pre-existing chronic illness. For example, a person with longstanding, well-controlled diabetes may experience an acute infection that drastically changes blood glucose and insulin requirements. Similarly, chronic illness may affect the manner in which an acute illness is managed. A person with chronic kidney disease who undergoes surgery will likely require a modified postoperative fluid regimen. The complexity of caring for patients with multiple illnesses, whether acute or chronic, demands a high standard of nursing knowledge and skill. The presence of two or more chronic illnesses that are not directly related to each other in a person at the same time is called **comorbidity** (Barnett, Mercer, Norbury, et al., 2012). An example of comorbidity would be a patient's having heart disease, arthritis, and cancer at the same. **Multimorbidity** is the simultaneous occurrence of several chronic medical conditions, which may or may not be related to each other, in the same person (Salisbury, Johnson, Purdy, et al., 2011). Achieving optimal health for a person with multimorbidity is challenging because a treatment targeting one condition

may make a coexisting condition worse. For example, a patient who is receiving nonsteroidal anti-inflammatory medications to relieve pain from arthritis finds that the medication worsens hypertension and renal disease.

Having multiple chronic medical conditions is associated with many negative outcomes: patients have decreased quality of life, more psychological distress, longer hospital stays, more postoperative complications, a higher cost of care, and higher mortality (Barnett, Mercer, Norbury, et al., 2012). In addition, multimorbidity affects the care process and may result in complex self-care needs; challenging organizational problems (accessibility, coordination, consultation time); polypharmacy; increased use of emergency facilities; difficulty in applying guidelines; and fragmented, costly, and ineffective care (Barnett, Mercer, Norbury, et al., 2012).

Factors Contributing to Chronic Illness

The key determinants of health (see Chapter 1, Table 1-2) are also critical considerations in the development of chronic illness. Although some chronic conditions have a specific and unique etiology, there are common factors identified by large, longitudinal studies that play an important role in the development of many types of chronic illness.

Lifestyle factors such as substance use and misuse and high-risk activities can be harmful to a person's long-term health. Studies such as the Framingham Heart Study and the Nurses' Health Study have demonstrated clear associations between chronic illness and tobacco use, alcohol misuse, high blood pressure, physical inactivity, obesity, and unhealthy diet (Centers for Disease Control and Prevention, 2011a). The term *lifestyle* not only includes choices made by individuals but also recognizes the influence of social, economic, and environmental factors on the decisions people make about their health. A healthy lifestyle is determined by an individual's behaviours within his or her social environment. As a key determinant of health, the social environment involves a strong social network (e.g., family, peers, community, workplace) and the ability to connect with others (PHAC, 2013). Poverty and socioeconomic disadvantage are recognized to have a major impact on the development of chronic illness (Lubkin & Larsen, 2013). Income significantly affects an individual's life expectancy, ability to obtain and provide nutritious food and good housing, and access to health care (PHAC, 2014).

Risk Factors for Chronic Illness

Both individuals and communities may possess risk factors for the development of chronic illness (PHAC, 2014). The recognition of these common risk factors and conditions is the conceptual basis for an integrated approach to chronic disease.

Individual risk factors can be classified as background, behavioural, or intermediate. Sex, age, level of education, and genetic characteristics are examples of background risk factors. Smoking, unhealthy diet, and physical inactivity would fall into the category of behavioural risk factors. Intermediate risk factors include comorbid conditions such as diabetes, hypertension, and obesity or being overweight. Besides risks that occur at the individual level, community-level factors can also contribute

significantly to the development of chronic illnesses. Examples of community-level risk factors include social and economic conditions, such as poverty, employment, and family composition; environmental conditions, such as climate and air pollution; cultural conditions, such as practices, norms, and values; and urbanization, which influences housing and access to products and services (PHAC, 2014).

Figure 5-2 illustrates the conceptual model used by the Centre for Chronic Disease Prevention at the PHAC to examine risk factors for chronic illness. Although some risk factors, such as age, sex, and genetic makeup, cannot be changed (**nonmodifiable risk factors**), many behavioural risk factors are considered **modifiable**. Cultural and environmental risk factors, such as air pollution, may play a significant role in the development of chronic illness and may be modifiable in some cases.

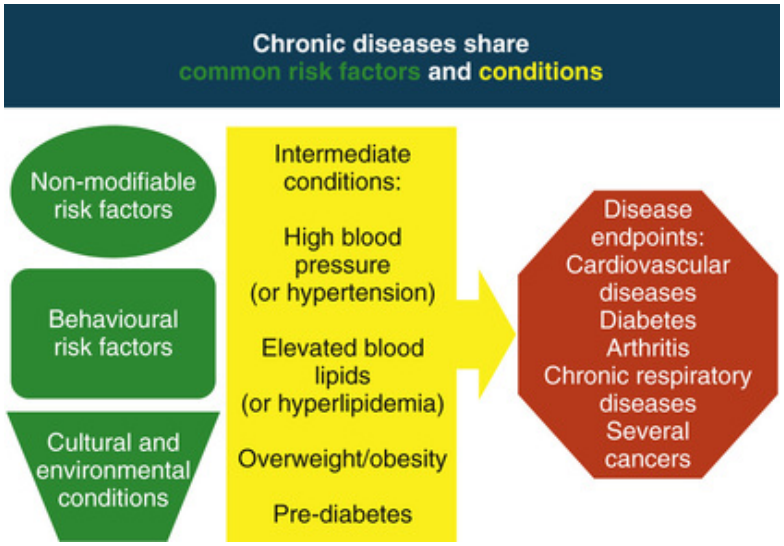

FIGURE 5-2 Chronic diseases share common risk factors and conditions. Source: © All rights reserved. Chronic Disease Risk Factors. Public Health Agency of Canada, 2015. Adapted and reproduced with permission from the Minister of Health, 2017.

Prevention of Chronic Illness

Prevention of chronic illness is the best way to deal with the chronic disease epidemic. Although not all chronic illnesses are preventable, four behavioural risk factors are considered key contributors to many of these conditions: tobacco use, unhealthy diet, insufficient physical activity, and the harmful use of alcohol (WHO, 2014b). Decades of research have determined the most effective means, or "best buys," of preventing chronic illness. "**Best buys**," according to the WHO (2014b), are actions that should be undertaken immediately to produce accelerated results in terms of lives saved, diseases prevented, and heavy costs avoided. Table 5-3 identifies these "best buys."

TABLE 5-3

"BEST BUYS" FOR CHRONIC ILLNESS PREVENTION

- Creating through laws completely smoke-free environments
- Warning about the dangers of tobacco use
- Enforcing bans on tobacco advertising, promotion, and sponsorship
- Raising taxes on tobacco
- Restricting access to retailed alcohol
- Enforcing bans on alcohol advertising
- Raising taxes on alcohol
- Reducing salt content of food
- Replacing *trans* fat in food with polyunsaturated fat
- Promoting public awareness about diet and physical activity, including through mass media

The Role of Genetics

Genetics, or the study of how a specific characteristic is passed from one generation to another, has long been recognized to play an important role in the development of certain chronic illnesses. Cystic fibrosis and Huntington's disease are two chronic illnesses for which genetic testing is available. Genetic testing can also show an inherited predisposition to several different types of cancer, including breast and ovarian cancer, melanoma, and colon cancer. Research continues to explore the development of screening methods for many other chronic illnesses, such as Alzheimer's disease.

With the completion of human genome sequencing, however, the role of genetic factors will assume increasing importance in prevention, detection, and treatment of many chronic illnesses. The student is referred to Chapter 15 for an in-depth discussion of genetics in nursing practice.

The Role of Aging

Chronic illnesses are on the increase as populations age and individuals live with one or more chronic conditions for decades. The profile of diseases contributing most heavily to death, illness, and disability among Canadians has changed dramatically over the past century. Whereas infectious diseases commonly posed the greatest threat to health in the past, improved sanitation, vaccination, and public health surveillance and the advent of antibiotics have been key factors in prolonging life expectancy rates. Life expectancy for Canadians is extending. In 2010, it was 78.5 years for males and 82.7 years for females; it is projected that males born in 2031 will have an average life expectancy of 81.9 years, and females, 86.0 years (Statistics Canada, 2015).

Aging is associated with the development of many chronic illnesses. As people age, they are more likely to have at least one chronic condition, and the oldest adults (aged ≥85 years) are more likely than those aged 65 to 74 years to have at least three chronic conditions (36% versus 20%) (Canadian Institute for Health Information [CIHI], 2011). The association between obesity, hypertension, and hypercholesterolemia in middle age and dementia in older adulthood has been identified (Ballard, Gauthier, Corbett, et al., 2011). The most frequently reported chronic conditions among persons aged 65 and older are hypertension (47%, ≈2 million seniors), followed by arthritis (27%, ≈1.2 million seniors) (CIHI, 2011). The most common combinations of chronic conditions among seniors are hypertension and arthritis (14%) and hypertension and heart disease (12%) (CIHI, 2011).

Disability in Chronic Illness

Chronic illness is often associated with disability, although many people are not disabled by their chronic illness. **Disability** is a term whose definition continues to be refined after significant global debate. It is a complex interaction between health conditions, personal factors, and the environment. As interpreted by the Supreme Court of Canada, disability "includes a wide and evolving range of permanent, temporary or intermittent impairments, both physical and mental, which can result in functional limitations as the person interacts with others and potentially with socially constructed barriers (Government of Canada, 2014, p. 9).

Two different conceptual models of disability have shaped the manner in which we think about disability (WHO, 2002): the medical model and the social model. The medical model views disability as directly caused by disease, trauma, or another health condition. From the medical model perspective, disability necessitates medical care provided in the form of individual treatment by health care providers to "correct" the problem with the individual. The social model of disability, conversely, sees disability as a socially created problem and not an inherent attribute of an individual (Barnes, 2012). The social model perspective calls for a political response, because the problem is created by an unaccommodating physical environment brought about by attitudes and other features of the social environment.

The WHO has taken the position that neither the medical nor the social model is fully adequate to define *disability,* although both models make a significant contribution to the discussion. Disability, according to the WHO (2002), is a complex phenomenon at the levels of both the body and society. Disability always comprises an interaction between features of the person and features of the overall context in which the person lives. In other words, both medical and social responses are appropriate and necessary to the problems associated with disability, but a model of disability that synthesizes both approaches is required. The integration of the medical and social approaches is contained in the biopsychosocial model, upon which the International Classification of Functioning, Disability and Health, known as the ICF (WHO, 2002), is based. Parallel to the determinants of health (see Chapter 1, Table 1-2), disability and functioning are viewed by the ICF as the outcomes of interactions between health conditions (diseases, disorders, and injuries) and contextual factors. Contextual factors are composed of external environmental factors (i.e.,

social attitudes, architectural characteristics, and legal and social structures, as well as climate, terrain, and so forth) as well as internal personal factors (i.e., gender, age, coping styles, social background, education, profession, past and current experience, overall behaviour pattern, character, and other factors that influence how disability is experienced by the individual).

Figure 5-3 identifies the three levels of human functioning classified by ICF: functioning at the level of the body or body part, of the whole person, and of the whole person in a social context. Disability involves dysfunction at one or more of these same levels: impairments, activity limitations, and participation restrictions.

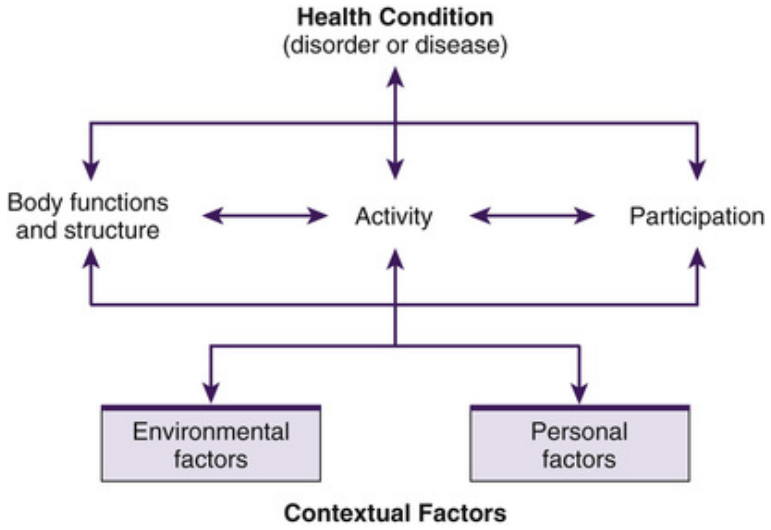

FIGURE 5-3 The International Classification of Functioning, Disability and Health (ICF) Bio–Psycho–Social Model. Source: Reprinted from *Towards a Common Language for Functioning, Disability and Health,* WHO, Page No. 9, Copyright 2002.

The ICF acknowledges that every human being can experience a decrement in health and thereby experience some degree of disability. Disability is a universal experience at some point in life and is not something that happens only to a minority of individuals.

Psychosocial Dimensions of Chronic Illness

The interaction between mind and body has received increasing and well-deserved attention in recent years. Because chronic illness affects the whole person, and not just a particular body system, the psychosocial dimensions of chronic illness assume great significance. The relational core of nursing practice, which emphasizes nurse–patient dialogue, partnership, and conscious participation, is integral to the care of persons with chronic illness (Kramer-Kile, Osuji, Larsen, et al., 2014).

The following section will address a number of key concepts related to the psychosocial dimensions of chronic illness. Although these concepts are described individually in this section, the student should remember that a holistic perspective embraces the many facets of patients as unique individuals, and it is the interplay between these dimensions that shapes the overall experience of chronic illness.

Illness Behaviour

Illness behaviour refers to the varying ways individuals respond to physical symptoms: how they monitor internal states, define and interpret symptoms, make attributions, take remedial actions, and use various sources of informal and formal care (Mechanic, 1995). The "sick role" was first described in 1951 by Talcott Parsons. Sickness was seen by Parsons as a form of deviant behaviour that permitted the avoidance of social responsibilities (Lubkin & Larsen, 2013). A form of learned behaviour, the sick role was achieved through failure to keep well. Table 5-4 describes the characteristics of the sick role.

TABLE 5-4

CHARACTERISTICS OF THE SICK ROLE

Component of the Role	Associated Behaviours and Expectations
Sick person is exempt from normal social roles.	Dependent on the nature and severity of illness. More severe illness allows patients to be exempt from more roles. Requires legitimization (validation) by a physician.
Sick person is not responsible for his or her condition.	Not responsible for becoming sick, the individual therefore has a right to be cared for. Physical dependency and the right to emotional support are therefore acceptable. Will need a curative process apart from personal willpower or motivation to get well.
Obligation to want to become well.	Being ill is seen as undesirable. Because privileges and exemptions of the sick role can become secondary gains, the motivation to recover assumes primary importance.
Obligation to seek and cooperate with technically competent help.	The patient needs technical expertise that the physician and other health care providers have. Cooperation with these providers for the common goal of getting well is mandatory.

Parsons's sick-role model, although useful for acute illnesses, has been criticized on many fronts because it does not address important issues related to the chronic illness experience. It fails to consider characteristics of chronic illness, the long-term nature of the illness, the reality that an expectation of full recovery is often not reasonable, the management role expected of the patient and family, and the adjustment to permanent change (Lubkin & Larsen, 2013). In the sick-role model, patients are seen as victims of their illness and are subordinate to physicians. This perspective differs significantly from the paradigm of the "expert patient," in which the patient knows his or her condition and its management far better than his or her health care providers (National Health Service, 2011). Unfortunately, many health care providers apply the sick-role model to patients with chronic illnesses in acute care settings (Lubkin & Larsen, 2013). The frequent readmissions often required by patients with chronic illness may create frustration for staff, who are bored by what they see as repetitive, tiresome care (Lubkin & Larsen, 2013). Patients with chronic illness who have experience with the health care system may use their knowledge to gain what they want or need from the system, demanding certain treatments, a specific schedule, or particular routines (Lubkin & Larsen, 2013). These patients may be perceived as "disruptive" to the normal routine of a hospital unit. Lack of sensitivity on the part of health care providers may lay the foundation for energy-draining power struggles with the patient (Thorne, 2006). Relationships between patients and health care providers tend to be most productive when providers are

able to recognize limitations in their own expertise and to respect the expertise of patients and their families. Patients with chronic illness have been found to move from "naive trust" to "disenchantment" and on to a stage of "guarded alliance" in their relationship with health care providers. Nurses must recognize the need to establish credibility and trust with patients who have chronic illness.

More recent work by Thorne (2006) and Thorne, Oglov, Armstrong, and Hislop (2007) noted the critical importance of communication between patients with chronic illness and health care providers. Effective communication must be timely, appropriate, and compassionate (Potter, Perry, Ross-Kerr, et al., 2014). Discussions evoking heightened emotions such as breaking bad news or those requiring patients to make end-of-life decisions are also difficult and stressful experiences for the nurse. Table 5-5 provides a comparison of effective and problematic communication.

TABLE 5-5
EFFECTIVE STRATEGIES AND BARRIERS TO COMMUNICATION DURING DIFFICULT CONVERSATIONS

Effective Strategies	Barriers to Communication
• Open and honest communication • Ongoing and early conversations • Communicating about treatment goals • Balancing hope and reality in communicating bad news • Taking cues from the patient about how much information he or she is able to process at one time	• Provider discomfort with issues (e.g., death and dying) • Lack of experience, training, or knowledge of protocols • Lack of good mentorship • Patient factors (e.g., reluctance to talk or face an issue, language barrier, unrealistic prognosis, not ready to hear news) • Age of the patient (i.e., a younger patient can make the discussion more difficult)

Source: Adapted from Kissane, D. W., Bylund, C. L., Banerjee, S. C., et al. (2012). Communication skills training for oncology professionals. *Journal of Clinical Oncology*, *30*(11), 1242–1247.

Ensuring clarity, a straightforward approach, receptiveness, and responsiveness to questions and providing written information to complement what was said are helpful characteristics of good communication. Unhelpful communications include those in which there is a mismatch between what patients feel their information needs are at a particular time and the manner in which health care providers supply this information. It is useful for nurses to reflect on the question "Am I treating this patient the way I would want to be treated?"

Given their own expertise and experience with health care, many individuals with chronic illness are demanding a new model of care in which they are truly equal partners. **Shared decision making** is a decision-

making process engaged in jointly by patients and their health care providers (Barry & Edgman-Levitan, 2012). It is a central tenet of the patient-centred approach described in Chapter 1. Shared decision making exemplifies the partnership between provider and patient and is essential for ethical care as it respects autonomy (the right to make informed choices), beneficence (the balance between benefits and risk of actions), and nonmaleficence (the avoidance of harm).

Self-Efficacy

The development and maintenance of self-efficacy is critical to effective self-management of chronic illness. Self-management programs based on self-efficacy principles have been demonstrated to be highly effective in reducing symptoms and facilitating behaviour change (Lubkin & Larsen, 2013) (Table 5-6). Effective self-management relies on a patient-centred care approach in which the individual works in partnership with health care providers to develop solutions to issues related to the patient's chronic condition (Registered Nurses' Association of Ontario [RNAO], 2010). Self-efficacy may be considered a type of self-confidence; it is the belief of an individual that he or she can successfully execute the behaviour required to produce the desired outcomes (Bandura, 1977). People's beliefs about their personal efficacy constitute a major aspect of their self-knowledge, according to Bandura's social cognitive theory. Judgements about personal self-efficacy can determine which behaviours will be attempted, how much effort will be devoted to the behaviour, and how long a person will persist in continuing that behaviour. Weight loss, for example, is often recommended as a means of promoting health. The patient's self-efficacy beliefs will influence the strategies the person might use to attempt to lose weight (perhaps calorie reduction or a combined program of calorie reduction and exercise); how much effort he or she might direct toward this process (a daily walking program or a once-per-week walking program); and how long he or she continues the intended program (for a few weeks or several years).

TABLE 5-6
TEACHING TECHNIQUES FOR BEHAVIOUR CHANGE

Teaching techniques that assist patients to learn behaviour change strategies include:

- Setting goals collaboratively with the patient, using templates that can be modified based on the patient's context
- Assessing a patient's readiness for self-management, based on tools that the patient can use in the future
- Helping the patient to break down goals and tasks into small steps as part of an action plan, using specific tools and templates that can be modified based on the patient's context
- Providing personalized feedback and helping the patient learn how to ask for, receive, and use feedback
- Teaching self-monitoring, using tools and templates
- Helping the patient obtain social support and informing the patient of and linking the patient to community resources
- Helping the patient assess his or her commitment to key tasks
- Building in follow-up processes to help patients measure their progress and milestone attainment

Source: Registered Nurses' Association of Ontario. (2010). *Strategies to Support Self-Management in Chronic Conditions: Collaboration with Clients.* Toronto, Canada. Registered Nurses' Association of Ontario.

Both outcome expectancies and efficacy expectancies have to be considered in light of self-efficacy. An *outcome expectancy* is the individual's belief that a specific behaviour will lead to certain outcomes. For example, the patient who tells the nurse that exercising helps people to lose weight is voicing an outcome expectancy. An *efficacy expectancy* is the individual's belief that she or he is able to achieve the outcome. The patient who tells the nurse that she or he is not able to exercise is voicing an efficacy expectancy. It is helpful if both outcome and efficacy expectancies are positive. A patient who believes that exercise helps other people lose weight but that it will not help her or him lose weight might benefit from some of the following influences.

Four primary influences shape an individual's self-efficacy beliefs: mastery; vicarious experience; verbal persuasion and other social influences; and physiological and affective states that help us judge our capability and our vulnerability to dysfunction (Lubkin & Larsen, 2013). *Mastery* reflects a belief about whether or not "we have what it takes to succeed" and is considered the most influential source of self-efficacy. Many chronic illnesses necessitate the mastery of certain skills—for example, monitoring heart rate and exertion level during exercise—to achieve a sense of self-efficacy. *Vicarious experience* is the observation of others' performances, from which we learn through modelling and against which we measure our own performance. These experiences inform our self-efficacy beliefs. In our weight loss example, the patient may be encouraged by the example of fellow participants in a walking program who have achieved weight loss through exercise. When people are *verbally*

persuaded that they are capable of performing a certain task, their self-efficacy beliefs may be enhanced. Nurses are in a key position to provide the verbal support the patient may need to undertake the exercise program. Finally, *physiological and affective states* such as stress have an impact on our self-efficacy beliefs. A patient who has just lost his or her job and is experiencing significant financial stress may not have the energy to begin a walking program.

Health-Related Hardiness

Health-related hardiness (HRH), a concept first described by Kobasa (1979) and expanded by Pollock, Christian, and Sands (1990) to apply to people with chronic illness, is a personality resource that buffers stress and allows people to experience a high degree of stress without falling ill. Hardy people are considered to possess three general characteristics: control, commitment, and challenge. *Control* refers to the belief that the individual can influence the events in his or her experience. *Commitment* refers to an ability to feel deeply committed to the activities of life. *Challenge* is the anticipation of change. The person with HRH, when confronted with a health stressor, possesses sufficient self-mastery and confidence to appraise and modify responses appropriately (control) and cognitively reappraises the health stressor so it is viewed as stimulating and beneficial or as an opportunity for growth (challenge). This is exemplified by the perception of individuals with diabetes that they have some control over their disease. *Hardiness* has recently been replaced by the term *resilience*, which shifts the emphasis from its being an inherent trait to its being an ability one can develop (Trivedi, Bosworth, & Jackson, 2011). Motivation and competence thus develop to enhance the patient's health status and to facilitate coping with the health stressor (Pollock & Duffy, 1990). Higher levels of hardiness or resilience show better psychosocial adaptation to chronic illness; thus nurses can make use of interventions that foster a sense of control, commitment, or challenge. These interventions are discussed in the subsequent nursing management chapters.

Mood Disorders

Along with assessments of self-efficacy and health-related hardiness, assessment for the presence of a mood disorder such as depression or anxiety is a key element in the nursing assessment of patients with chronic illness since this population experiences a high burden of mood disorders

(Barnett, Mercer, Norbury, et al., 2012). Illness-related anxiety and stress can trigger symptoms of depression. Prevalence rates of depression for patients with cardiac disease range from 20 to 40% while between 12 and 18% of persons with diabetes experience depression (Celano & Huffman, 2011; Katon, 2011). The burden imposed by mood disorders on persons with chronic illness, their families, and Canadian society is significant. Major depression, in particular, may adversely affect the course of chronic illness and amplify disability (National Institute of Mental Health, 2015). The presence of a mood disorder in a person with a chronic physical illness has been found to be associated with short-term disability, the need for help with instrumental activities of daily living, and suicidal ideation.

The likelihood of depression increases with the number of chronic conditions affecting a patient. This is due in part to the fact that inflammation has been proven to be an important etiological factor in mood disorders. Individuals with inflammatory illnesses such as cardiovascular disease, cancer, Parkinson's disease, chronic obstructive pulmonary disease (COPD), and multiple sclerosis (MS) often struggle with depression (Felger & Lotrich, 2013; McNamara & Lotrich, 2012). This new understanding of the mechanism by which inflammation influences mood disorders will lead to the development of preventive and therapeutic treatments.

In spite of the evidence that mood disorders are common in persons with chronic physical illness, conditions such as depression remain both under-recognized and undertreated in this population. The nurse must be alert for the presence or the development of depressive symptoms when caring for patients with chronic illness.

Fatigue

Fatigue is often associated with chronic illness and has been described as one of the most distressing symptoms people with chronic illness experience. Fatigue may be both a symptom of an underlying condition and an outcome of that condition. It interferes with normal, customary, and desired activities and pervades every aspect of life. The invisibility of fatigue is one of the most frustrating aspects of the experience and leads to lack of understanding and misunderstanding by others. The impact of fatigue on functioning is substantial and under-recognized.

Although there is no universally accepted definition of **fatigue**, it is generally recognized to be a complex, multidimensional experience. A classic nursing definition of *fatigue* was developed by Ream and

Richardson (1996, p. 527), who stated that fatigue is "a subjective, unpleasant symptom which incorporates total body feelings ranging from tiredness to exhaustion, creating an unrelenting overall condition which interferes with individuals' ability to function to their normal capacity."

There are many reasons that fatigue is common in people with chronic illness. Pain, mood disorders, sleep problems, physical deconditioning, metabolic abnormalities, infection, dietary problems, hypoxia, and medications can lead to profound fatigue. It is important for the patient to incorporate interventions to reduce fatigue such as yoga, acupuncture, and nutritional supplements.

Stigma

People with chronic illness often experience **stigmatization**, in which they are regarded others as unworthy or disgraceful. Canadian culture contributes to this stigmatization, as it places value on youth, physical fitness, and productivity. Such stigma can have a significant impact on the quality of life of those who are challenged to meet these standards due to the constraints of illness. They may be set apart and labelled by others according to the disease they have and the treatments they use. Lubkin and Larsen (2013) note that older adults and the chronically ill carry a "yoke of undesirability" in health care settings, where caring for these groups is seen as less rewarding in terms of recovery, treatment, and economics than caring for other types of patients. Stigma is an important concept in nursing because it may influence the manner in which care is provided as well as the patient's willingness to disclose information. Individuals who are concerned about being stigmatized if they disclose certain facts may feel threatened and be less likely to share this information. For instance, people with substance abuse problems may not share information with their nurse about the nature and frequency of their drug usage. Lacking this vital information, health care providers may make care decisions that inadvertently adversely affect patient outcomes.

There are several types of stigma. The stigma of physical deformity relates to situations in which there is a difference between the expected and valued norm of perfect physical condition and the actual physical condition of the person (Lubkin & Larsen, 2013). The changes or deformities in physical appearance that may occur as a result of chronic illness set the individual apart. The person with multiple sclerosis, for example, may have difficulty walking or require the use of a mobility aid, which can create stigmatization. Character blemishes, often associated

with undesirable traits such as dishonesty, addiction, lack of control, or mental illness, are another type of stigma (Lubkin & Larsen, 2013). Moral judgements are made about the "unworthy" character of the individual. For example, a woman with obesity may experience the stigma of character blemish when others pass judgement about her being responsible for her illness because she is unable to control her appetite and because of her perceived laziness. This leads to the scenario of "blaming the victim" and is not uncommon among health care providers.

Quality of Life

Given the many physical and psychosocial challenges inherent in the experience of living with a chronic illness, **quality of life** is a primary outcome measure in evaluating treatment for many health conditions. *Quality of life,* in its broadest definition, refers to subjective evaluations of both the positive and the negative aspects of life (Centers for Disease Control and Prevention, 2011b). Quality of life is influenced by a host of factors, including financial status, employment, housing, spirituality, social support network, and health. The term **health-related quality of life (HRQL)** has often been used as a means of focusing on the ways health influences and is influenced by overall quality of life. At an individual level, HRQL usually includes perceptions of physical and mental health status and the key variables that are associated with health status, such as health conditions, functional ability, social support, and socioeconomic status (Centers for Disease Control and Prevention, 2011b). At a community level, HRQL includes resources, conditions, policies, and practices that influence a population's health perceptions and functional status. The concept of HRQL enables health agencies to examine broader areas of healthy public policy around a common theme (Centers for Disease Control and Prevention, 2011b).

Living With Chronic Illness

Reduced quality of life, depression, fatigue, and stigma, together with physical symptoms, may make living with a chronic illness a daily challenge for many individuals and their families. Over time, the losses a person sustains as a result of living with a chronic illness cause a decrease in self-esteem. Loss of self is a primary source of suffering for people with chronic illness. Experiencing social isolation, living a restricted life, and being a burden to others all contribute to this loss of self.

People with chronic conditions use various strategies to try to maintain a "normal life." Normalization is a key strategy in living with chronic illness. When individuals fail to exhibit an expected norm, they become viewed as abnormal. Individuals with chronic illness may attempt to conceal their disease from others to pass themselves off as "normal," which is an idealized notion of being the same as the rest of the presumably normal population. Although the objective of this behaviour is to fit in, this strategy may serve as a constant source of stress because of the danger of being discovered.

"Covering" a visible chronic illness is a strategy employed by some individuals. Covering involves acknowledging the condition while attempting to decrease any anxiety and stress experienced by those who do not have the same condition (Egan, Harcourt, Rumsey, et al., 2011). An example of covering may be making jokes about the condition in an effort to downplay the illness. The nurse must be sensitive to the strategies used by patients with chronic illness and explore with the person whether these strategies are adaptive and helpful or whether they are maladaptive. It is also important for the nurse to recognize that cultural expectations may limit a person's coping strategies. When a culture devalues chronic disease, such as mental illness, people often remain undiagnosed and fail to receive adequate treatment.

Chronic Illness and Caregiving

Living with a chronic illness affects not only the individual who has the condition but also those in the patient's immediate social network. Nursing assessment of a person with a chronic illness is incomplete without considering the way in which significant others are affected. Families are frequently called on—and sometimes friends and neighbours—to provide the often complex and long-term care necessitated by some chronic illnesses. In fact, more than 8 million Canadians (28% of the population) provide care to people with long-term health problems (Turcotte, 2013). The term **informal caregiver** is defined as anyone who provides care without pay and who usually has personal ties to the care recipient (Lubkin & Larsen, 2013).

Family caregivers in Canada are predominantly female and are most likely to be providing care to a spouse or partner or to a parent. Even though it is generally thought that older adults are the ones requiring care, it is important to know that older Canadians are often key care providers to spouses, children, grandchildren, friends, and neighbours.

The vast majority of people with chronic conditions live in the community. The shift away from institutionalization has meant that most of the responsibility for caregiving is left to families and friends. While this shift has reduced the demands on and costs of health care and social systems, it has done so often at the expense of the care provider. It has been demonstrated that the overall health of caregivers is adversely affected by the caregiving experience. One in five considers caregiving to have negatively impacted his or her own physical and emotional health (Statistics Canada, 2013). The overall physical, emotional, and financial cost of caregiving is known as **caregiver burden**. Issues that arise include increasing difficulty meeting the physical demands of the care- giving role; lack of time to engage in adequate self-care and health-promotion activities; the physiological sequelae of psychological distress, predisposing the individual to changes in immune function; and increased risk of hypertension and cardiovascular disease (Capistrant, Moon, Berkman, et al., 2011). The nurse plays a critical role in assessing the level of caregiver distress present, if any, and taking appropriate action to attempt to reduce or eliminate the factors that contribute to the distress.

Conceptual Models of Chronic Illness

Conceptual models are useful in understanding the chronic illness experience, particularly because caring for a patient with a chronic illness requires a different framework for practice than may be useful in caring for a patient with an acute illness. The following section highlights several of the key models of chronic illness.

Illness Trajectory

The concept of an **illness trajectory** was first advanced in 1967 by Glaser and Strauss as a way of understanding the complex, dynamic path of chronic illness. An illness trajectory can be defined as an experiential pathway along which the person with an illness progresses. Some illnesses have more predictable trajectories than others, but all trajectories are subject to individual variation. There have been a number of conceptualizations of illness trajectories. Rolland (1987) identified three critical time phases within the illness trajectory:

Crisis phase: The period before and immediately after diagnosis, when learning to live with symptoms and illness-related demands takes place.

Chronic phase: The time span between initial diagnosis and the final time phase, when the key task is continuing to live as normal a life as possible in the face of the abnormality of having a chronic illness whose outcomes are uncertain.

Terminal phase: This phase is marked by issues surrounding grief and death. Depending on the illness, some patients will enter this phase only after many years.

Further important work in the area of illness trajectories was conducted by Corbin (1998). These authors defined a trajectory of the course of an illness over time, identifying nine phases: (a) pretrajectory; (b) trajectory onset; (c) stable; (d) unstable; (e) acute; (f) crisis; (g) comeback; (h) downward; and (i) dying. Table 5-7 describes the phases and the associated goals of management. Although the illness trajectory is set in motion by pathophysiology and changes in health status, there are strategies that patients, families, and health care providers can use to shape the course of the trajectory. Shaping means that the illness trajectory

can be altered by actions that stabilize the disease course, minimize exacerbations, and better control symptoms (Corbin & Strauss, 1992). This model recognizes that each person's illness trajectory is unique.

TABLE 5-7

ILLNESS TRAJECTORY PHASES AND GOALS OF MANAGEMENT

Phase	Definition	Goal of Management
Pretrajectory	Genetic factors or lifestyle behaviours that place an individual or community at risk for the development of a chronic condition.	Prevent onset of chronic illness
Trajectory onset	Appearance of noticeable symptoms; includes period of diagnostic workup as person begins to discover and cope with implications of diagnosis.	Form appropriate trajectory projection and scheme
Stable	Illness course and symptoms are under control. Biography and everyday life activities are being managed within limitations of illness. Illness management centres in the home.	Maintain stability of illness, biography, and everyday activities
Unstable	Period of instability to keep symptoms under control or reactivation of illness. Biographical disruption and difficulty in carrying out everyday life activities. Adjustment being made in regimen; care usually taking place at home.	Return to stable
Acute	Severe and unrelieved symptoms or the development of illness complications necessitating hospitalization or bed rest to bring illness course under control. Biographical and everyday life activities temporarily placed on hold or drastically cut back.	Bring illness under control and resume normal biographical and everyday life activities
Crisis	Critical or life-threatening situation necessitating emergency treatment or care. Biography and everyday life activities suspended until crisis passes.	Remove life threat
Comeback	A gradual return to an acceptable way of life within limits imposed by disability or illness.	Set in motion and continue the trajectory projection and scheme
Downward	Illness course characterized by rapid or gradual physical decline accompanied by increasing disability or difficulty in controlling symptoms.	Adapt to increasing disability with each major downward turn
Dying	Final days or weeks before death. Characterized by gradual or rapid shutting down of body processes, biographical disengagement, and closure and relinquishment of everyday interest and activities.	Bring closure, let go, and die peacefully

Source: Corbin, J. (2002). Introduction and overview: Chronic illness and nursing. In R. Hyman & J. Corbin (Eds.), *Chronic illness: Research and theory for nursing practice* (pp. 4–5). New York: Springer.

These models provide a useful starting point from which to consider the concept of trajectories of chronic illness, although they have been criticized for not fully recognizing individual variation.

Shifting Perspectives Model of Chronic Illness

Models that describe living with a chronic illness as a phased process have also been criticized because they imply that an end goal exists and that this goal can be reached only if the person has lived long enough to progress through previous stages. The Shifting Perspectives Model of Chronic

Illness (Figure 5-4) described by Paterson shows living with a chronic illness as an ongoing, continually shifting process. This perspective of chronic illness contains elements of both illness and wellness. As the reality of the illness experience and its context change, the person's perspective shifts in the degree to which illness or wellness is in the foreground or background of their world. Perspectives of chronic illness are not seen as right or wrong but as reflections of people's needs and situations.

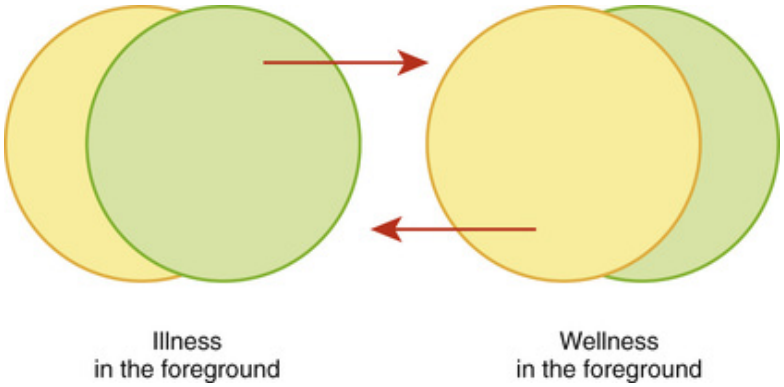

FIGURE 5-4 The Shifting Perspectives Model of Chronic Illness.

Source: Paterson, B. (2001). The shifting perspectives model of chronic illness. *Journal of Nursing Scholarship, 33*(1), 21–26. Copyright © 2001, John Wiley and Sons.

When illness is in the foreground, individuals are focused on the sickness, suffering, loss, and burden associated with living with a chronic illness. This perspective is marked by self-absorption and difficulty attending to the needs of others. This perspective often occurs in people who are newly diagnosed or overwhelmed by their illness. When wellness is in the foreground, the person attempts to create consonance between self-identity and the identity shaped by the disease and between the construction of the illness by others and by life events (Paterson, 2001). The body is objectified and placed at a distance; it is not allowed to control the person. This perspective can be gained by learning as much as possible about the disease, creating supportive environments, developing skills such as negotiating, identifying the body's unique patterns of response, and sharing with others knowledge about living with the illness. This distance provides for a focus on social, emotional, and spiritual aspects of life, rather than a focus on the diseased body.

The perspective that is in the foreground shifts depending upon circumstances. Perceived threats to control may cause a shift in the

foreground from wellness to illness, as may self-help groups that focus on sickness (Paterson, 2001). Returning to having wellness in the foreground may result from changes or interventions that resolve or accommodate the situation that has resulted in the illness focus.

Self-Management

Self-management is the foundation for optimizing health outcomes for people living with chronic illness. A large body of empirical literature demonstrates that successful self-management is related to better overall physical and psychological health outcomes (Clark, Gong, & Kaciroti, 2014). **Self-management** refers to "the ability of the individual, in conjunction with family, community, and healthcare professionals, to manage symptoms, treatments, lifestyle changes, and psychosocial, cultural, and spiritual consequences of health conditions" (Richard & Shea, 2011, p. 261). This emphasizes the primary role patients have in managing their illness to achieve the best possible quality of life (Canadian Nurses Association, 2014). Every day, patients decide what they are going to eat, whether they will exercise, and to what extent they will take their prescribed medications. These activities, although usually undertaken in cooperation with a health care provider, go beyond merely adhering to a prescribed behavioural regimen. As Glasgow and Anderson (1999, p. 2090) noted:

Patients are in control. No matter what we as health professionals do or say, patients are in control of these important self-management decisions. When patients leave the clinic or office, they can and do veto recommendations a health professional makes.

The actions people take to manage their conditions are often based on the advice given by health care providers. Sometimes, however, patients choose not to accept this advice, resulting in less than optimal outcomes (Clark, Gong, & Kaciroti, 2014).

Compliance, adherence, and self-care make up the three levels of patient response to health care recommendations on a continuum of self-care. *Compliance* reflects coercion of the patient to engage in particular recommendations, whereas *adherence* implies conformity of the patient to the recommendations. *Self-care* connotes a therapeutic alliance between the patient and the provider. *Adherence* is now the term most widely accepted because it incorporates the notion of the patient agreeing with the treatment plan presented by the health care provider.

Partnership between the nurse and the patient, which focuses on an open, caring, mutually responsive, and nondirective dialogue, is a key aspect of relational nursing practice and is essential in the promotion of

self-management. The process of self-management involves empowering the patient, thereby ensuring some autonomy with respect to adjusting the regimen as necessary. Four tasks related to coping with chronic illness are as follows: (a) processing emotions, including grieving, in response to health or functioning; (b) adjusting to the changes to self and life as a result of the illness; (c) integrating illness into daily life; and (d) determining the meaning of the illness so as to help identify tasks and skills that will promote personal growth and satisfaction (Schulman-Green et al., 2012).

The nurse must be alert to potential barriers to successful self-management. People of low socioeconomic status and those who are marginalized are more difficult to attract and retain in self-management programs. Similarly, patients who have limited health literacy may be seriously compromised in their ability to self-manage their conditions successfully. In addition to health literacy, other barriers to self-management that the nurse must be sensitive to the presence of include poorer health, financial constraints, and persistent depressive symptoms (Hinder & Greenhalgh, 2012). The principles of self-management have been the foundation of numerous chronic illness management programs. Evidence-informed self-management (see, for example, the "Evidence-Informed Practice" box) starts with the premise that there is a partnership between patients and health care providers. New paradigms of self-management examine the beliefs and the problems of people with chronic illness, connecting this information with health care providers' views of what knowledge patients must have and what behaviours they must change to manage their condition.

Evidence-Informed Practice

Research Highlight

How Effective Is the Teach-Back Method on Adherence and Self-Management in Health Education For People With Chronic Disease?

Clinical Question

Adults aged 18 years and over with one or more chronic disease(s) (P), teach-back method used in a chronic disease education program (I), chronic disease education program that did not use the teach-back

method (C), on health outcomes and use of health care services (O) adherence, self-management, disease-specific knowledge, readmission, knowledge retention, self-efficacy, and quality of life.

Best Available Evidence

A systematic review of randomized control trials (RTC), non-randomized control trials, cohort studies, before–after studies and case-control studies.

Critical Appraisal and Synthesis of Evidence

The reviewers assess a broad range of studies that used the teach-back method. Four studies found improved disease-specific knowledge; one study showed a statistically significant improvement in medication and diet adherence among type 2 diabetics in the intervention group compared to the control group ($p < 0.001$). Two studies found a statistically significant improvement in self-efficacy ($p = 0.0026$ and $p < 0.001$) in the intervention group. One study examining quality of life in heart failure patients did not improve with the intervention ($p = 0.59$). Although not statistically significant, five studies found lower hospitalization and readmission rates. Two studies showed improvement in daily weighing among heart failure patients, and in adherence to diet, exercise, and foot care among those with type 2 diabetes.

Conclusions

The health education teach-back method improves disease-specific knowledge, adherence, and self-efficacy. There was a positive association with self-care, reduction in hospital readmission, hospitalization, or deaths. Teach-back did not improve health-related quality of life or knowledge retention.

Implications for Nursing

Using the teach-back method for educating patients with chronic disease maximizes understanding of the disease, improves self-efficacy and self-care skills.

P, Patient population of interest; *I*, intervention or area of interest; *C*, comparison of interest or comparison group; *O*, outcomes of interest (see Chapter 1).

The Emerging Paradigm of Chronic Care

Our present health care system is organized around an acute, episodic model of care that fails to meet the needs of many patients, including those with chronic illnesses. Patients, families, caregivers, health care providers, and decision makers must recognize that a new model of care must be enacted that better addresses the needs of those with chronic illness. The shortcomings of the current health care system are well-known to the dissatisfied patients, the frustrated families, and the weary staff who have struggled to deal with the complexities of chronic illness. In response, the Canadian government has established priorities that will support health care system innovations such as telehealth and that will enhance the integration and coordination of home care services, especially for Indigenous and northern communities (Health Canada, 2015) (see Chapter 6 for further information). There is increasing evidence that patient-centred care, a concept described in Chapter 1, produces better outcomes for patients than do traditional approaches (Battersby, Lawn, & Pols, 2010). Table 5-8 describes what patients with chronic illness want from the health care system and what they believe has been missing. These reasonable expectations are embedded within the chronic care model.

TABLE 5-8

WHAT PATIENTS WITH CHRONIC ILLNESS WANT FROM THE HEALTH CARE SYSTEM

Access to information concerning:
• Diagnosis and its implications
• Available treatments and their consequences
• Potential impact on the patient's future
• Continuity of care and ready access to it
• Coordination of care, particularly with specialists
• Infrastructure improvements (scheduling, wait times, prompt care)
• Ways to cope with symptoms such as pain, fatigue, disability, and loss of independence
• Ways to adjust to disease consequences such as uncertainty, fear and depression, anger, loneliness, sleep disorders, memory loss, exercise needs, nocturia, sexual dysfunction, and stress

Source: Holman, H., & Lorig, K. (2004). Patient self-management: A key to effectiveness and efficiency in care of chronic disease. *Public Health Reports*, *119*, 239–243.

Building on the notion of self-management and the need for an integrated, patient-centred system of care, the chronic care model was first advanced by Bodenheimer, Wagner, and Grumbach (2002). This model predicted that improvements in the following six interrelated components

would improve care for persons with chronic illness: (a) self-management support, (b) clinical information systems, (c) delivery system redesign, (d) decision support, (e) health care organization, and (f) community resources. The original model was expanded to include a greater focus on prevention and health promotion by Barr, Robinson, Marin-Link, and colleagues (2003). The Expanded Chronic Care Model (ECCM) appears in Figure 5-5.

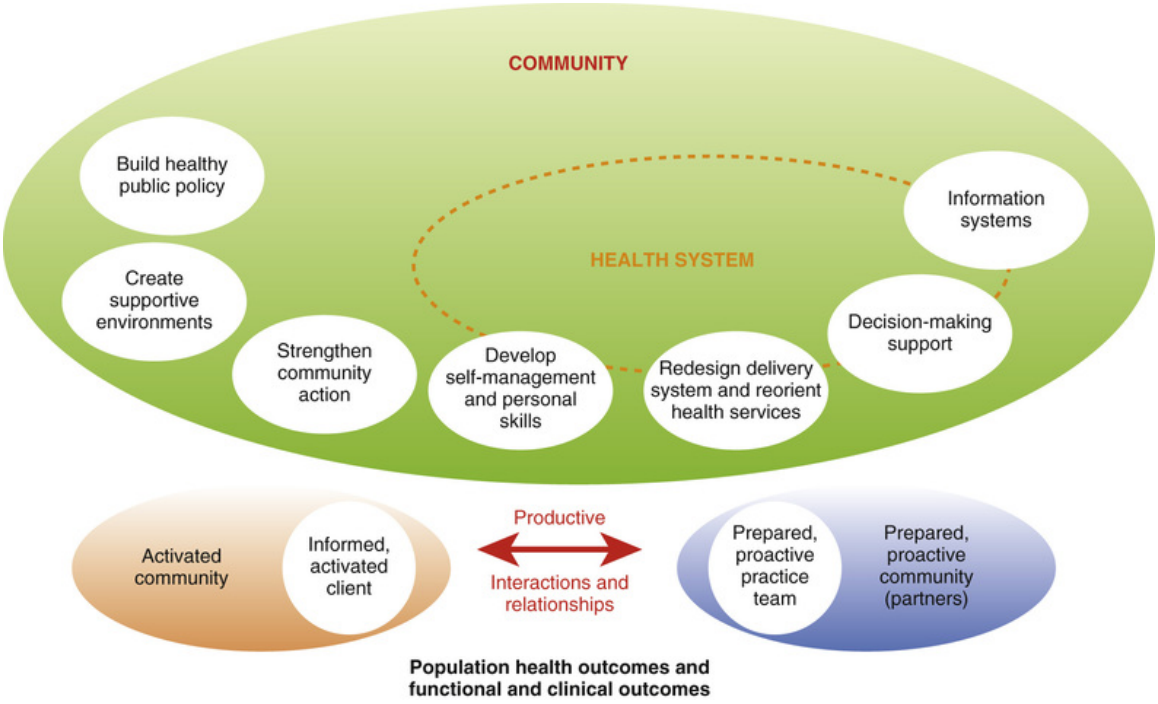

FIGURE 5-5 The Expanded Chronic Care Model. Source: Barr, V., Robinson, S., Marin-Link, B., et al. (2003). The Expanded Chronic Care Model: An integration of concepts and strategies from population health promotion and the chronic care model. *Healthcare Quarterly,* 7(1), 73–82.

The ECCM supports the important role that the social determinants of health play in influencing individual, community, and population health. Support of self-management and the development of personal skills for health and wellness in the ECCM may be accomplished by providing information and enhancing life skills. For example, smoking cessation programs are a cost-effective means of positively affecting health.

Delivery system redesign and reorientation of health services encourage health care providers to move beyond the provision of cure-focused services to an expanded mandate that promotes a holistic perspective. Decision support encompasses the gathering of evidence not only on

disease and treatment but also on staying healthy. Information systems can be used to evaluate established systems and support new ways of providing care. Healthy public policy involves working toward organizational and governmental legislation and policy that foster greater equity in society and leads to safer and healthier goods, services, and environments. The ECCM notes the significant impact of social supports on overall health and quality of life. It promotes the creation of supportive environments that are safe, stimulating, satisfying, and enjoyable. The creation of safe, affordable housing is one example in this area. Finally, strengthening community action involves working together with community groups to set priorities and achieve goals that enhance the health of the community.

Nurses have a vital role to play within the vision of the ECCM and can serve as leaders in the challenge to improve the care of Canadians living with chronic illness.

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. What is the most common cause of death in Canada?
   a. Cancer
   b. Cardiovascular disease
   c. Respiratory disease
   d. Community-acquired pneumonia
2. Which of the following are characteristics of a chronic illness? *(Select all that apply)*
   a. It has reversible pathological changes.
   b. It has a consistent, predictable clinical course.
   c. It results in permanent deviation from normal.
   d. It is associated with many stable and unstable phases.
   e. It always starts with an acute illness and then progressesslowly.
3. Select the modifiable risk factor for developing chronic illness.
   a. Activity level and sex
   b. Age and genetic background
   c. Air pollution and occupation
   d. Smoking and weight
4. According to the World Health Organization, which model best accounts for disability?
   a. The biopsychosocial model
   b. The medical model
   c. The social model
   d. The shifting perspectives model
5. Which statement from a 47-year-old client with COPD reflects her efficacy expectancy?
   a. “I have this disease only because I worked in an auto body shop for years and was exposed to toxic fumes.”
   b. “I know I can't quit smoking. I've tried too many times in the past 5 years.”
   c. “My mother quit smoking, and she still died from lung disease.”

d. “It's too late to quit smoking now, so what's the point of trying?”

6. Identify the situation in which caregiver burden is most likely to occur.
   a. A husband must administer medications to his cognitively impaired wife.
   b. A daughter must empty her mother's drains following a mastectomy.
   c. A wife with heart failure must assist her husband to the toilet following a cerebro-vascular accident.
   d. A neighbour prepares meals for a client recently discharged from hospital following cataract surgery.
7. A client has had multiple sclerosis for the past 2 years and is admitted to hospital to manage symptoms of an exacerbation. According to the illness trajectory model, which phase of chronic illness would she be in?
   a. Trajectory onset
   b. Unstable
   c. Acute
   d. Crisis
8. A 53-year-old with fibromyalgia has followed her prescribed exercise program for the past month. What would this behaviour be an example of?
   a. Compliance
   b. Adherence
   c. Self-management
   d. Chronic care
9. A nurse is part of a citizen group initiative to start a food bank for disadvantaged people. Within the ECCM, in which domain does this work of the nurse fall?
   a. Delivery system redesign
   b. Healthy public policy
   c. Social support
   d. Strengthening community

1. a; 2. c, d; 3. d; 4. a; 5. b; 6. c; 7. c; 8. b; 9. d.

CHAPTER 6

Community-Based Nursing and Home Care

Written by, Julie H. Fraser

With contributions from, Barbara L. Mildon

LEARNING OBJECTIVES

1. Understand the history of community nursing.
2. Define *primary health care* and explain its importance to the health care system and community health nursing practice.
3. Describe the trends that are threatening the sustainability of Canada's health care system.
4. Describe the role that home care plays in promoting the sustainability of Canada's health care system.
5. Understand how home care in Canada is organized and funded.
6. Describe the practice of the home health nurse, including key clinical competencies.

KEY TERMS

chronic disease management, p. 79
family-centred care, p. 82
home health nursing, p. 77
hospice palliative care, p. 83
nurse practitioners (NPs), p. 78
nursing-sensitive outcomes, p. 85

primary care, p. 79

primary health care, p. 79

public health nursing, p. 78

The community offers a diversity of exciting and professionally fulfilling roles in which community health nurses (CHNs) make a meaningful difference to the health of individuals, families, communities, and populations. Home and community care have increasingly been recognized as essential components of the health care system (Canadian Nurses Association [CNA], 2013, Canadian Healthcare Association, 2009; Health Council of Canada, 2008a; Nagle, 2008; Canadian Home Care Association [CHCA], 2013). This chapter is a discussion of community-based nursing, including its history, roles, and practice, with an emphasis on home health care.

In its report of the 2015 nursing workforce, the Canadian Institute for Health Information (CIHI, 2015a) reported that 14.6% of regulated nurses worked in the community health sector, which includes community health centres, home care nursing organizations, nursing stations (outpost or clinic), and public health departments or units.

The History of Home Health Nursing

Home health nursing (also known as *visiting nursing, district nursing,* and *home care nursing*) is a specialized area of nursing practice firmly rooted in community health nursing. "The role is characterized by the flexibility, adaptability, and creative approaches to situations and problems encountered in the context of service delivery where clients live" (Community Health Nurses of Canada [CHNC], 2010, p. 7). This specifically includes "teaching, curative interventions, end of life care, rehabilitation, support, maintenance, social adaptation and integration, and support for the family caregiver" (American Nurses Association, 2008, p. 2).

The history of home health nursing in Canada can be traced back through the centuries. Voluntary, charitable organizations were the first to address the health needs of citizens in the community. For example, the Grey Nuns, founded in Montreal in 1738, established hospitals and refuges and travelled to the homes of ill persons to provide care (Allemang, 2000). Thus the philosophy of attending to the well-being of the individual, as well as to the health of the community at large, came to uniquely characterize community health nursing (Chalmers & Kristjanson, 1992). In 1897, the Victorian Order of Nurses (VON) was established in Canada, followed in 1908 by the Saint Elizabeth Visiting Nurses Association. It has been speculated that the association of volunteerism and charity with community nursing has contributed to the continuing struggle for recognition of the formal education required by CHNs and for appropriate compensation (Chalmers & Kristjanson, 1992).

As this history demonstrates, home health nursing was already well established when public health nursing emerged. Public health nursing came into existence as a result of scientific breakthroughs, including vaccinations, pasteurization, the germ theory of disease, and antisepsis, which provided the basis for preventing infection. The movement of people from rural areas to cities fostered ideal conditions for disease transmission, necessitating new attention to sanitation (Allemang, 2000). In view of these changes, public health nursing focused on health promotion and disease prevention, and home health nurses attended to the needs of people already ill, while also incorporating health promotion and disease prevention into their care. The links between public health and home care nursing were captured by Emory (1953), who identified that the inclusion

of both bedside nursing and health teaching delineates home health nursing as a branch of public health nursing.

Public health nursing is defined today as a specialized area of nursing practice in which the nurse combines knowledge from public health science, primary health care (including the determinants of health), nursing science, and the social sciences and focuses on promoting, protecting, and preserving the health of populations. Public health nursing recognizes that a community's health is closely linked to the health of its members and is often reflected first in individual and family health experiences. It recognizes, in turn, that healthy communities and systems that support health contribute to opportunities for health for individuals, families, groups, and populations. Public health nurses practise in increasingly diverse settings such as community health centres, schools, street clinics, youth centres, and nursing outposts and with diverse partners to meet the health needs of specific populations (adapted from Canadian Public Health Association, 2010, p. 8).

The shared history of visiting and public health nursing continues to unify the two groups of CHNs, who are now joined by nurses in many other community-based roles.

Community Health Nursing Roles

CHNs "promote, protect and preserve the health of individuals, families, groups, communities and populations in the settings where they live, work, learn, worship and play in an ongoing and episodic process" (CHNC, 2011, p. 4). A variety of titles exist for nurses who work in community-based settings. These titles include *public health nurse, home health nurse, prevention nurse, faith community nurse* (also called *parish nurse*), *family practice nurse, outpost* or *rural–remote nurse, case manager, primary care nurse, outreach nurse, occupational health nurse,* and *school nurse.* More recent community health nursing roles that have been introduced include those of the forensic nurse, the sexual assault nurse examiner, the nurse entrepreneur, and the nurse practitioner (also known as a *family* or *adult nurse practitioner*).

Nurse practitioners (NPs) are "autonomous health professionals with advanced education [who] provide essential health services grounded in professional, ethical and legal standards" (CNA, 2010, p. 5). NPs "integrate their in-depth knowledge of advanced nursing practice and theory, health management, health promotion, disease/injury prevention, and other relevant biomedical and psychosocial theories to provide comprehensive health services" (CNA, 2010, p. 5). Their education and experience allow them to function both independently and collaboratively in a range of settings (CNA, 2010). Primary care clinics are an example of a setting where both NPs and other nurses are demonstrating positive impacts on individuals' health outcomes (CNA, 2014).

Although the community is the context of care for community-based nurses, they possess an understanding of the entire health system continuum. For example, a person may be hospitalized in a burn unit after suffering burns in a fire at home. When the patient's condition is no longer critical, he or she may be transferred to a general medical-surgical unit and then to a rehabilitation facility. Once the patient is back home, a home health nurse may visit to care for unhealed burn injuries, to provide care for other health needs, or both. When the individual is ready to return to work, an occupational health nurse may be involved to facilitate the reintegration to the workplace.

The continuum of care does not always include hospitalization. Health problems may be identified in a variety of outpatient settings, including physicians' offices, workplace health units, health care clinics, or community health centres. For example, a patient may be screened for

diabetes mellitus at work by an occupational health nurse. Screening results may prompt a referral to a family physician or nurse practitioner, who makes the diagnosis of diabetes. Instead of hospitalization, the patient may be monitored by a chronic disease management nurse or certified diabetes educator in the family practice office or community health centre, who will collaborate with the patient to design a care plan. The care plan may include monitoring and education in a variety of settings, as well as follow-up by a home health nurse to initiate, teach, and monitor the prescribed insulin therapy. In turn, the home health nurse would communicate with the appropriate members of the health care team to promote comprehensive, timely, and appropriate patient care.

A Health Care System Under Pressure

Several trends are putting pressure on Canada's health care system and influencing its evolution. The significance of select trends for CHNs is highlighted in the sections below.

Changing Demographics

The average age of Canadians is increasing (older adults are discussed further in Chapter 7). In 2015, for the first time, Statistics Canada reported that there were more persons aged 65 years and older (16.1%) in Canada than children aged 0 to 14 years (16%) and that the number of older adults will continue to increase to 20.1% of the population by 2024 (Statistics Canada, 2015). It has been reported that persons aged 65 and older accounted for 45.4% of health care expenditures by provincial and territorial governments in 2009 (CIHI, 2015b). In addition, community-based services for older persons, such as home nursing and personal care support, day care programs, and foot care programs, are playing important roles. In 2011, one in six Canadians aged 65 and older had received home care services (CHCA, 2013).

Health Human Resources.

Nurses are the largest group of health care providers in Canada (CIHI, 2015a). Concerns about a nursing shortage continue to be raised across the country (CNA, 2012) and globally (World Health Organization, 2015a). According to CIHI (2015a), in 2014, nurses aged 40 to 59 represented 52.6% of registered nurses, 48.2% of licensed practical nurses, and 57.2% of registered practical nurses. Not only are nurses aging, but many may also retire before the traditional retirement age of 65 (CIHI, 2015a). The health of nurses is also causing concern: a national survey reported that 61% of nurses had taken time off in the previous year for health reasons and that the average number of days absent from work among all nurse respondents was 14.5 per nurse (Statistics Canada, 2006). More nurses than non-nurse health care providers reported musculo-skeletal problems, and nurses were more likely to have experienced depression in the previous year than were non-nurse health care providers (Statistics Canada, 2006).

Concern about a shortage of nurses and other health care providers in home care has also been documented (CHCA, 2013; Canadian Healthcare

Association, 2009; Carter, 2009). Shortages cause concern because they lengthen waiting lists for services, impose a burden on family members who take on the care of loved ones, and may undermine quality of care due to providers' feeling rushed because of high numbers of patients.

Patient Safety.

Since the release of a report entitled *To Err Is Human: Building a Safer Health System* (Institute of Medicine, 1999), the health care system has focused increasingly on enhancing patient safety. Factors influencing safety for home care patients include lack of control over a patient's home environment, lack of uniformity of procedures in private homes in comparison to hospital units, and a reliance on unpaid or untrained caregivers (Canadian Patient Safety Institute [CPSI], 2013; Lang, 2010; Lang, Edwards, & Fleiszer, 2008), as well as challenges in coordinating services from hospital to the home, the cost of equipment and supplies, and continuity of care within the home care team (CPSI, 2013). A pan-Canadian study revealed that 13% of individuals receiving home care services will experience an adverse event, 50% of which are considered preventable (CPSI, 2013). Adverse events in the home include falls, medication-related incidents, and infections resulting from such interventions as urinary catheterization or venous access or wounds (CPSI, 2013).

Sustainability of the Health Care System

Health care costs consume between 22% (Yukon) and 46% (Nova Scotia) of provincial and territorial budgets in Canada (CIHI, 2016a). Costs of over $228 billion per year (CIHI, 2016b) have raised an alarm regarding the ability to sustain Canada's health care system and have prompted calls for health care system reform or renewal. In particular, elements identified as in need of change include policies and programs that address the determinants of health, access to a consistent primary care provider, and a national strategy on chronic disease prevention and management (Morgan, Zamora, & Hindmarsh, 2007). These elements are reflected in the philosophy and principles of primary health care.

Primary Health Care.

Community health nursing practice is informed and guided by nursing theory and knowledge, social sciences, public health science, and the

philosophy and principles of primary health care (CHNC, 2011). According to the Declaration of Alma Ata (World Health Organization, 1978),

Primary health care is essential health care based on practical, scientifically sound, and socially acceptable methods and technology made universally accessible to individuals and families in the community through their full participation and at a cost that the community and country can afford.

There are six key principles of primary health care:

1. Universal access to health care services on the basis of need
2. Focus on the determinants of health as part of a commitment to health equity and social justice
3. Active participation on the parts of individuals and communities in decisions that affect their health and lives
4. Partnership with other disciplines, communities, and sectors for health (intersectoral approach)
5. Appropriate use of knowledge, skills, strategies, technology, and resources
6. Focus on health promotion–illness prevention throughout the life experience from birth to death

Although the terms *primary care* and *primary health care* are often used interchangeably, there is an important difference between them. The focus of **primary care** is disease, and the key participants are health care providers. In contrast, **primary health care** is both a philosophy and an approach to the delivery of health care (Health Canada, 2012). Its focus is system-wide, and key participants are intersectoral partners in the fields of health, social services, housing, and the environment. Primary health care includes a range of activities from the health care of individuals to activity on the determinants of health. Confusion often arises between the terms *primary care* and *primary health care* because the health care provider whom an individual visits for health care is often known as the individual's primary care provider. Moreover, having access to a consistent primary care provider (e.g., a family physician or nurse practitioner) is an essential component of primary health care. Lack of access to a consistent primary care provider may result in more visits to an emergency department or more hospitalizations (Health Council of Canada, 2008b). It may also

result in a delay in seeking care, fragmented care, and less effective chronic disease management.

Primary health care is increasingly being embraced as a strategy to shift the health system's emphasis from diagnosis and treatment of illness and injury to health promotion and disease prevention. This shift is also known as *reforming the system*. Decreasing the prevalence and severity of illness through effective chronic disease management has been identified as a key strategy to promote the well-being of Canadians and the sustainability of the health care system (Health Council of Canada, 2008b; Morgan, Zamora, & Hindmarsh, 2007). **Chronic disease management** refers to the use of elements and tools within the health care system (e.g., information systems, decision support tools, self-management promotion, and realignment of health services) and within the community (e.g., a supportive environment, health policy, and strengthened community action) to help patients living with chronic diseases (Canadian Public Health Association, 2008). Primary health care encompasses values and principles that are central to the practice of nurses: promoting health, preventing disease, and working with other members of the multidisciplinary team. Thus it is imperative that all nurses be aware of primary health care philosophy and principles and incorporate them into their practice (CNA, 2014).

Home Care

Definition and Importance of Home Care

Home care in Canada is defined as

> *an array of services for people of all ages, provided in the home and community setting, that encompasses health promotion and teaching, curative intervention, end-of-life care, rehabilitation, support and maintenance, social adaptation, and integration and support for the informal (family) caregiver. (CHCA, 2013, p. xi)*

In 2011, 1.4 million Canadians received home care services (CHCA, 2013). Home care, however, is *not* one of the insured services covered by the *Canada Health Act,* the legislation that created and protects Canada's universal, publicly funded health care system. Therefore, provinces and territories have no legal obligation federally to ensure that their citizens have access to home care services. A recent Nanos poll found that 90% of Canadians consider home care essential to aging at home (CNA, 2015). Although every province and territory now has a home care program, they offer varied access to and types of programming (CHCA, 2013). Canadian Home Care Association (2013) has established national harmonized principles of care: (a) patient- and family-centred, (b) integrated, (c) accessible, (d) evidence-informed, (e) sustainable, and (f) accountable. The Canadian Nurses Association (2015) and Canadian Medical Association (2015) have called on the federal government to adopt national home care standards.

Home Care Services

The CHCA (2013) reported that home care programs are designed to promote independence; prevent, delay, or substitute for acute or long-term care; assist with the use of community services; and supplement the care and support provided by friends and family. Recipients of home care include individuals who are frail or disabled or who have an acute or chronic medical condition. Some require only intermittent services; others need assistance 24 hours a day. Family members may also receive home care services such as respite care to support them in their caregiving efforts. Equipment for the home such as electrical beds, wheelchairs,

pressure-relief mattresses, commodes, walkers, raised toilet seats, and other assistive devices may also be provided.

Home care services may be categorized as acute, chronic, palliative, or rehabilitative. In addition, coordination and management of admission to a facility may be provided when it is no longer possible for the individual to remain at home (CHCA, 2013). Services may be provided in the home (e.g., private home or residential facility) or in adult day centres, workplaces, schools, shelters, or clinics. Community clinics staffed by home care nurses have been shown to be cost-effective and are attractive to patients who are well enough to leave their homes because they can choose their own appointment time and not have to wait in their homes for the nurse's arrival (VanDeVelde-Coke, 2004). However, it is important to note that skilled nursing observation and assessment of the patient's home environment, social supports, caregiver stress, and risk for falls cannot be achieved in a clinic, and thus serious health problems may be overlooked (Pastor, 2006).

Quality and Accountability in Home Care

As a demonstration of quality and accountability, many home care provider organizations voluntarily apply for accreditation from Accreditation Canada. However, accreditation is mandatory only in Quebec, where it is obtained through the Quebec Council of Accreditation (Accreditation Canada, 2015).

Standardized home care data are collected to demonstrate the impact of nursing on safety and quality outcomes (Doran, Mildon, & Clarke, 2011). For example, CIHI has developed the Home Care Reporting System (HCRS), which is a standardized data set to support comparison of specific indicators for home care. At present, eight provinces and territories are submitting to the HCRS partial or complete data generated by their use of the Resident Assessment Instrument—Home Care (RAI-HC) (CIHI, 2015c). Nurses are involved in collecting such data, which is then used for several purposes. For example, data from the RAI-HC system are now being used to gain a more comprehensive understanding of the health status and demographics of specific groups of home care patients such as those with heart failure (Foebel, Hirdes, Heckman, et al., 2011). The data also support quality monitoring and comparison among health care provider organizations (Hutchinson, Draper, & Sales, 2009) and the identification of patient outcomes (Doran, Hirdes, Poss, et al., 2009).

Funding and Utilization of Home Care Services

The majority of home care is funded by provincial and territorial governments through health budgets that are administered by regional health authorities, departments of health and social services, local health integration networks, or, in Ontario, community care access centres. The federal government also funds home care services through departments such as the First Nations and Inuit Branch of Health Canada and Veterans Affairs Canada (Table 6-1).

TABLE 6-1
FUNDING MECHANISMS FOR HOME CARE

1. Publicly funded, provincial–territorial health care plan
2. Private insurance (e.g., employment benefit plans)
3. Veterans Affairs Canada
4. First Nations and Inuit branch of Health Canada
5. Indigenous and Northern Affairs Canada
6. Workers' compensation boards
7. Private payment (also known as *self-payment* or *out-of-pocket payment*)
8. Associations and foundations (e.g., Canadian Red Cross)

The use of home care services in Canada has grown considerably since the 1990s. In the period 1994 to 1995, the government spent $1.6 billion on home care. By 2003/04, home care spending had risen to $3.4 billion and represented 4.2% of total government health spending (Canadian Healthcare Association, 2009). Even though in 2010/11 spending grew to $5.9 billion, the total government spending ratio remained relatively the same at 4.1% (CHCA, 2013). Factors contributing to the rising costs include not only the increased numbers of individuals using the services but also the costs associated with medical technology and equipment, access to mobile electronic records, and demand for both professional and supportive care for older adults with complex health care needs who are discharged from hospitals.

Sometimes the frequency or duration of the government-funded home care services (e.g., the number of nursing visits, the number of hours of supportive care services such as homemaking, and length of time on the program) is not deemed sufficient by the patient or the family. In those instances, they may choose to purchase additional services either through insurance or with their own financial resources. The Canadian Healthcare Association (2009) reported that between 2 and 5% of Canadians purchase home care services not funded by government. In addition, it is estimated that 70 to 80% of the care of older adults in the community is provided by

family and friends, which, if paid, would amount to approximately $25 billion annually (Carers Canada, n.d.).

Home Health Care Team

Nursing Roles.

The home health care team is composed of the *home health nurse* and a variety of team members who work in close collaboration with the patient, the family, and medical practitioners (Table 6-2). Nurses who work on the home health care team include registered nurses and licensed practical nurses, as well as nurse practitioners and clinical nurse specialists. Home health nurses are *registered nurses* and *licensed practical nurses* who provide a variety of nursing assessments, planning and implementing of interventions, and teaching to assist individuals in optimizing their health in their home setting. *Nurse practitioners* use their in-depth nursing knowledge and their advanced scope of practice to diagnose and treat acute and chronic diseases. Nurse practitioners often provide care for homebound patients who do not have access to a primary care physician (CNA, 2008). *Clinical nurse specialists* promote the use of evidence-informed practice and system changes by providing expert consultation and leadership in guideline and policy development in the community setting (CNA, 2008). *Unregulated care providers* make an essential contribution to quality of life for the patient by supporting the patient's activities of daily living (ADLs), including bathing, preparing meals, and performing household chores and personal errands (Canadian Research Network for Care in the Community, 2010). They provide an important social connection with patients and are often the team members who spend the most time with them. These individuals also may provide delegated or assigned nursing care for patients with long-term frequent and predictable health needs (e.g., daily routine medication). Rehabilitation specialists—including physiotherapists, occupational therapists, and speech–language pathologists—are crucial members of the home care team, as are social workers, pharmacists, dietitians, and respiratory therapists. The role of the *case manager* is to coordinate the comprehensive care plan and services for the patient, including arranging for and funding services. All members of the home health care team work collaboratively to evaluate the patient's progress, make appropriate changes to the care plan, and develop the discharge plan. The home health care team members actively include the patient's family members in all aspects of care.

TABLE 6-2

MEMBERS OF THE HOME HEALTH CARE TEAM

Member	Description
Community health nurse	A registered nurse whose practice specialty promotes the health of individuals, families, communities, and populations and an environment that supports health. A CHN practices in diverse settings such as homes, schools, shelters, churches, community health centres, and on the street (CHNC, 2011).
Home care or home health nurse	A CHN who uses knowledge from primary health care (including the determinants of health), nursing science, and social sciences to focus on disease prevention, health restoration and maintenance, or palliation for patients, their caregivers, and families (CHNC, 2011) and who generally travels to the patient to provide care.
Case manager	The health care team member who leads the process of case management: "a collaborative strategy undertaken by health care professionals and clients to maximize the client's ability and autonomy through advocacy, communication, education, identification of and access to requisite resources, and service coordination" (CHCA, 2007, p. 3).
Community health worker or home support worker	An unlicensed care provider who assists individuals with ADLs such as bathing, dressing, and meal preparation, as well as IADLs such as housekeeping, shopping, and social recreational activities (Canadian Research Network for Care in the Community, 2010).
Nurse practitioner	An advanced-practice nurse who provides "direct care focusing on health promotion and the treatment and management of health conditions. [Nurse practitioners] are registered nurses with additional educational preparation and experience who possess and demonstrate the competencies to autonomously diagnosis, order and interpret diagnostic tests, prescribe pharmaceuticals and perform specific procedures within their legislated scope of practice" (CNA, 2008, p. 16).
Clinical nurse specialist	An advanced-practice nurse who provides expertise for specialized populations. Clinical nurse specialists play a leading role in the development of clinical guidelines and the use of evidence, provide expert consultation, and facilitate system change (CNA, 2008).

ADLs, activities of daily living; *CHCA*, Canadian Home Care Association; *CNA*, Canadian Nurses Association; *CHN*, community health nurse; *CHNC*, Community Health Nurses of Canada; *IADLs*, instrumental activities of daily living.

Home Health Care Patients

Although home health nurses may care for newborns, young children, teenagers, and adults of all ages, in the period 2009 to 2010, 82% of individuals who received home care services were 65 years of age or older (CIHI, 2011)—a statistic that reflects Canada's aging population. The individuals served also reflect the growing cultural diversity in Canada. The most common diagnosed health conditions in home care patients relate to dementia, cardiovascular disease, musculo-skeletal and neurological diseases, and other common chronic diseases (e.g., cancer, chronic obstructive pulmonary disease, diabetes). CHNs in all roles play an important part in the prevention and management of chronic illness by (a) promoting regular health screening, (b) incorporating health promotion

and disease prevention strategies into their practice, and (c) assisting individuals and families in managing chronic illness in the home.

As they face the physical and cognitive decline associated with many chronic conditions, many home care patients live alone. Nearly 40% of home care patients (CIHI, 2011) receive home support services to assist with both their ADLs and instrumental ADLs, and close to one-third receive nursing services (CIHI, 2011). The majority of patients who receive home care services require long-term supportive care or acute, short-term-focused services (e.g., postoperative care); smaller percentages receive end-of-life and rehabilitative care (CIHI, 2011). These patient characteristics have implications for home care nurses' role, competencies, and standards.

Home Health Nursing Practice

Overview.

Home health nursing is a unique and diverse practice that requires specific clinical competencies. Home health nurses navigate the full spectrum of traffic and weather conditions and cope with unexpected situations ranging from power failures to uncooperative family pets. They work in isolation and use strategies to protect patient privacy and confidentiality within neighbourhoods. Home health nurses need to be extremely organized and be able to work with a high level of autonomy. They require knowledge of community resources and proficiency in time management, case management, communication, and physical, psychosocial, and environmental assessment, as well as in care planning and evaluation. They must understand and work within funding models, service limits, productivity expectations, referral processes, and employer and funder reporting requirements. Many of these competencies differ from those of nurses in other care settings and sectors. Accordingly, the CHNC (2011) developed standards of practice for community health nurses. The following seven interrelated standards of practice form the core expectations for community health nursing:

1. Health promotion
2. Prevention and health protection
3. Health maintenance, restoration, and palliation
4. Professional relationships
5. Capacity building
6. Access and equity

7. Professional responsibility and accountability

On the basis of the standards, detailed practice competencies were developed by CHNC in 2010, and these are described later in this chapter.

Home Health Nursing and Family-Centred Care.

Nursing in the home occurs in a very different context than nursing in the hospital. In the hospital, the health care team has the dominant role and the environment is controlled. In the home, the patient, caregiver, or family (or a combination of these) plays the dominant role; the nurse is a guest in the house and must adapt to the home environment. Consequently, it is especially important that the home health nurse demonstrate a holistic, nonjudgemental, and family-centred philosophy and negotiate the care with the patient and family.

Family-centred care is "bringing the perspectives of patients and families directly into the planning, delivery, and evaluation of health care, and thereby improving its quality and safety" (Institute for Patient- and Family-Centered Care [IPFCC], 2011, p. 3). The core concepts of family-centred care include dignity and respect, information sharing, participation, and collaboration (IPFCC, 2011). The patient's knowledge, beliefs, values, and culture are considered in the planning and provision of care. Information sharing must be timely, accurate, unbiased, and complete to ensure patients and families can participate in decision making to the extent they choose (MacKay & Gregory, 2011). Family-centred care also involves collaboration among health care providers and patients and their families to develop, implement, and evaluate policies, programs, and professional education.

Family-centred care involves the recognition that an illness experienced by one family member will affect the entire family (Saint Elizabeth Health Care, 2011). Families often provide care for ill members and assist in decision making about all aspects of the care provided, including priority setting. Visits by community health care professionals are usually episodic, leaving the family with the burden of care. Home health nursing visits may be as frequent as several times a day or as infrequent as once a month. Visits may be lengthy, such as the initial visit, when the extensive admission assessment is completed; or they may be fairly short, such as visits to assess health status, including wound healing, pain control, or symptom management. Nursing care during a visit may be administered according to a predetermined routine such as one specified in a care

pathway, or it may be directed toward newly arising symptoms or health concerns.

In some situations, an older patient may be cared for by a spouse of similar age with chronic illnesses. In other situations, an older parent needing care may live with a busy middle-aged family member with dependent children, or a person may be caring for a dying spouse at home. In these situations, it is not uncommon for caregivers to become physically, emotionally, and economically overwhelmed with the responsibilities and demands of caring for a family member (Carers Canada, n.d.; Saint Elizabeth Health Care, 2010). The home health nurse is a lifeline for the family, helping them understand their loved one's health condition and needs, cope with changing roles and responsibilities, and make decisions about ongoing care arrangements.

Assessment of the signs of caregiver burnout (e.g., sleeplessness, difficulty concentrating) is a critical role of the home care nurse (Saint Elizabeth Health Care, 2010). The focus of care is on empowering the patient and family to meet the identified health care needs while also feeling in control of their lives. The goals of care may be short- or long-term in nature. One way a nurse can help family members cope with their increased responsibilities is to provide referrals to various support groups in the community or to other resources. The nurse can also work with the case manager to advocate for additional home care services to reduce the burden of care, for example, through a personal support worker, more frequent nursing visits, short-term respite placement, or support from a social worker.

Culturally Competent Care

Home Health Nursing Practice

Home health care is delivered within the context of the family's and the patient's cultural values and beliefs. Strategies to overcome language barriers may be needed, and the home health nurse is more likely than other nurses to encounter the patient's use of healing practices arising from cultural beliefs and the use of home remedies and complementary and alternative therapies. The ability to apply culturally relevant care is one of the competencies expected of home health nurses (CHNC, 2010). The home health nurse demonstrates culturally sensitive care by having an understanding of how culture can affect beliefs and behaviours (College of Nurses of Ontario, 2009) and the social and spiritual needs of the individual. Exploring and recognizing the individual's cultural practices, values, and needs and including them in the plan of care are essential to home health nursing practice. (Culture is discussed in Chapter 2, and complementary and alternative therapies are discussed in Chapter 12.)

Home Health Nursing Practice Knowledge and Skills.

It is generally acknowledged that the acuity of patients who require home health nursing has been rising steadily and is now very high (CNA, 2013; Lang & Edwards, 2006). As Lang and Edwards (2006) observed,

Unlike working on a specialized unit in a hospital, home care providers must maintain a breadth of general and specific knowledge. This poses a significant safety challenge because of the diversity and varied frequency of health conditions and treatments. It is not unusual to come across particular conditions or treatments only once every few months, making it difficult to maintain competence. This is heightened by: the trend for earlier discharge from hospitals and the corresponding increase in the acuity of patients receiving home care services; the lack of resources for continuing education and proficiencies; and the isolated nature of the practice of home care. (p. 24)

Specific competencies for home care nurses have been established in Canada (CHNC, 2011) and in the United States (American Nurses Association, 2008). These competencies reflect the knowledge, skills,

judgement, and attitudes associated with home care nursing practice. The CHNC (2011) listed three categories of competencies: (a) elements of home health nursing, (b) foundations of home health nursing, and (c) quality and professional responsibility (Table 6-3). Competencies associated with the elements of home health nursing focus on the nursing activities, functions, goals, and outcomes that are central to home care nursing practice (CHNC, 2011). Competencies associated with the foundations of home care nursing are related to the philosophy of primary health care and the core knowledge necessary in home care nursing practice (CHNC, 2011). Competencies associated with quality and professional responsibility focus on the strategies and activities that demonstrate professionalism and promote quality care (CHNC, 2011). Because many of the standards and competencies of community health nursing are unique, this branch of nursing is recognized as a specialty practice by the Canadian Nurses Association. Today, any nurse whose practice is community-based may choose to earn a national credential—CCHN (Certified in Community Health Nursing—Canada)—to indicate her or his expertise.

TABLE 6-3
SPECIFIC COMPETENCIES FOR CANADIAN HOME CARE NURSES

Elements of Home Health Nursing
• Assessment, monitoring, and clinical decision making • Care planning and care coordination • Health maintenance, restoration, and palliation • Teaching and education • Communication • Relationships • Access and equity • Building capacity
Foundations of Home Health Nursing
• Health promotion • Illness prevention and health protection
Quality and Professional Responsibility
• Quality care • Professional responsibility

In addition to needing specific skills, home health nurses require general knowledge of the range of health care equipment or assistive devices used to promote independence. They must also be familiar with a wide variety

of medical supplies and devices, such as chest and wound drainage tubes, intravenous therapy supplies, urinary catheters, enterostomy supplies, wound care products, enteral feeding equipment (Figure 6-1), central vascular access devices (Figure 6-2), and infusion pumps. Understanding rehabilitation techniques and terminology is helpful in collaborating with therapists, supporting the patient's progress, and evaluating the plan of care. Home care nurses also teach self-management strategies to assist individuals in managing chronic disease; the ideal result is to delay their placement in a residential home or admission to hospital. Assigning and delegating care to members of the health care team as part of the overall plan of care is a critical competency. Clinical documentation skills are also important for reflecting professional accountability and substantiating recommendations made about the patient's needs, the care provided, and the patient's response.

FIGURE 6-1 Nurse providing skilled care in the home. Source: Victorian Order of Nurses Canada.

FIGURE 6-2 Nurse providing peripherally inserted central catheter (PICC) care in the home. Source: Victorian Order of Nurses Canada.

Establishing and maintaining a therapeutic nurse–patient relationship is fundamental for effective home care nursing practice. Therefore, effective communication strategies and techniques are crucial. Because family members are encouraged to learn how to administer treatments and manage equipment, the nurse must be able to teach certain skills to both the patient and family. Providing such care may seem overwhelming to them initially. The home health nurse assesses the readiness of the caregiver to assume the care, teaches it in a way that is most helpful for the learner, and evaluates the outcomes of care, including the coping of the caregiver.

Hospice palliative care is another important component of home health nursing practice. The Canadian Hospice Palliative Care Association defines **hospice palliative care** as

an approach that improves the quality of life of patients and their families facing the problems associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial and spiritual. (as cited in World Health Organization, 2015b)

Hospice palliative care is not limited to those with cancer diagnoses; it "is appropriate for any patient and/or family living with, or at risk of

developing, a life-threatening illness due to any diagnosis, with any prognosis, regardless of age, and at any time they have unmet expectations and/or needs, and are prepared to accept care" (Canadian Hospice Palliative Care Association, 2009, p. 8). The home health nurse is often the linchpin in achieving the highest possible quality of life for the patient and family throughout the palliative and bereavement experience.

Trends in Home Health Nursing

New Nursing Graduates and Licensed Practical Nurses in Home Health Nursing.

Because of the breadth and depth of knowledge and skills required by the home health nurse, it was widely believed for many years that nurses required a minimum of 2 years of acute care hospital experience before being hired as a home health nurse. Furthermore, registered nurses generally received hiring preference over licensed practical nurses because it was believed that registered nurse preparation provided the best foundation for home care nursing. However, partly because of the growing nursing shortage, enhancements to the scope of practice and educational programs for licensed practical nurses, and the need to provide long-term interventions to a growing population with complex and unpredictable care needs, many home health employers now hire both registered nurses and licensed practical nurses right after graduation. To support these new graduates and new home health nurses, a variety of intensive orientation programs and tools have been developed to complement student placement and employment experiences (Meadows, 2009). Figure 6-3 depicts a sample orientation tool.

Technology in Home Health Nursing Practice

Surgical innovations, such as microscopic surgical techniques that have transformed many operations into day-surgery procedures, and medical interventions, such as advances in life support of premature infants, have allowed individuals to live longer and have shifted both acute and long-term care to community-based settings. An array of mechanical devices—including ventilators, infusion pumps, and peritoneal dialysis night cyclers—have been redesigned and miniaturized for portability and ease of use, making it possible for patients to remain at home while receiving intravenous antibiotics, chemotherapy, or total parenteral nutrition. Internet-based education and information programs are now common, and telemonitoring systems are enabling nurses and other health care providers to assess a patient's physical status from a remote location (Figure 6-4). As well, digital cameras are being used to take pictures of complex wounds; the pictures are then transferred via computer to a wound specialist for expert assessment and treatment recommendations (Figure 6-5).

FIGURE 6-4 Patient at a telemonitoring station in his home. Source: Saint Elizabeth Health Care, Markham, ON.

FIGURE 6-5 Home health nurse examining digital photos of a wound, using Pixalere software. Source: Fraser Health, Surrey, BC.

Home care nurses are accessing clinical information and best practice evidence at the point of care through devices such as smartphones; such devices are also used to document patient health data that, in turn, is used to monitor and track clinical outcomes (Ontario Ministry of Health and Long-Term Care, 2008). Several of the nursing best practice guidelines published by the Registered Nurses' Association of Ontario are now available as applications for hand-held devices, including the iPhone and Android smartphones. Indeed, today's home health nurses are as likely to arrive at the patient's home holding a digital device, a digital camera, or a laptop or tablet as they would a stethoscope. Computerized clinical documentation systems (Figure 6-6) and electronic health records are now being used by a growing number of home health nurses. The home health nurse is able to review the patient's history and plan of care and update the electronic health record as care is given. The accessibility of electronic health records facilitates continuity of care, promotes quality, and reduces documentation time. The complexity of ensuring privacy and confidentiality, however, grows with nurses managing both technological devices and transitional paper charts.

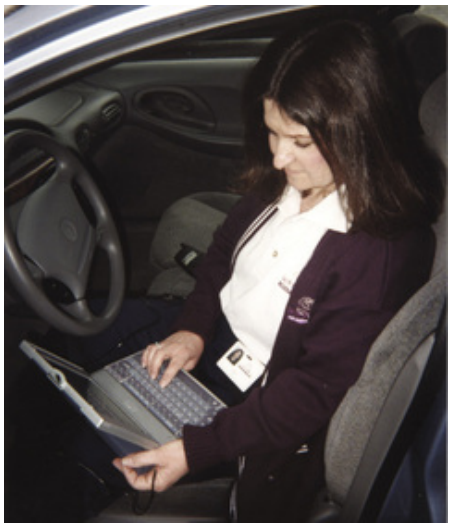

FIGURE 6-6 Home health nurse using a laptop computer in her car. Source: Saint Elizabeth Health Care, Markham, ON.

Measurement of Nursing-Sensitive Outcomes

Nursing-sensitive outcomes are "those that are relevant, based on nurses' scope and domain of practice, and for which there is empirical evidence linking nursing inputs and interventions to the outcomes" (Doran, 2003, pp. vii–ix). Nurses need to know the outcomes associated with their care in order to assess the effectiveness of the patient's care plan and make revisions as indicated. They may also use outcomes data to evaluate their own practice or that of their team or program. Decision makers and funders require outcomes data to support budget needs, program design and delivery, and the development of accountability mechanisms such as balanced scorecards. Research has demonstrated that it is feasible for nurses to collect electronic or manual data on nursing-sensitive outcomes in home health, acute care hospitals, and long-term care settings (Doran, Harrison, Laschinger, et al., 2004). On the basis of those results, the Canadian Health Outcomes for Better Information and Care (C-HOBIC, 2015), a two-phase project, was launched to test the collection of patient outcome information related to nursing care in the electronic health records of Ontario, Prince Edward Island, and Saskatchewan.

Summary

Nursing in the community represents a dynamic and fulfilling practice specialty for nurses. Community-based nursing is an essential component of the health care system and offers the opportunity to positively influence the health and outcomes of individuals, communities, and populations.

Case Study

Home Health Care for Patient With Infected Leg Ulcer

Source: Shutterstock.com.

Patient Profile

Melody Tennant, 43 years old, has been referred to home care for care of her infected leg wound and intravenous antibiotics. She lives alone in an apartment with her cat in an area of town identified as having a high number of calls to the police. Ms. Tennant worked as a food server but is currently out of work. She is candid with the nurse completing her admission and shares the fact that she has been trying to stop her intravenous drug use for years. Her right lower leg ulcer is the result of injection drugs 6 months ago. The injection site became a "sore" and "just never healed." Ms. Tennant went to the walk-in clinic when she could no longer stand the pain and her boyfriend noticed her leg was pink and warm to touch. The walk-in clinic physician sent her to the emergency department, where a methicillin-resistant *Staphylococcus aureus* (MRSA)–infected leg wound was diagnosed.

Subjective Data

- Has a history of being hepatitis B positive (3 years)
- Has varicose veins in both legs; worries that, because of these, the home care nurses will want her to wear support stockings, which she finds "ugly"
- Complains of pain in her right lower leg and asks for "something to take the edge off"

Objective Data

Physical Examination

- Peripheral intravenous site (saline lock) in left hand
- Dressing to right lower leg: 10- × 10-cm foam dressing with adhesive edges
- Right lower leg ulcer: 10% pink base, 90% yellow base, irregular flat edges. Wound size is 0.5 cm deep, 7 cm long, 4.4 cm wide. Periwound skin is deep pink, and the diameter of the right lower leg calf is greater than that of the left.

Collaborative Care

- Methadone, 50 mg PO once daily
- Vancomycin, 1 000 mg intravenously BID
- Multivitamin, 1 tablet PO daily
- High-protein diet

Discussion Questions

1. ***Priority decision:*** What are the initial priorities for the home health nurse?
2. What other members of the health care team should be involved in the care of Ms. Tennant? What are their roles and responsibilities?
3. ***Priority decision:*** What type of patient education program should be implemented? What are the priority teaching goals to promote self-management?

4. What should the nurse consider in the nutrition assessment? How will the nurse address economic considerations related to Ms. Tennant's diet?
5. How can the nurse address Ms. Tennant's coping skills and use community resources to intervene with her mental health and substance use?
6. What types of supplies will Ms. Tennant need? What diagnostics, teaching, and community resources should accompany the use of these supplies?
7. What are the expected long-term outcomes for Ms. Tennant?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. Which of the following statements is correct about public health nursing?
   a. It predates home health nursing.
   b. It focuses on health promotion and disease prevention.
   c. It does not include health teaching.
   d. It takes place predominantly in private homes.
2. Which of the following statements best describes nurses working in community health settings?
   a. They function autonomously in meeting client needs.
   b. They focus only on client needs specific to the setting.
   c. They use the same skills as in acute care settings.
   d. They use case-management skills along the continuum of care.
3. Which of the following trends is affecting home care and threatening the sustainability of Canada's health care system?
   a. The long wait times for surgery
   b. The increased number of people hospitalized with acute illness
   c. The shortage of health care providers
   d. The high rate of health care–associated infections
4. Which of the following best describes primary health care?
   a. The first health care provider a client sees
   b. Public health nursing
   c. A philosophy that emphasizes health promotion, disease prevention, and client participation in care
   d. A theoretical model
5. Which of the following statements best reflects the reality of home care services in Canada?
   a. The use of home health services is increasing.
   b. The use of home health services is decreasing.
   c. Home health services are not yet available in all provinces and territories.

d. Home health services are used more by families than by single clients.

6. Which of the following is a home care nurse competency? *(Select all that apply)*
   a. Appreciate and understand the roles and responsibilities and the contributions of other regulated and unregulated health care workers involved in the client's care plan.
   b. Assist clients and their families to recognize that their capacity for managing their own health care needs is limited by the resources available to them.
   c. Limit participation in collaborative, interdisciplinary, and intersectoral partnerships to enhance the health of clients and families.
   d. Keep knowledge current to ensure optimal case management.

1. b; 2. d; 3. c; 4. c; 5. a; 6. a, b.

CHAPTER 7

Older Adults

Written by, Sherry A. Greenberg

Adapted by, Veronique M. Boscart

LEARNING OBJECTIVES

1. Describe the effects of ageism on the care of older adults.
2. List the major biological theories about aging.
3. Describe the needs of special populations of older adults.
4. Describe nursing interventions to assist chronically ill older adults.
5. Describe common problems of older adults in relation to acute illness and the role of the nurse in assisting them.
6. Describe challenges and concerns related to the caregiving role.
7. Identify care alternatives to meet specific needs of older adults.
8. Identify the legal and ethical issues related to the care of older adults.
9. Identify the role of the nurse in health screening and promotion and in disease prevention for older adults.

KEY TERMS

ageism, p. 91
assisted-living facilities (ALFs), p. 100
elder abuse, p. 98
elder mistreatment, p. 98
elder neglect, p. 98
ethnogeriatrics, p. 97

frail older adults, p. 96

gerontological nursing, p. 90

long-term care (LTC) facilities, p. 100

polypharmacy, p. 104

Gerontological nursing is a nursing specialty that revolves around the care of older adults. The nurse delivers care from a patient-centred perspective, valuing what is important to the patient. This chapter presents specific information about older adults to assist nurses in providing medical-surgical care to such patients in a variety of settings, such as inpatient care units, clinics, ambulatory care units, community and home health care, long-term and chronic care, nursing homes, and emergency care departments. Gerontological care presents opportunities and challenges that call for highly skilled assessment and creative adaptations of interventions.

Demographics of Aging

Older adults are one of the fastest-growing populations in Canada. There is no absolute threshold chronological age at which a person becomes "old." Most Canadian statistical summaries define older adults as those aged 65 and older. Psychologists have further divided the "old" into three groups: the young-old, aged 65 to 74 years; the middle-old, aged 75 to 84 years; and the old-old, older than 85 years. Since 1980, the older population has grown about twice as fast as the overall population: 14.4% of the population were aged 65 and older in 2011 (Statistics Canada, 2011a). This rapid growth is expected to continue well into the future. The population aged 65 years and older is projected to double by 2036 (Statistics Canada, 2010a). By then, almost 10.4 million people will be older adults, representing 23.7% of the total population (Statistics Canada, 2011a).

In general, Canada's population is younger than those of most Western industrialized countries, and yet a large proportion of older adults are immigrants. By 2031, one in four Canadians will be an immigrant, and one in three will belong to a visible minority (Statistics Canada, 2011a). Approximately 5% of the Indigenous population in Canada were aged 65 years or older in 2006; this proportion is expected to increase to 6.5% by 2017 (Health Council of Canada, 2013). Furthermore, there are significant age-related differences between Canada's provinces and territories; the largest share of the older population is in Nova Scotia (16.5%) and New Brunswick (16.2%), and the smallest is in Northwest Territories (5.6%) and Nunavut (3.2%; Statistics Canada, 2011a).

The most rapidly increasing age group is those of people 85 years and older. Since 1960, this group has increased 250%. In addition, there are currently 5 852 centenarians living in Canada; this number is projected to increase to 45 000 by 2046 (Statistics Canada, 2011c).

Gender can have a significant effect on various aspects of aging. Women usually live longer than men. Female Canadians born today have a life expectancy of 83 years, and male Canadians have a life expectancy of 79 years (Statistics Canada, 2017). The majority of adults older than 65 years remain in their home; 7.9% reside in a care facility (Statistics Canada, 2011b).

Because the needs and expectations of the population are changing rapidly, nurses need to acquire and demonstrate the required knowledge levels, clinical expertise, and leadership skills, and a strong understanding

of health organizations and policy to deliver the best care possible to older adults.

Attitudes Toward Aging

Today's health care system promotes the concept of aging from a holistic perspective, in which health and wellness are defined as a balance between a person's internal and external environments and the person's emotional, spiritual, social, cultural, and physical processes. According to this perspective, aging is influenced by many factors, including emotional and physical health, developmental stage, socioeconomic status, culture, and ethnicity.

As people age, they are exposed to more and different life experiences. The accumulation of these differences creates a great diversity among older adults. Nurses should acknowledge and incorporate this diversity and older adults' perceptions of aging. Research has indicated that older adults who report a high sense of subjective well-being live longer, healthier lives than do older adults with a low sense of subjective well-being (Diener & Chan, 2011). Age is important, but it may not be the most relevant factor for determining the appropriate care of an individual older adult. In approaching aging from a viewpoint of health and well-being, a person's strengths, resilience, resources, and capabilities are emphasized, rather than her or his existing pathological conditions.

Unfortunately, myths and stereotypes about aging are found throughout society and are often supported by media (Victor, 1994). These stereotypes provide the basis of commonly held misconceptions that lead to errors in nursing assessments and limitations to interventions. For example, if nurses perceive older people to be confused or disoriented, necessary assessments for delirium will be neglected, which can result in morbidity and mortality (Baker, Taggart, Nivens, et al., 2015).

This negative attitude based on age is defined as **ageism**. Ageism leads to discrimination and disparities in the care of older people. Research has indicated that nurses who demonstrate an ageist attitude provide lower quality care to their older patients (Skirbekk & Nortvedt, 2014). In today's aging society, it is essential for nurses to demonstrate expertise, knowledge, and practice to care for older adults. Nurses can receive a Specialty Certification in Gerontological Nursing with the Canadian Nurses Association (CNA) to demonstrate their capabilities in providing care and services to older adults and their families.

Biological Theories of Aging

Several theories aim at describing the process of aging. From a biological view, aging is defined as the progressive loss of function. The exact cause of biological aging remains to be determined, but aging is clearly a multifactorial process involving genetics, diet, and environment (Daniel & Tollefsbol, 2015). Nurses' knowledge of biological changes is impor-tant because it allows for differentiation between the normal aging process and health problems that necessitate specific interventions.

Several theories regarding biological aging are currently proposed. An overview of some biological theories of aging is presented in Table 7-1.

TABLE 7-1

SUMMARY OF SOME BIOLOGICAL THEORIES OF AGING

Theory	Dynamics
Free radical	Oxidation of fats, proteins, and carbohydrates creates free electrons that attach to other molecules, altering cellular function.
Cross-link	Lipids, proteins, carbohydrates, and nucleic acid react with chemicals or radiation to form bonds that cause an increase in cell rigidity and instability.
Immunological-autoimmunological	Alteration of B and T cells leads to loss of capacity for self-regulation; normal cells or cells with age-related changes are recognized as foreign matter; system reacts by forming antibodies to destroy these cells.

Free Radical Theory

The *free radical theory* was initially proposed in 1956 by Harman, but has become the focus of new research only more recently. A free radical is a highly reactive atom or molecule that carries an unpaired electron and thus is prone to combine with another molecules, which causes an oxidative process. This process, also called *oxidative stress*, can ultimately disrupt cell membranes and alter DNA and protein synthesis. Common diseases such as atherosclerosis and cancer are associated with oxidative stress (Shaw, Werstuck, & Chen, 2014). Free radicals are natural by-products of many normal cellular processes and are also created under the influence of noxious environmental factors such as smog, tobacco smoke, and radiation. Numerous natural protective mechanisms are in place to prevent oxidative damage. Research since 2000 has focused on the roles of various antioxidants, including vitamins C and E, in slowing down the oxidative process and, ultimately, the aging process.

Cross-Link Theory

According to the *cross-link theory,* over time and as a result of exposure to chemicals and radiation in the environment, cross-links form between lipids, proteins, and nucleic acids (Höhn & Grune, 2013). These cross-links result in decreased flexibility and elasticity, and this causes increased rigidity in tissues (e.g., blood vessels). Such changes in cell structure may explain the observable changes associated with aging, such as wrinkles and a decreased distensibility of arterial blood vessels. However, it is unlikely that such changes account for all of the physical events associated with aging.

Immunological Theory

According to the *immunological theory,* declining functional capacity of the immune system is the basis of the aging process (Fuente & Miquel, 2009). It suggests that aging is not a passive wearing-out of systems but an active self-destruction mediated by the immune system. This theory is based on observations of an age-associated decline in T cell functioning, accompanied by a decrease in resistance and an increase in autoimmune diseases with aging. The result is an autoimmune phenomenon in which normal body cells are mistaken as foreign and are attacked by the individual's own immune system.

Despite the many different theoretical views, the exact cause of aging is unknown. Nurses need to be aware that each older person exhibits an individual aging process, which will necessitate a unique approach.

Age-Related Physiological Changes

Age-related changes affect every body system and are part of healthy aging. However, the age at which specific changes become evident differs from person to person. For instance, a person may have greying hair at age 45 but relatively unwrinkled skin at age 80. Nurses need to recognize and assess age-related changes because they form the basis to differentiate from non–age-related changes. Table 7-2 presents an overview of assessments based on age-related physiological changes and associated clinical manifestations.

TABLE 7-2

AGE-RELATED DIFFERENCES IN ASSESSMENT
Age-Related Changes and Associated Clinical Manifestations

Function	Normal Age Changes	Clinical Manifestations
Cardiovascular System		
Cardiac output	• Force of contraction decreases • Fat and collagen increase • Heart muscle weakens • Ventricular wall thickens	• Myocardial oxygen demand increases • Stroke volume and cardiac output decrease • Fatigue, shortness of breath, and tachycardia occur • Blood flow to vital organs and periphery decreases
Cardiac rate and rhythm	• Dependence of atrial contraction increases • Fibres from bundle of His are lost • Mitral valve stretching occurs • Ventricles are slower to relax • Sinus node pacemaker cells decrease in number	• HR slows to increase with stress • Maximum HR decreases (e.g., in 80-year-old, HR = 120 bpm; in 20-year-old, HR = 200 bpm) • Possible AV block • Recovery time from tachycardia is prolonged • Frequency of premature beats increases
Structural changes	• Aortic valves become sclerotic and calcify • Baroreceptor sensitivity decreases • Mild fibrosis and calcification of valves occur	• Diastolic murmur is present in 50% of older people • Heart-position landmarks change
Arterial circulation	• Elastin and smooth muscle are reduced • Vessel rigidity increases • Vascular resistance increases • Aorta becomes dilated	• Systolic BP modestly increases • Rigidity of arteries contributes to coronary artery disease and peripheral vascular disease
Venous circulation	• Vessel tortuosity increases	• Inflamed, painful, or cordlike varicosities appear
Peripheral pulses	• Arteries become more rigid	• Pulses are weaker but equal • Circulation to periphery slows • Feet and hands are cold
Respiratory System		
Structures	• Cartilage degeneration occurs • Vertebral rigidity occurs • Strength of muscles decreases • Respiratory muscles atrophy • Rigidity of thoracic wall increases • Ciliary action decreases	• Kyphosis occurs • Anterior-posterior diameter increases • Use of accessory muscles decreases • Chest becomes rigid and barrel-shaped • Respiratory excursion decreases • Ability to cough and deep breathing ability diminish
Change in ventilation and perfusion	• Pulmonary vascular bed shrinks • Alveoli decrease in number • Alveolar walls thicken • Elastic recoil decreases	• Lung compliance decreases • Total lung volume is unchanged • Vital capacity decreases • Residual lung volume increases • Mucus thickens • PaO_2 and O_2 saturation decreases • Hyperresonance
Ventilation control	• Response to hypoxia and hypercarbia diminishes	• Ability to maintain acid-base balance decreases • Respiratory rate 12–24/min
Integumentary System		

Function	Normal Age Changes	Clinical Manifestations
Skin	• Amounts of collagen and subcutaneous fat decrease • Sweat glands decrease in number • Epidermal cell turnover slows • Skin tissue fluid decreases • Capillary fragility increases • Pigment cells decrease in number • Sebaceous gland activity decreases • Sensory receptors diminish • Thresholds for touch, vibration, heat, and pain increase	• Skin elasticity decreases • Wrinkles and folds increase • Extremity fat is lost; fat on trunk increases • Skin heals more slowly • Skin more dry • Skin tears and bruises easily • Skin colour uneven • Skin lesions increase in number • Ability to respond to heat and cold decreases • Ability to feel light touch decreases • Cutaneous pain sensitivity declines
Hair	• Melanin decreases • Germ centres and hair follicles decrease in size and number	• Hair turns grey or white • Hair quantity decreases and thins • Amounts of scalp, pubic, and axillary hair decrease • Amount of facial hair on men decreases • Amount of facial hair on women increases
Nails	• Blood supply to nail bed decreases • Longitudinal striations increase	• Growth slows • Nails are brittle and thicken • Nails are easily split • Potential for fungal infection increases
Urinary System		
Kidney	• Renal mass decreases • Number of functioning nephrons decreases • Glomerular filtration rate decreases • Renal plasma flow decreases	• Protein in urine increases • Potential for dehydration increases • Creatinine clearance decreases • Serum levels of creatinine and BUN increase • Excretion of toxins and drugs decreases • Nocturia increases
Bladder	• Amounts of bladder smooth muscle and elastic tissue decrease	• Capacity decreases • Control decreases; potential for stress incontinence increases
Micturition	• Sphincter control decreases	• Frequency, urgency, and nocturia increase
Reproductive System		
Male structures	• Prostate enlarges • Testicular volume decreases • Sperm count decreases • Seminal vesicles atrophy • Serum testosterone levels remain constant • Estrogen level increases	• Sexual response becomes less intense • Achieving an erection takes longer • Erection is maintained without ejaculation • Force of ejaculation decreases
Female structures	• Estradiol, prolactin, and progesterone levels diminish • Sizes of ovaries, uterus, cervix, fallopian tubes, and labia decrease • Associated glands and epithelium atrophy • Elasticity in the pelvic area decreases • Breast tissue decreases • Vaginal pH becomes alkaline	• Responses to changing hormone levels are altered • Cervical and vaginal secretions decrease • Intensity of sexual response decreases • Potential for vaginal infections increases • Potential for vaginal and uterine prolapse increases
Gastro-Intestinal System		
Oral cavity	• Dentine decreases • Gingival retraction occurs • Bone density is lost • Papillae of tongue decrease in number • Taste thresholds for salt and sugar increase • Salivary secretions decrease	• Taste perception changes • Potential for loss of teeth is increased • Gingivitis is more likely to occur • Gums may bleed, and dry mouth occurs • Oral mucosa is dry

Function	Normal Age Changes	Clinical Manifestations
Esophagus	• Pressure of lower esophageal sphincter decreases • Motility decreases	• Epigastric distress occurs • Dysphagia occurs • Potential for hiatal hernia and aspiration is increased
Stomach	• Gastric mucosa atrophies • Blood flow decreases	• Gastric emptying decreases
Small intestine	• Intestinal villi decrease in number • Enzyme secretions decrease • Motility decreases	• Intestinal transit slows • Absorption of fat-soluble vitamins is delayed
Large intestine	• Blood flow decreases • Motility decreases • Sensation of defecation urge decreases	• Potential for constipation and fecal impaction increases
Pancreas	• Pancreatic ducts become distended • Lipase production decreases • Pancreatic reserve is impaired	• Fat absorption is impaired • Glucose tolerance decreases
Liver	• Number and size of cells decrease • Hepatic protein synthesis is impaired • Ability to regenerate liver cells decreases	• Lower border extends past costal margin • Drug metabolism decreases
Musculo-Skeletal System		
Skeleton	• Intervertebral disc space narrows • Cartilage of nose and ears increases	• Height diminishes 2.5–10 cm (1–4 inches) • Nose and ears lengthen • Kyphosis occurs • Pelvis widens
Bone	• Amounts of cortical and trabecular bone decrease	• Bone resorption exceeds bone formation • Potential for osteoporotic fractures increases
Muscles	• Number of muscle fibres decreases • Muscle fibres atrophy • Muscle regeneration slows • Contraction time and latency period are prolonged • Flexion of joints increases • Ligaments stiffen • Tendons become sclerotic • Tendon flexor reflexes decrease	• Strength decreases • Agility decreases • Rigidity in neck, shoulders, hips, and knees increases • Potential for restless legs syndrome increases
Joints	• Cartilage erosion occurs • Calcium deposits increase • Water in cartilage decreases	• Mobility decreases • ROM becomes limited • Osteoarthritis can occur
Nervous System		
Structure	• Neurons in brain and spinal cord are lost • Brain size decreases • Dendrites atrophy • Amount of major neurotransmitters decreases • Size of ventricles increases	• Conduction of nerve impulses slows • Peripheral nerve function is lost • Reaction time decreases • Response time slows • Potential for altered balance, vertigo, and syncope increases • Postural hypotension becomes more common • Proprioception diminishes • Sensory input decreases • EEG alpha waves slow down
Sleep	• Amount of deep sleep decreases • Amount of REM sleep decreases	• Falling asleep becomes more difficult • Period of wakefulness increases
Visual System		

Function	Normal Age Changes	Clinical Manifestations
Eye structure	• Orbital fat is lost • Eyebrows and eyelashes turn grey or white • Elasticity of eyelid muscles decreases • Tear production decreases	• Eyes become sunken • Eyes become dry • Potential for ectropion and entropion increases • Potential for conjunctivitis increases
Cornea	• Corneal sensitivity decreases • Corneal reflex decreases • Arcus senilis becomes more common	• Potential for corneal abrasion is increased
Ciliary	• Aqueous humor secretion decreases • Ciliary muscle atrophies	• Ability of lens to accommodate declines • Presbyopia occurs • Peripheral vision decreases
Lens	• Lens becomes less elastic, more dense	• Lens becomes yellow and opaque • Ability to adapt to light and dark lessens • Tolerance of glare decreases • Incidence of cataracts increases • Night vision is impaired
Iris and pupil	• Pigment is lost • Pupil size decreases • Amount of vitreous gel debris increases	• Visual acuity decreases • Pupils appear constricted • Floaters are common
Auditory System		
Structure	• Hairs in external auditory canals of men increase • Ceruminal glands decrease in number	• Potential for conductive hearing loss increases • Cerumen is drier • Sound conduction decreases
Middle ear	• Middle-ear bone joints degenerate • Eardrum thickens	
Inner ear	• Vestibular structures decline • Hair cells are lost • Cochlea atrophies • Organ of Corti atrophies	• Sensitivity to high tones and perception of "s," "t," "f," and hard "g" sounds decrease • Understanding of speech decreases • Discrimination of background voice decreases • Equilibrium–balance deficits occur • Potential for tinnitus increases
Immune System	• Amount of secretory IgA declines • Thymus gland becomes involuted • Amount of lymphoid tissue decreases • Antibody production is impaired • Proliferative response of T and B cells decreases • Number of autoantibodies increases	• Potential for infection on mucosal surfaces increases • Cell-mediated immune response is impaired • Malignancy incidence increases • Response to acute infection is weakened • Recurrence of latent herpes zoster and tuberculosis is more likely • Susceptibility to autoimmune disease increases

AV, atrioventricular; *BP,* blood pressure; *bpm,* beats per minute; *BUN,* blood urea nitrogen; *EEG,* electroencephalographic; *HR,* heart rate; *IgA,* immunoglobulin A; PaO_2, arterial partial pressure of oxygen; *REM,* rapid eye movement; *ROM,* range of motion.

Older Populations at High Risk

Some subgroups within the older population, such as women, adults with cognitive challenges, and individuals from minority groups, are at a higher risk for developing certain conditions or for their conditions to be misdiagnosed. Some people belong to several of these subgroups, and their care requires skilled expertise in nursing assessment, interventions, and evaluations.

Older Women

Gender is an important factor that influences the natural history of diseases and determines management and treatment in situations in which gender roles and preferences could influence care-seeking behaviour and treatment. For example, female patients tend to be older and more likely to rely on children for support, whereas male patients are more likely to have a spouse as a caregiver (Gruneir, Forrester, Camacho, et al., 2013). Home care clients and residents in long-term care facilities are predominantly female, given contemporary differences in life expectancy and caregiving patterns. With dementia, the progression of disease is faster in women, even after age is controlled in analysis (Irvine, Laws, Gale, et al., 2012). Other differences include a higher risk for inappropriate medications to be prescribed to women (Gruneir, Forrester, Camacho, et al., 2013).

In addition to having a high number of chronic health conditions, older people face challenges such as reduced financial resources, lack of informal caregiving responsibilities, or both; these challenges have a significant effect on the health of older women. As a result, older women often experience disparities in treatment in comparison with men, including unequal access to quality health care (see Chapter 2). Nurses should act as advocates for women's equity in the health care system. Advocacy organizations such as the Canadian Women's Health Network can be helpful in this undertaking. Last but of importance, older women are more likely to be victims of family violence than are older men, in part because they usually live longer (Bennett & Kingston, 2013). Several resources, organizations, and programs are in place to raise awareness of, prevent, diagnose, and address the abuse of older people in Canada. The Registered Nurses' Association of Ontario (RNAO) has partnered with the CNA for the pan-Canadian Promoting Awareness of Elder Abuse in Long-

Term Care Homes (PEACE) initiative. Resources are listed at the end of this chapter.

Older Adults With Cognitive Impairments

The majority of older adults do not have any noticeable decline in mental abilities. There will be some normal age changes, such as a memory lapse or benign forgetfulness, which are significantly different from cognitive impairment. These normal age changes are often referred to as *age-associated memory impairment* (Table 7-3).

TABLE 7-3

AGE-RELATED DIFFERENCES IN ASSESSMENT
Effects of Aging on Cognitive Functioning

Function	Manifestations of Healthy Aging
Fluid intelligence (the ability to solve new problems or use logic in new situations)	Declines
Crystallized intelligence (the ability to use learned knowledge and experience)	Improves
Vocabulary and verbal reasoning	Improves
Spatial perception	Remains constant or improves
Synthesis of new information	Declines
Mental performance speed	Declines
Short-term recall memory	Declines
Long-term recall memory	Remains constant

An older adult who is forgetful can benefit from using memory aids, attempting recall in a calm and quiet environment, and actively engaging in memory improvement techniques. Memory aids include clocks, calendars, notes, marked pillboxes, safety alarms on stoves, and identity necklaces or bracelets. Memory improvement techniques include word association, mental imaging, and mnemonics.

Declining physical health is an important factor in cognitive impairment. Older people who experience sensory losses or cerebrovascular disease may show a decline in cognitive functioning. An appropriate cognitive assessment includes hearing and vision, functional ability, memory recall, orientation, use of judgement, and appropriateness of emotional state. Standard mental status examinations and behavioural descriptions provide data for determining cognitive status. Cognitive impairment is further discussed in Chapter 62.

Older Adults Living in Rural Settings

Between 19% and 30% of older Canadians live in rural areas (Strengthening Rural Canada Initiative, 2014), and some face barriers to remaining at home and staying active and engaged in their communities. Such barriers include a lack of or limited availability of support to enable older people to remain independent, as well as very limited housing and transportation options. In addition, older adults in rural and remote areas are frequently required to travel out of their communities for health services, which creates challenges (Spina & Menec, 2015). Some research has indicated that older adults living in rural areas present with more symptoms of ill health than do older adults living in urban areas (Bacsu, Jeffery, Johnson, et al., 2012). Furthermore, rural communities offer fewer health-promoting activities, such as structured exercise programs (Spina & Menec, 2015), and are often underserved by health care providers.

Nurses working with older adults in rural communities must clearly recognize the lifestyle values and practices of rural life (Figure 7-1) and acknowledge that lack of or difficulty with transportation is a possible barrier to providing service. Alternative service approaches such as computer-based Internet sources and chat rooms, videos, radio, community centres, and church social events should be used to promote healthful practices or to conduct health screening. The development of telehealth devices for monitoring people in their home environments has enhanced the ability to provide care to isolated individuals.

FIGURE 7-1 Transportation is a possible barrier to providing service to older adults in rural areas. Source: Budmir Jevtic/Shutterstock.com.

Older Adults Who Are Homeless

According to careful estimates, Canada might have 6 000 homeless older people; however, older adults account for only a little more than 1.7% of shelter users (Gaetz, Donaldson, Richter, et al., 2013), which may be explained by a much higher mortality rate among chronically homeless people (Hwang, Wilkins, Tjepkema, et al., 2009). Key factors associated with homelessness include (a) a low income, (b) reduced cognitive capacity, and (c) living alone. According to Statistics Canada, 3.6% of men and 7.6% of women 65 years of age and older are living below the low-income cut-off, the point at which a family is spending 70% or more of their income on necessities (food, clothing, and shelter; Statistics Canada, 2010b). Among older Canadians, single or widowed women are at higher risk for living in poverty. Such low-income older people may become homeless because of a lack of affordable housing.

When homeless, older individuals may have increased new health problems or experience an exacerbation of existing problems because most services provided to the homeless population are not designed to reach out to older adults. Long-term care placement is often an alternative to homelessness, especially when the individual is cognitively impaired and alone. A distinct fear of such institutionalization may explain why older homeless people do not use shelter- and meal-site services. Homelessness among older people requires more research related to risk factors as well as solutions.

Frail Older Adults

Frail older adults is a term used to identify older adults who, because of declining physical health and resources, are most vulnerable to poor outcomes. *Frailty* has been defined as the presence of three or more of the following: unplanned weight loss (≥10 lb [4.5 kg] in the past year), weakness, poor endurance and energy, slowness, and low activity (Clegg, Young, Iliffe, et al., 2013). Risk factors include disability, multiple chronic illnesses, and the presence of geriatric syndromes. Frailty is not related directly to age per se, although age is a risk factor. Hardiness or psychological strength may be a significant factor in preventing frailty among older adults.

Most frail older adults have difficulty coping with declining functional abilities and decreasing daily energy. When stressful life events (e.g., the death of a loved one) occur and daily strain (e.g., caring for an ill spouse) is present, the frail individual may have difficulties with the effects of

stress and may become ill. Common health problems of the frail older adult include mobility and strength limitations, sensory impairment, cognitive decline, and falls.

The frail older adult is at particular risk for malnutrition and problems with hydration (Clegg, Young, Iliffe, et al., 2013). Malnutrition and dehydration are related to sociopsychological factors such as living alone, depression, and low income. Physical factors such as loss of vision or hearing, declining cognitive status, inadequate dental care, physical fatigue, and limited mobility also add to the risks of malnutrition and dehydration. Because many frail older adults have therapeutic diets and multiple drug regimens, their nutritional state may be altered. It is important for the nurse to monitor the frail older adult for adequate calorie, protein, iron, calcium, vitamin D, and fluid intake.

Assessment tools that include a focus on physical, social, and environmental risk factors (Table 7-4) have been developed to monitor older patients for poor nutritional status. In addition, it is important to review the medications that an older adult takes because many medications affect appetite and can therefore affect nutritional status. Once an older adult's nutritional needs are identified, interventions can include home-delivered meals, dietary supplements, food stamps, dental referrals, congregate dining sites, home visits by registered dietitians, and vitamin supplements.

TABLE 7-4

NUTRITIONAL ASSESSMENT OF OLDER ADULTS

The acronym **SCALES** can remind the nurse to assess important nutritional indicators:
Sadness, or mood change
Cholesterol level: high
Albumin level: low
Loss or gain of weight
Eating problems
Shopping and food preparation problems

Older Adults With Chronic Illness

Daily living with chronic or persistent illness is a reality for many older adults. Although people of all ages have chronic health problems, illness is most common in older adults. It is estimated that 76% of older adults had one or more chronic condition in 2010 (Canadian Institute for Health Information, 2011). The most common conditions for older Canadians are high blood pressure (47%), arthritis (27%), and heart disease (19%;

Canadian Institute for Health Information, 2011). Other chronic persistent conditions such as diabetes, vision or hearing problems, and dementia also have a significant effect on health-related quality of life for older adults.

Chronic illness is composed of multiple health problems that have a protracted, unpredictable course. Diagnosis and the acute phase of a chronic persistent illness are often managed in an acute care setting, and all other phases of such an illness are usually managed at home. The management of a chronic illness can profoundly affect the lives and the self-concepts of the affected older person and the family. Although health status encompasses acute and chronic illness, it also includes an individual's level of daily functioning. Functional health includes activities of daily living (ADLs), such as bathing, dressing, eating, toileting, and transferring. Instrumental activities of daily living (IADLs), such as using a telephone, shopping, preparing food, housekeeping, doing laundry, arranging transportation, taking medications, and handling finances, are also included in a functional health assessment.

As age increases, functional health declines, and disability increases. Nurses caring for older adults need to advocate for appropriate, comprehensive assessment in which health and disease states are diagnosed accurately, as well as for the utilization of health-promotion strategies.

Treatment for chronic conditions can often cause new problems. As one disease is treated, another may be affected. For example, the use of a drug with anticholinergic properties, such as a tricyclic antidepressant (e.g., amitriptyline [Elavil]), may cause urinary retention. In older adults, disease symptoms are atypical, and sometimes manifestations of disease are asymptomatic. For example, the only symptom of cardiac disease may be fatigue. Pathological entities with similar symptoms are often confused. Negative consequences of chronic illness include physical suffering, loss, worry, grief, depression, functional impairment, and increased dependence (Lundman & Jansson, 2007). Daily living with chronic illness can be very difficult for older adults. The nurse must involve the patient in any decision making related to interventions, goals planning, and quality of life and well-being (Table 7-5).

TABLE 7-5

SUPPORTIVE INTERVENTIONS FOR OLDER ADULTS WITH CHRONIC ILLNESS

- Prevent social isolation.
- Control symptoms of the chronic illness.
- Adjust to changes in the course of the disease.
- Prevent and manage episodes of acute illness.
- Carry out prescribed therapies for the chronic illness.
- Use technology to enhance function, independence, and safety.

Socially Isolated Older Adults

As people age and social networks contract, they may become increasingly isolated and lonely. Although social isolation and loneliness are related factors, they are distinctly different concepts. Social isolation is defined as being separated from one's environment to the point of having few satisfying and rewarding relationships. Loneliness, conversely, is one's feeling of dissatisfaction with social contacts in terms of quantity or quality, or both (Holwerda, Deeg, Beekman, et al., 2014). Thus the feeling of loneliness can be present even if an older person is living with another person, with family, or in an institution. It is the quality of the social contacts that is critical for the maintenance of well-being and hardiness.

Both social isolation and loneliness have consistently been found to be associated with poorer physical and psychological health (Holwerda, Deeg, Beekman, et al., 2014). Although many social, personal, and health factors are involved in social isolation and loneliness, it is difficult to predict which older adults are most at risk for poor health. Older adults who are isolated and lonely should be closely monitored. Keeping these vulnerable older adults engaged in meaningful social relationships and activities is a significant health-promoting intervention, and nurses have an important role to play.

Culturally Competent Care

Older Adults

The term **ethnogeriatrics** is used to describe the specialty area of providing culturally competent care to older people who are identified with a particular ethnic group (Touhy, Jett, Boscart, et al., 2011; Figure 7-2). Canada is officially a multicultural society, and culturally diverse care is essential in order to provide for the needs of a very diverse group of older adults. Vast differences or heterogeneity are found among and within various ethnic groups in relation to health beliefs and practices, access to and utilization of health care, health risks, family dynamics and caregiving, decision-making processes and priorities, and responses to interventions and changes in health care policies (Huff, Kline, & Peterson, 2014). Nurses are challenged to provide culturally competent care in all types of settings and communities: home care settings, institutionalized settings, day programs, and acute and chronic health care facilities. Although it is unrealistic to expect a health care provider to be proficient in working with every category and subgroup of minority older people, it is possible to develop levels of awareness, skill, and sensitivity that can be applied to interactions with older people of ethnic minorities and their families. The nurse must assess each older adult's ethnic orientation. Several tools or instruments can assist nurses in eliciting health care beliefs and help identify a patient's perceptions of alternative beliefs (see the Resources at the end of this chapter; Kleinman, Isenberg, & Good, 1978; Touhy, Jett, Boscart, et al., 2011). Culturally competent care is discussed in Chapter 2.

FIGURE 7-2 Culture and heritage can be important facets of many older adults' lives. Source: W8 Photography/Shutterstock.com.

Social Support and the Older Adult

Social support is essential for all older adults to maintain their level of well-being. Social support occurs at three levels. Family and kinship relations are most often the first level of providers of social support. Second, a semiformal level of support is found in clubs, places of worship, neighbourhoods, and senior citizen centres. Third, older adults may be linked to a formal system of social welfare agencies, health facilities, and government support. In general, the nurse is part of the formal support system.

Caregivers

A caregiver is someone who provides supervision and direct care and coordinates services. In Canada, 8.1 million caregivers provide an estimated 70% to 80% of all home care, thereby supporting the public system for an estimated $24 to $31 billion (Sinha, 2013). Caregiving includes many tasks but focuses mostly on assisting older patients with ADLs and IADLs, providing emotional and social support, and managing health care.

Caregivers often experience their caregiving as rewarding, but it can also be a physically and emotionally demanding task, even leading to increased medical illnesses and a greater risk of mortality for the caregiver (Sinha, 2012; Table 7-6).

TABLE 7-6

CAREGIVER CHALLENGES

• Lack of respite or relief from caregiving • Conflict in the family unit related to decisions about caregiving • Lack of understanding of the time and energy needed for caregiving • Inability to meet personal self-care needs, such as socialization and rest • Inadequate information about specific tasks of caregiving • Financial depletion of resources as a result of a caregiver's inability to work and the increased cost of care

Some caregivers may develop a sense of being overwhelmed and have feelings of inadequacy, powerlessness, and depression (Kim, Chang, Rose, et al., 2011). The stress of caregiving may result in emotional problems such as depression, anger, and resentment. The burden of caregiving can be isolating, inasmuch as it limits social, emotional, and interactional opportunities. Time commitments, fatigue, and at times, socially

inappropriate behaviours of the dependent older adult contribute to social isolation. The socially isolated caregiver must be identified, and plans should be designed to meet his or her needs for social support and interaction.

Many family members involved in direct caregiving activities also identify rewards associated with this role. Positive aspects of caregiving include knowing that a loved one is receiving good care (often in a home environment), learning and mastering new tasks, and finding opportunities for intimacy. At the same time, the tasks involved in caregiving often provide opportunities for family members to learn more about one another and strengthen their relationships.

The nurse should consider the caregiver as a patient and plan interventions to reduce caregiver strain if necessary. The nurse can communicate a sense of empathy to the caregiver while allowing discussion about the burdens and joys of caregiving. The caregiver can be taught about age-related changes and diseases and specific caregiving techniques. The nurse can also assist the caregiver in seeking help from the formal social support system regarding matters such as respite care, housing, health coverage, and finances. Finally, the nurse should monitor the caregiver for indications of declining health, emotional distress, and caregiver role strain.

Elder Mistreatment and Abuse

Elder abuse can be defined as "any action by someone in a relationship of trust that results in harm or distress to an older person. Neglect is a lack of action by that person in a relationship of trust with the same result" (Public Health Agency of Canada [PHAC], 2012). The term **elder mistreatment** is used to describe acts of commission (elder abuse) or omission (**elder neglect**) that harm or threaten to harm an older adult's health or welfare. Elder abuse may occur in private homes or in any type of care facilities. *Institutional abuse* refers to abuse of people living in long-term care homes and residential care facilities. An older person may experience more than one form of abuse (Table 7-7).

TABLE 7-7

TYPES OF ELDER MISTREATMENT

Types	Characteristics	Manifestations
Physical abuse	Slapping; restraining; incorrect positioning; oversedation	Bruises, bilateral injuries, repeated injuries in various stages of healing; use of several emergency departments
Physical neglect	Withholding of food, water, medications, clothing, hygiene; failure to provide physical aids such as dentures, eyeglasses, hearing aid; failure to ensure safety	Pressure injuries; loss of body weight; laboratory values showing dehydration (e.g., HCT; serum sodium) and malnutrition (serum protein); poor personal hygiene
Psychological or emotional abuse	Berating; harassment; intimidation, threats of punishment or deprivation; treating older person like a child; isolation	Depression, withdrawn behaviour; agitation; ambivalent attitude toward caregiver
Psychological or emotional neglect	Failure to provide social stimulation; leaving alone for long periods; failure to provide companionship	Depression, withdrawn behaviour; agitation; ambivalent attitude toward caregiver
Sexual abuse	Touching inappropriately; forcing sexual contact	Unexplained vaginal or anal bleeding; bruises; unexplained STIs or genital infections
Financial abuse	Denying access to personal resources; stealing money or possessions; coercing to sign contracts or durable power of attorney; making changes in will or trust	Living situation is below level of personal resources; sudden change in personal finances or transfer of assets
Violation of personal rights	Denying right to privacy or right to make decisions regarding health care or living environment; forcible eviction	Sudden inexplicable changes in living situation; confusion

HCT, hematocrit; *STIs*, sexually transmitted infections.

Overall, elder abuse is an underreported problem and has been difficult to quantify. According to police reports, in 2010 nearly 2 800 Canadians older than 65 were victims of family violence, and grown children were most often the perpetrators of violence against older people (Statistics Canada, 2010c). Victims often do not report it because of isolation; impaired cognitive or physical function; feelings of shame, embarrassment, guilt, or self-blame; fear of reprisal; pressure from family members; fear of losing the home and independence; and cultural norms. Health care providers may fail to report it because of lack of confidence in identifying or reporting victims; perceived inability to successfully intervene; and a desire to avoid responsibility for further action.

The primary risk factors for elder abuse are the characteristics of the abuser. Abusers tend to be adult children who are dependent on the parent for housing and financial means; have a history of violence or antisocial behaviour; are unemployed; and are disabled because of substance abuse or mental illness, or both (Department of Justice Canada, 2009). Victim characteristics, such as frailty, dementia, immobility, and social isolation also add to the risk of mistreatment. These characteristics

increase the likelihood that an older person is unable to seek help or defend herself or himself.

The nursing approach to a suspected victim of elder abuse should begin with a carefully documented history and a thorough examination for mistreatment. Nurses should assess the individual for the presence of dehydration, malnutrition, pressure injuries, poor personal hygiene, and lack of compliance with the medical regimen. Of importance is that failure to follow the care plan, unauthorized use of restraints, and use of medication or isolation as punishment are also considered forms of abuse.

Key assessment findings include (a) explanations for findings (e.g., injuries) that are not consistent with objective data and (b) contradictory explanations from the patient and the caregiver. The nurse should follow the facility or employer intervention protocol for elder abuse. A screening tool for abuse by a caregiver is available as a pocket tool from the National Initiative for the Care of the Elderly (see the Resources at the end of this chapter).

In institutionalized settings, nurses should be alert to patterns of recurrent infections, poor hygiene, lack of interest in activities or eating, behavioural changes, new incontinence, sleep problems, and complaints about staff. Specific nursing interventions to reduce the risk of elder abuse include close management of the patient's plan of care and regular review of the use of restraints and psychotropic medications in addition to the interventions listed in Table 7-8.

TABLE 7-8
NURSING MANAGEMENT OF ELDER MISTREATMENT

- It is mandatory to make reports to the appropriate provincial or territorial body about the suspicion of abuse or neglect.
- The nurse should screen for possible elder abuse, including domestic violence.
- A thorough history should be documented and a head-to-toe assessment conducted. It is important to document the findings, including any statements made by the patient or an accompanying adult.
- If an older adult appears to be in immediate danger, a safety plan should be developed and implemented in collaboration with the interdisciplinary team involved in the person's care.
- The nurse should identify, collect, and preserve physical evidence (e.g., dirty or bloody clothing, dressings, or sheets).
- After obtaining consent, photographs should be taken to document physical findings of suspected abuse or neglect. If possible and appropriate, this should be done before the alleged victim is treated or bathed.
- If abuse is suspected, the findings should be reported to the appropriate provincial agency or law enforcement, or both, as mandated by local laws.
- Social work, forensic nursing, and other consultations should be initiated as appropriate.

When managing elder abuse, the nurse must be familiar with both federal and provincial laws governing reporting procedures and patient

privacy. Information on mandatory reporting can be found on the Canadian Network for Prevention of Elder Abuse website.

Universal Health Care

The older population requires specific consideration within Canada's health care system. Because of the growth in the older population and the associated increase in chronic health conditions, the health care needs of this population sector are greater than in other population segments.

The Canadian health care system is based on the *Canada Health Act* (1984) and is publicly funded. Health care is administered and delivered by the provinces and territories. The system is referred to by Canadians as "Medicare" and provides for universal comprehensive coverage for "medically necessary" services, including primary health care, care in hospitals, and surgical–dental services. Each province and territory determines which services are publicly funded, and so there is significant variation among areas for "not urgent" services such as the provision of home care, long-term care, medications outside of hospital, physiotherapy, optometry services, and other services. As a result of the focus on Canada's health care reform, there has been increased advocacy for more realistic provision of health care for older adults, including an emphasis on health promotion and expanded community care (Health Canada, 2016; Hollander, Chappell, Prince, et al., 2007).

Care Alternatives for Older Adults

Most older adults prefer to continue living at home, but they may have to move to a more restrictive environment at a time of crisis. Several living arrangements and care options for older people are described as follows.

Independent Living Options

Many older adults stay in their place of residence and do not move to a different home or geographic location as they age. The community becomes important to older adults as an environment that is safe and that supports social contacts. Older adults needs privacy and companionship, as well as a sense of belonging. The community should be accessible. Older adults may need housing assistance in the form of property tax relief and assistance with home repair and the cost of utilities (Figure 7-3). A variety of subsidized, low-income housing arrangements are available for older adults in many areas.

FIGURE 7-3 Home maintenance is part of an older adult's independent lifestyle. Source: Halfpoint/Shutterstock.com.

For an older adult who chooses to remain in the home as functional abilities decline, some home adaptations and modifications can be made to accommodate for some functional decline, including walker and wheelchair accessibility, increased lighting, and safety devices in bathrooms and kitchens. The *Safe Living Guide—A Guide to Home Safety for*

Seniors (see the Resources at the end of this chapter) includes strategies for home adaptations that improve safety and accessibility.

Adult lifestyle communities or retirement communities may be an option for some older adults. These communities are age-segregated, self-contained developments and provide social activities, security, and recreational facilities. Some retirement communities offer expanded health care and social support services. An entrance fee and monthly fees for continuing care are charged. Chapter 6 discusses community-based care settings.

Assisted-living facilities (ALFs) are residential care facilities that provide housing and personal care. Because over half of community-based older adults require assistance with ADLs or IADLs, this is the most rapidly developing area of care. According to a Canadian Mortgage and Housing Corporation (2016) survey, up to 9.1% of Canadians aged 75 years and older lived in 2 812 ALFs in 2016. Services vary per facility. Nurses working in this area are challenged by questions related to regulations, use of the services of unregulated care providers, assessment to ensure safe "fit of resident to facility," and shared resident decision making. The Canadian Accreditation Council is developing standards for use in accreditation of ALFs (see the Resources at the end of this chapter).

Community-Based Care for Older Adults

Many older adults with special care needs can be aided by services in the community, such as adult day care programs or home health care.

Adult Day Care Programs.

Adult day care programs provide daily supervision, social activities, management of chronic disease, and ADL assistance for older adults who are cognitively impaired and for people who have problems with ADLs. The services offered in the adult day care programs are based on patient needs. Restorative programs offer health monitoring, therapeutic activities, one-on-one ADL training, individualized care planning, and personal care services. Programs designed for people with cognitive impairments offer therapeutic recreation, support for family, family counselling, and social involvement. Adult day care programs provide relief to the caregiver, allow continued employment for the caregiver, and delay institutionalization for the patient. Centres are regulated and standards are set by the province. Costs are not covered by health insurance but are tax

deductible as dependent care. The nurse's role consists of knowing the available adult day care services and assessing the needs of the patient.

Home Health Care.

Home health care can be a cost-effective care alternative for an older person who is homebound but has health needs that are intermittent or acute. In 2011, one in every six older people received home care services; and up to 2.2 million people across this country—many of them vulnerable older people—relied on home care services to enable them to stay safely in their homes (Accreditation Canada & Canadian Home Care Association, 2015). Home health care services offer skilled nursing care and care by other regulated health care providers, nonregulated workers, volunteers, friends, and family members, all to help an older adult remain in the community. Emphasis of the care and services is often on the management of chronic disease, supporting ADLs, and promoting well-being. Home health care is discussed in more detail in Chapter 6.

Long-Term Care Facilities

Long-term care (LTC) facilities are a placement alternative for adults who can no longer live alone, who need continuous supervision, who have three or more disabilities involving ADLs, or who are frail. Three main factors precipitate placement in an LTC facility: (a) rapid deterioration of the patient's condition, (b) the caregiver's inability to continue care, and (c) an alteration in or loss of family support system. Changes in orientation (e.g., increased confusion), incontinence, or a major health event (e.g., stroke, fall) can accelerate the need for placement in LTC.

Since 2005, LTC facilities have been caring for residents with more complex health care needs (Hirdes, Mitchell, Maxwell, et al., 2011). Not only has the prevalence of chronic diseases such as diabetes, heart failure, and arthritis increased, but also conditions such as frailty and dementia necessitate high-quality care by a competent and interprofessional workforce. Nurses are instrumental in the care planning and chronic disease management to address an older person's health care needs while balancing the person's quality of life and wishes. Many LTC facilities provide an environment that truly represents the best of caring and quality of life and an extraordinary commitment and dedication of staff. Several initiatives are under way to shift from an institutional model to LTC facilities as places that nurture quality of life and well-being for older people (Figure 7-4).

FIGURE 7-4 Social interaction and acceptance are important for older adults. Source: belushi/Shutterstock.com.

Legal and Ethical Issues

Legal assistance is an issue for many older adults concerned about advance directives, estate planning, taxation issues, and appeals for denied services. In Canada, legal aid is available for all citizens (Figure 7-5). There is some variation between provinces and territories about legal matters affecting capacity, advanced directives, and consent.

FIGURE 7-5 Some residential facilities for older adults post notices announcing when free legal help is available. Source: EdBockStock/Shutterstock.com.

Mental capacity is a person's ability to make decisions. It is a legal construct, not a clinical condition (Touhy, Jett, Boscart, et al., 2011). To be deemed capable of making a decision, the person must *understand* information that is relevant to making a decision, *evaluate* data, and *appreciate* the consequences of the decision or of not making a decision (Wahl, 2008). People are presumed to have capacity unless there is clear evidence to the contrary and the person has been legally deemed incapable. Capacity can improve, decrease, or fluctuate (Wahl, 2008).

A *power of attorney* is a legal document and legal device in which one person designates another person (e.g., family member, friend) to act on his or her behalf.

There are primarily two types of advance directives: instruction directives and those in which a substitute decision maker or proxy is

named (CNA, 1998). An instruction directive (or *living will*) specifies what kinds of interventions are desirable for different health situations. In a proxy directive, the patient specifies who is to make health care decisions if he or she becomes unable to make his or her wishes known. Often, these two terms are used interchangeably; however, they serve different purposes (CNA, 1998). (Advance directives are discussed in Chapter 13.)

The nurse who works with older adults will encounter areas of ethical concern that influence practice and care. Issues may include the need to evaluate the patient's ability to make decisions, resuscitation, treatment of infections, issues of nutrition and hydration, and transfer to more intensive treatment units. These situations are often complex and emotionally charged. The nurse can assist the patient, the family, and other health care providers by acknowledging when an ethical dilemma is present, by keeping current on the ethical implications of biotechnology, and by advocating for an institutional ethics committee to help in the decision-making process. For more information, see the "Resources" section at the end of the chapter.

Nursing Management Older Adults

Nursing Assessment

The assessment of an older adult provides the database and baseline information for the rest of the nursing process; however, it is a complex undertaking. First, older people may face any health problem with fear or anxiety, and the problem may present in an atypical manner. In addition, health care providers may be perceived as helpful, but institutions may be perceived as negative, potentially harmful places. The nurse beginning an assessment needs to establish a nurse–patient relationship by communicating a sense of concern and care by use of direct and honest statements, appropriate eye contact, and direct touch when appropriate. When beginning the assessment process, the nurse should attend to primary needs first: for example, ensure that the patient is free of pain, is adequately hydrated, is wearing appropriate clothing, and does not need to go to the bathroom. All assistive devices such as glasses and hearing aids should be in place. The interview should be short so that the patient does not become fatigued. The nurse should allow adequate time to give information, as well as to respond to any questions. The medical history may be lengthy, and the nurse must determine what normal age changes are and which information is relevant. If possible, medical records and any current medications should be reviewed.

To truly assess an older adult, a comprehensive geriatric assessment is required (Ramani, Furmedge, & Reddy, 2014). The focus of a comprehensive geriatric assessment is to determine appropriate interventions to maintain and enhance the functional and cognitive abilities of the patient. This assessment is interdisciplinary and, at a minimum, includes the medical history, the physical examination, a functional abilities assessment, a cognitive assessment, and an assessment of social and financial resources. The interdisciplinary team may represent many disciplines, but at minimum it should include the nurse, the physician, and the social worker. After the assessment is complete, the interdisciplinary team meets with the patient and family to present the team's findings and recommendations.

Nursing assessment is a key component of the comprehensive geriatric assessment. Elements in a comprehensive nursing assessment include a history, documented in a functional health pattern format (see Chapter 3); physical assessment; cognitive assessment; assessment of ADLs and

IADLs; and a social–environmental assessment. Evaluation of cognitive status is particularly important for older adults because results of this evaluation often determine a patient's potential for independent living. Evaluation of the results of a comprehensive nursing assessment helps determine the services needed. A good match between needs and services should be the goal of the assessment. The nurse also collects data regarding community resources that are needed to assist the patient and her or his family to maintain maximal functioning.

The comprehensive nursing assessment should be based on instruments that are reliable, valid, and specific to older adults. Several standardized assessment tools for gerontology are available and can be used in accordance with the purpose of the assessment and the status of the patient. However, difficulties often arise in the interpretation of the results of findings because of age-related changes and parameters that are not well defined for older adults. The nurse is in an important position to recognize and correct inaccurate interpretation of laboratory test results.

Nursing Diagnoses

With few exceptions, the same nursing diagnoses apply to an older adult as to a younger individual. However, the causes and defining characteristics are related to age and are unique to older adults. Table 7-9 lists nursing diagnoses that are seen in older adults as a result of age-related changes. The identification and management of nursing diagnoses result in higher quality care and improved patient function.

TABLE 7-9
NURSING DIAGNOSES

Associated With Age-Related Changes	
Cardiovascular System	**Nervous System**
• Activity intolerance • Decreased cardiac output • Fatigue	• Impaired memory • Risk for acute confusion • Hyperthermia • Hypothermia
Reproductive System • Disturbed body image • Ineffective sexuality pattern • Sexual dysfunction	**Urinary System** • Deficient fluid volume • Impaired urinary elimination
Respiratory System • Impaired gas exchange • Ineffective airway clearance • Ineffective breathing pattern • Risk for aspiration • Risk for infection	**Senses** • Disturbed body image • Impaired verbal communication • Social isolation
Gastro-Intestinal System • Constipation • Imbalanced nutrition: less than body requirements • Impaired oral mucous membrane • Obesity	**Musculo-Skeletal System** • Impaired physical mobility • Chronic pain • Risk for injury • Self-care deficits • Sedentary lifestyle
Integumentary System • Impaired skin integrity	**Immune System** • Risk for infection

Planning

When setting goals with an older adult, the nurse must identify the patient's strengths and abilities. Caregivers, if appropriate, should be included in goal development. Personal characteristics such as hardiness, persistence, and the ability to learn contribute to the setting of individualized goals. Priority goals for the patient may be focused on well-being, such as gaining a sense of control, feeling safe, and reducing stress.

Nursing Implementation

When carrying out a plan of action, the nurse may have to modify the approach and techniques used according to the physical and cognitive status of a particular older patient. Sensory changes, such as auditory and visual deficits, may interfere with communication. Small body size, common among frail older adults, may necessitate the use of pediatric equipment (e.g., blood pressure cuff). Bone and joint changes often necessitate assistance with transfers, altered positioning, and use of gait belts and lift devices. An older adult with declining energy reserves may require additional time to complete tasks. A slower pace of interaction, more limited scheduling of interventions and activities, and the

availability of a bedside commode or other adaptive equipment may be necessary.

Cognitive impairment, if present, mandates careful explanations and a calm approach to avoid producing anxiety in the patient. Depression can result in apathy, malnutrition, and a decline in mobility. Several guidelines and interventions are available to enhance nursing care for people with cognitive impairment (Touhy, Jett, Boscart, et al., 2011).

Health Promotion.

Health promotion and prevention of health problems in older adults is one of the most important areas for nurses and is focused mainly on three areas: reduction in diseases, increased participation in health promotion activities, and targeted services that reduce health hazards. The Division of Aging and Seniors of the PHAC provides federal leadership on health issues affecting older adults, including fall prevention, emergency preparedness, and age-friendly communities (PHAC, 2017).

Within gerontology, nurses need to place a high value on health promotion and positive health behaviours. Several programs have been successfully developed for chronic health condition screening, smoking cessation, geriatric foot care, vision and hearing screening, stress reduction, exercise programs, drug usage, crime prevention, elder mistreatment, delirium prevention and treatment and home hazards assessment (RNAO, 2017). The nurse can carry out and teach older adults about the need for specific preventive services. The nurse interested in health promotion for older adults can reference Health Canada's “Healthy Living” web page (see the Resources at the end of this chapter).

Health promotion and prevention can be included in nursing interventions at any location where nurses and older adults interact and at any level of care delivery. The nurse can use health promotion activities to strengthen patients' self-care, increase their personal responsibility for their own health, and increase independent functioning that will enhance their well-being (Figure 7-6).

FIGURE 7-6 Strength training is an example of a health promotion activity for older adults. Source: belushi/Shutterstock.com.

Teaching Older Adults.

Throughout the continuum of care, nurses are involved in instructing and teaching older adults specific self-care practices to enhance health and well-being and modify disease processes (Table 7-10). Individual patient teaching is discussed in Chapter 4.

TABLE 7-10

PATIENT & CAREGIVER TEACHING GUIDE
Older Adults

Challenges for Older Adults	Specific Strategies
• Time needed to learn is increased. • New learning must relate to the patient's actual experience. • Anxiety and distractions decrease learning. • Lack of willingness to take risks and cautiousness decrease motivation to learn. • Sensory–perceptual deficits and cognitive decline necessitate modifications in teaching techniques.	• Present material at a slower rate. • Use visual aids when possible. • Use peer educators when appropriate. • Encourage participation of a spouse or family member. • Use simple phrases or sentences, and provide for repetition. • Support the belief that change in behaviour is worth the effort. • Emphasize that a person is never too old to learn new things.

Source: Adapted from Rankin, S. H., Stallings, K. D., & London, F. (2004). *Patient education: Principles and practice* (5th ed.). Philadelphia: Lippincott.

Acute Care Settings.

When an emergency arises and a person cannot be cared for at home or in a residential care environment, admittance to an acute care hospital might be necessary. Some conditions that might necessitate hospitalization include exacerbations of chronic conditions, stroke, fluid and electrolyte imbalances, pneumonia, and trauma caused by falls. Unfortunately, the complexity of the acute situation often results in the loss of the whole-person perspective and focuses the care only on the diseased part. Nurses' integrated approach and emphasis on individualized care are primordial to restoring an older adult's health and well-being within this setting.

In addition, an acute care stay often results in negative consequences for older patients, including functional decline and iatrogenic events, such as falls, pressure injuries, and delirium, (Fox, Persaud, Maimets, et al., 2012). To prevent any of these complications, care of such patients requires an interdisciplinary approach, including very succinct nursing components (Table 7-11). Involvement of the patient and the family is essential in supporting the individualized perspective and creating a support network for when the patient is discharged.

TABLE 7-11

CARE OF THE HOSPITALIZED OLDER ADULT

- Identify patients at risk for iatrogenic effects of hospitalization.
- Plan and communicate discharge goals and assess needs as soon as a person is admitted.
- Involve interdisciplinary teams and providers who focus on the special needs of older adults.
- Conduct a comprehensive geriatric assessment, and be aware of the complexity and interplay of several conditions.
- Involve appropriate community-based services (see Chapter 6).

Geriatric Rehabilitation.

Geriatric rehabilitation interventions are focused on adapting to a new situation or recovering from trauma. Collaborative and interdisciplinary teams focus on building up functional reserve and emotional wellness, with the use of appropriate assistive equipment and supportive personal care, and creating a supportive network in which an older adult can live as independently as possible. The patient can receive rehabilitative assistance through inpatient rehabilitation (limited days are covered), day programs, or home care programs (Figure 7-7).

FIGURE 7-7 The nurse assists an older person in a geriatric rehabilitation facility. Source: GWImages/Shutterstock.com.

Rehabilitation of older adults is influenced by several factors. First, older adults show greater initial variability in functional capacity than do adults at any other age. Pre-existing factors associated with reaction time, visual acuity, fine motor ability, physical strength, cognitive function, and motivation affect the rehabilitation potential of older adults.

Within the interdisciplinary team, nurses assess and develop interventions for existing chronic illnesses; fears and anxieties specific to falling; fatigue; sensory–perceptual deficits; malnutrition; and social and financial challenges. Many older adults lose functional ability in the acute care setting because of inactivity and immobility. This deconditioning can occur as a result of unstable acute medical conditions or environmental barriers that limit mobility. Older adults can improve flexibility, strength, and aerobic capacity even into very old age. The interdisciplinary team develops passive and active range-of-motion exercises to prevent deconditioning and subsequent functional decline.

Last, the goal of geriatric rehabilitation is to strive for maximal function and physical and cognitive capabilities with regard to the individual's current health status. For example, a woman with a history of osteoporosis receives a falls-risk appraisal and specific exercises to build stability and balance. Older adult patients with diabetes receive a geriatric foot assessment and appropriate follow-up care.

Assistive Devices.

Using appropriate assistive devices such as dentures, glasses, hearing aids, walkers, wheelchairs, adaptive utensils, elevated toilet seats, and skin

protective devices can greatly improve independency for older adults. The need for and use of these devices are assessed by the interdisciplinary team, and findings are included in the patient's care plan. Electronic monitoring equipment can be used to monitor heart rhythms, blood pressure, and potential falls, as well as to locate the wandering patient in the home or LTC facility. Computerized assistive devices can be used to help patients with speech difficulties following stroke, and pocket-sized devices can serve as memory aids.

Safety.

Environmental safety is crucial in the maintenance of health and independence by older adults. With normal sensory age changes, slowed reaction time, decreased thermal and pain sensitivity, changes in gait and balance, and medication effects, older adults are prone to accidents. Most accidents, such as trips and falls, occur in or around the home. Older adults' impaired thermoregulating system can cause hypothermia and heat prostration (hyperthermia).

The nurse and the care team can provide valuable counsel regarding environmental safety and changes. Measures such as enhanced lighting, coloured step strips, tub and toilet grab bars, and stairway handrails can be effective in “safety-proofing” the living quarters of an older adult. The nurse can also advocate for home fire and security alarms. Uncluttered floor space, railings, increased lighting and night lights, and clearly marked stair edges are some of the easiest and most practical adaptations.

In addition, an older adult who moves to a different location needs a thorough orientation to the environment. The nurse should repeatedly reassure the patient that he or she is safe and attempt to answer all questions. The unit should foster orientation to time and place by displaying large-print clocks, avoiding complex or visually confusing wall designs, clearly designating doors, and using simple bed and nurse-call systems. Beds should be close to the floor to prevent serious injury from falls. Lighting should be adequate while avoiding glare. Environments that provide consistent caregivers and an established daily routine assist older adults.

Medication Use.

Medication use in older adults necessitates thorough and regular assessment and care planning. Twenty-seven percent of older patients reported taking five or more medications on a regular basis (Reason, Terner, Moses McKeag, et al., 2012). The frequency of adverse drug

reactions increases as the number of prescribed drugs increases, and as a result, hospital admissions of older adults are often for drug reactions.

Age-related changes alter the pharmacodynamics and pharmacokinetics of drugs. Drug–drug, drug–food, and drug–disease interactions all influence the absorption, distribution, metabolism, and excretion of drugs. Figure 7-8 illustrates the effects of aging on drug metabolism. The most dramatic changes with aging are related to drug metabolism and clearance. Overall, by age 75 to 80, there is a 50% decline in the renal clearance of drugs. Hepatic blood flow decreases markedly with aging, and the enzymes largely responsible for drug metabolism are decreased as well. Thus the drug half-life is increased in older patients as compared with one who is younger (Jett, 2016).

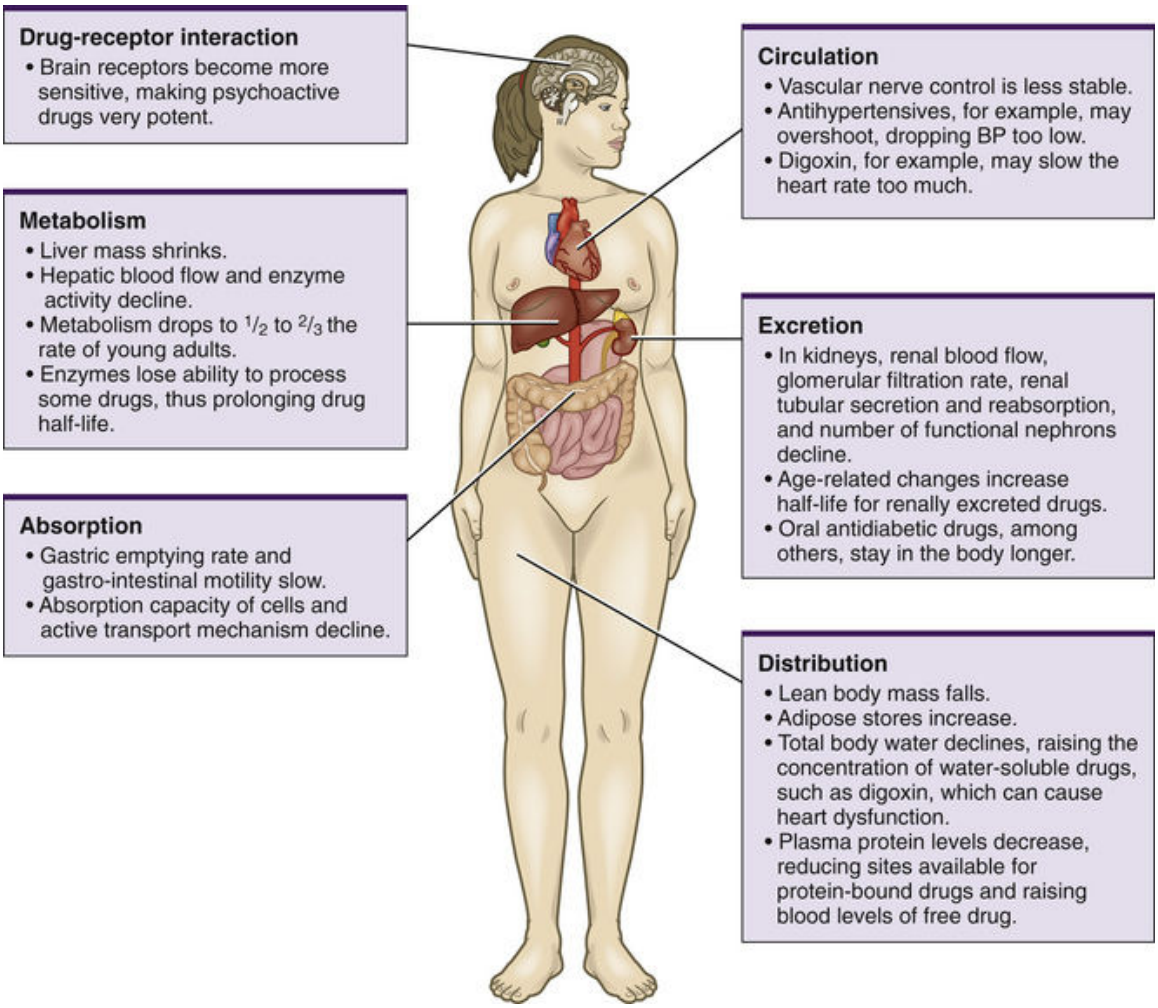

FIGURE 7-8 The effects of aging on drug metabolism. Source: Redrawn from Benzon, J. (1991). Approaching drug regimens with a therapeutic dose of suspicion. *Geriatric Nursing, 12*(4), p. 1813.

In addition to changes in the metabolism of drugs, older adults may have medication-related difficulty resulting from malnutrition and dehydration, cognitive decline, altered sensory perceptions, limited hand mobility, and the high cost of many prescriptions. Common reasons for drug errors made by older adults are listed in Table 7-12. **Polypharmacy** (the use of multiple medications by a patient who has more than one health problem), overdosage, or forgetting to take medications are recognized as major risk factors for adverse effects in older adults (Reason, Terner, Moses McKeag, et al., 2012).

TABLE 7-12
COMMON CAUSES OF MEDICATION ERRORS BY OLDER ADULTS

- Poor eyesight
- Forgetting to take drugs
- Use of nonprescription (over-the-counter) drugs
- Use of medications prescribed for someone else
- Failure to understand instructions or the importance of drug treatment
- Refusal to take medication because of undesirable adverse effects

To accurately assess drug use and knowledge, many nurses ask their older adult patients to bring all medications to the health care appointment (including over-the-counter medications, prescriptions, herbal remedies, and nutritional preparations) that they take regularly or occasionally. The nurse and pharmacist can then accurately assess all medications that the patient is taking, including drugs that the patient may have overlooked or thought unimportant to include. Some medications can be tapered or discontinued, especially those medications that may be causing harm or are no longer providing benefit. Specific guidelines for deprescribing of proton pump inhibitors, benzodiazepines, and antipsychotics in older adults have been developed and can be found at the website of the Ontario Pharmacy Evidence Network (see the Resources at the end of this chapter).

Additional nursing interventions to assist older adults in following a safe medication routine are listed in Table 7-13.

TABLE 7-13
DRUG THERAPY
Medication Use by Older Adults

1. Conduct a medication reconciliation review with the physician and the pharmacist.
2. Emphasize medications that are essential.
3. Discuss use of medication that is not essential or counterproductive.
4. Screen use of medications—including over-the-counter drugs, herbaceuticals, eyedrops and eardrops, antihistamines, and cough syrups—by using a standard assessment tool.
5. Assess medication interactions.
6. Assess patient's alcohol use.
7. Encourage the use of written or other medication-reminder systems.
8. Monitor drug dosage; normally, the dosage should be less than that for a younger person.
9. Encourage the patient to use one pharmacy.
10. Work with health care providers and pharmacists to establish routine drug profiles on all older adult patients.
11. Advocate (with drug companies) for low-income prescription support services and generic substitutions.
12. Assess financial status and discuss which medications are essential to buy for older adult patients.

Several medications are considered inappropriate or dangerous for older adults and are identified on the Beers list (American Geriatrics Society 2015 Beers Criteria Update Expert Panel, 2015). This list has been

recommended as a "best practice" by several Canadian regulating and professional organizations (see the Resources at the end of this chapter for the web link.)

Depression.

Many older people have experienced multiple, simultaneous stressors, such as loss of loved ones, dealing with chronic illness, financial stress, and social isolation. For some older adults, the accumulation of these stressors can result in a mental health issue. The prevalence of mental illness is the same among older adults as among the general population (3%–10%), except for dementia and delirium, which is more prevalent among older adults (Inouye, Westendorp, & Saczynski, 2013). Rates of depressive symptoms in institutionalized older adults are higher than those in the community (González-Colaço Harmand, Meillon, Rullier, et al., 2014). Unfortunately, depression is an underrecognized problem for many older adults.

Depression can exacerbate medical conditions by affecting nutritional intake, mobility, or drug regimens. An older adult who is at high risk for or exhibits depressive symptoms should be encouraged to seek treatment. Because many patients feel unworthy of special attention and may withdraw and become isolated, the nurse may have to enlist the support of the family in helping the patient seek treatment. Nursing assessment consists of observation of appearance and behaviour and examination of cognitive function, functional abilities, anxiety, adjustment reactions, depression, substance abuse, and suicidal risk. A comprehensive guide to assessment and treatment of depression in older adults is available at the website of the Hartford Institute for Geriatric Nursing (see the Resources at the end of the chapter).

Specific interventions include nonpharmacological approaches and, if needed, pharmacological treatment. Depression is often reversible with prompt and appropriate treatment. Older patients experience improvement with appropriate medication, psychotherapy (Krishna, Jauhari, Lepping, et al., 2011), or psychosocial interventions (Kiosses, Leon, & Areán, 2011), or a combination of these.

Sleep.

Adequacy of sleep is often a concern for older adults because of altered sleep patterns. Older people experience a marked decrease in deep sleep and are easily aroused. In individuals older than 75, the percentage of sleep time spent in the rapid eye movement (REM) stage decreases. In

addition, older adults have difficulty maintaining prolonged sleep. Although the demand for sleep decreases with age, older adults may be disturbed by insomnia and complain that they spend more time in bed but still feel tired. Many older people prefer to spread sleep periods throughout 24 hours with short naps that, combined, provide adequate rest. Other factors that contribute to sleep difficulties include medical problems, such as sleep apnea and restless legs syndrome, as well as effects of medications (e.g., furosemide [Lasix]). In many cases, a later bedtime promotes a better night's sleep and a feeling of being refreshed on awakening.

Behavioural Management.

Patients with cognitive impairment often are confused and anxious during specific care situations (e.g., while showering) or when left alone. These people might respond with certain behaviours, such as wandering, trying to resist care, or pushing away the care provider. In addressing these responsive behaviours, it is important for the nurses to understand that the person with cognitive impairment is responding to a "perceived threat." Ignoring this behaviour and continuing the care task will only cause the person to become more anxious or frightened and result in an exacerbation of this responsive behaviour. In caring for people with these behaviours, nurses need to understand *why* they respond in such a way, and the nurse should intervene with competent and compassionate person-centred care.

The nurse should check for changes in vital signs and urinary and bowel patterns that could account for behavioural problems. It is important to use a relational approach with a focus on empathy and nurturing and to keep care assignments consistent. When a patient is agitated by the environment, either the patient or the stimulus should be moved. Most responsive behaviours can be redirected with activities such as holding a towel during the bath or exercising or walking with staff when starting to wander. Reality orientation can be used to recall the patient to time, place, and person. A family member can be asked to stay with the patient until the person becomes calmer. The patient should be monitored frequently, and all interventions should be documented. An interdisciplinary approach is important to identify the best redirective strategies. The use of evidence-informed nursing interventions significantly reduces the use of physical and chemical (drug therapy) restraints (Enns, Rhemtulla, Ewa, et al., 2014; RNAO, 2012).

Use of Restraints.

Restraints are physical, environmental, or chemical measures used to limit the activity or control the behaviour of a person or a portion of his or her body (RNAO, 2012). Devices such as seat belts, "geri-chairs," or side rails that cannot be removed by the patient are considered physical restraints, and it has been proven that these actually increase a person's risks for falls and injury (Enns, Rhemtulla, Ewa, et al., 2014). Chemical restraints are any form of psychoactive medication used not to treat illness but to intentionally inhibit a patient's particular behaviour or movement. Several researchers have indicated that antipsychotic medications have limited effectiveness and significant risks for older persons with cognitive impairment (Enns, Rhemtulla, Ewa, et al., 2014; RNAO, 2012). Despite abundant research findings, chemical and physical restraints continue to be used in the care of people with responsive behaviours. Several Best Practice Guidelines outline alternatives for care (RNAO, 2011, 2012).

Evaluation.

The evaluation phase of the nursing process is similar for all patients. Evaluation is ongoing throughout the nursing process. The results of the evaluation direct the nurse to continue the care plan or revise it as indicated.

When evaluating nursing care for an older adult, the nurse should focus on improving or maintaining the patient's functional and cognitive status and his or her quality of life and well-being, rather than a cure. Useful questions to consider when evaluating the care plan for an older adult are included in Table 7-14.

TABLE 7-14
EVALUATING NURSING CARE FOR OLDER ADULTS

Evaluation questions may include the following:
1. Has there been an identifiable change in ADLs, IADLs, cognitive status, or disease signs and symptoms?
2. Does the patient consider his or her health and well-being state to be improved?
3. Does the patient think the treatment is helpful?
4. Do the patient and the caregiver think the care is worth the time and cost?
5. Can the nurse document positive changes that support interventions?

ADLs, activities of daily living; *IADLs*, instrumental activities of daily living.

Case Study

Older Adults

Source: Muellek Josef/Shutterstock.com.

Patient Profile

Lee Xiang, a 79-year-old Chinese woman, was admitted through the emergency department with shortness of breath. She was diagnosed with community-acquired pneumonia. Her history also indicates that she has chronic obstructive pulmonary disease (COPD), hypertension, diabetes, mild cognitive impairment, depression, macular degeneration, and significant hearing loss.

Subjective Data

- Had a stroke 5 years ago and has right-sided weakness.
- Has a two-pack/week history of tobacco use but quit smoking after her stroke.
- Has not seen primary care physician in 1 year.
- In past year has had an unplanned weight loss of 20 pounds.
- Spends her days either in bed or in a recliner watching television.

Psychosocial Data

- Came to the Canada 15 years ago from China.
- Speaks Mandarin with limited English proficiency.
- Lives with her unemployed adult son, who provides assistance with ADLs and IADLs.
- Has three daughters who live within a 2-hour drive.

- Has limited financial resources.
- Her son has not visited her in the hospital, but her daughters raise concerns about their mother's care and safety at home, given their brother's history of gambling addiction.
- When daughters ask their brother about how he is caring for his mother, he says, “I'm doing the best I can. She refuses help. She refuses to go to the doctor. What do you want me to do? She's old. She does what she wants.”

Objective Data

- Matted hair, poor oral hygiene, overgrown toenails.
- Two stage III sacral pressure injury.
- Unstageable right heel pressure injury.
- Multiple small bruises on her forearms and shins.
- 5 × 10-cm bruise in the middle of her back.

Discussion Questions

1. Compare Mrs. Xiang's experience as an older woman to known gender differences for older adults.
2. Define *ageism,* and explain how it may be manifested in this case.
3. What risk factors does Mrs. Xiang have for development of frailty? Which of these factors are modifiable?
4. ***Priority Decision:*** On the basis of your assessment of Mrs. Xiang, what are the priority nursing diagnoses?
5. ***Priority Decision:*** What are the priority nursing interventions for Mrs. Xiang?
6. Explain ethnogeriatric considerations that affect Mrs. Xiang and how they will influence your nursing care.
7. Based on your knowledge of caregiver support and care alternatives for older adults, what support is required for the son and daughters, and what setting or settings might be appropriate for Mrs. Xiang on hospital discharge?
8. What risk factors does Mrs. Xiang have for becoming a victim of elder mistreatment?

Answers available at *http://evolve.elsevier.com/Canada/Lewis/medsurg*.

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. What is one characteristic of ageism?
   a. Denial of negative stereotypes regarding aging.
   b. Positive attitudes towards older adults that are based on age.
   c. Negative attitudes towards older adults that are based on age.
   d. Negative attitudes towards older adults that are based on physical disability.
2. The prevalence of autoimmune diseases increases with aging. Which theory of aging accounts for this phenomenon?
   a. Immune theory of aging.
   b. Programmed theory of aging.
   c. Neuroendocrine theory of aging.
   d. Intrinsic mutation theory of aging.
3. Which of the following nursing interventions would promote a sense of self-worth for an older adult member of an ethnic minority?
   a. Informing the person about ethnic support services.
   b. Allowing the person to rely on ethnic health beliefs and practices.
   c. Using an interpreter to provide explanations and teaching.
   d. Emphasizing that a therapeutic diet does not allow ethnic foods.
4. Which of the following nursing actions would be helpful to a chronically ill older adult? *(Select all that apply.)*
   a. Discussing future lifestyle changes.
   b. Informing the patient that the condition is stable.
   c. Treating the patient as a competent manager of the disease.
   d. Encouraging the patient to "fight" the disease as long as possible.
5. When older adults become ill, which of the following are they more likely to do than younger adults?
   a. Complain about the symptoms of their problems.
   b. Refuse to carry out lifestyle changes to promote recovery.
   c. Seek medical attention because of limitations on their lifestyle.
   d. Alter their daily living activities to accommodate new symptoms.

6. What should the nurse know about a patient's caregivers?
   a. They may need the nurse to assist them in reducing caregiver strain.
   b. They are usually trained health care workers who do not live with the client.
   c. They are generally strong and healthy but need teaching to carry out care activities.
   d. They are often reluctant to share the burden of caregiving with other family members.
7. For an older adult requiring constant assistance and living with an employed daughter, what is an appropriate care choice?
   a. Adult day care.
   b. Nursing home care.
   c. A retirement centre.
   d. An assisted-living home.
8. What is a characteristic of a living will?
   a. Legally binding.
   b. Encourages the use of artificial means to prolong life.
   c. Allows a person to direct her or his health care in the event of terminal illness.
   d. Designates who can act for the patient when the patient is unable to do so for himself or herself.
9. In promotion of health for older adults, what is the primary focus of nursing interventions?
   a. Disease management.
   b. Controlling symptoms of illness.
   c. Teaching positive health behaviours.
   d. Teaching the role of nutrition in enhancing longevity.

1. c; 2. a; 3. a; 4. a, c; 5. d; 6. a; 7. a; 8. c; 9. c.

CHAPTER 8

Stress and Stress Management

Written by, Sharon L. Lewis, Peter N. Bonner

Adapted by, Jane Tyerman

LEARNING OBJECTIVES

1. Define the terms *stressor, stress, demands, coping, adaptation,* and *allostasis.*
2. Describe the three stages of Hans Selye's general adaptation syndrome.
3. Explain the role of coping in managing stress.
4. Describe the role of the nervous and endocrine systems in the stress process.
5. Describe the effects of stress on the immune system.
6. Describe the effects of stress on health and illness.
7. Describe coping strategies that can be used by persons experiencing stress.
8. List variables that may influence an individual's response to stress.
9. Describe the nursing assessment and management of a patient experiencing stress.

KEY TERMS

emotion-focused coping, p. 116

eustress, p. 111

general adaptation syndrome, p. 112

imagery, p. 118

problem-focused coping, p. 116

psychoneuroimmunology, p. 114

resilience, p. 113

sense of coherence, p. 112

stage of exhaustion, p. 112

stage of resistance, p. 112

stress, p. 110

stressors, p. 110

Stress is a fact of daily living that can have a positive or negative effect on the mind and body. Stress, especially if it is intense or chronic, is linked to numerous psychological and physiological disorders. Anticipating potentially stressful situations, identifying stress, and implementing appropriate measures to minimize its effect is an important aspect in health promotion and disease prevention. Because high levels of stress are common among patients and their caregivers, nurses play a very important role in helping patients manage stressful events. Understanding the relationship of stress to physical and emotional health and how people cope with stress is the primary focus of this chapter.

Definition of Stress

Stress is the inability to cope with perceived (real or imagined) demands or threats to an individual's mental, emotional, or spiritual well-being (Seward, 2014). Like pain or grief, it is a subjective condition: It is what the affected person says it is. Stress occurs when individuals perceive that they cannot adequately cope with demands being made on them or when their well-being is threatened (Lazarus & Folkman, 1984). These stress-inducing demands are known as **stressors** (Selye, 1983). What is perceived as stressful and the response to the stressor vary greatly among individuals and are influenced by a multitude of factors such as genetic makeup, life experience, family influences, and culture. This is demonstrated in the following examples:

- A woman becomes depressed and refuses to participate in normal self-care activities after a laparoscopic hysterectomy. In this situation, the removal of her uterus is a great stressor because the woman perceives it as a loss of her womanhood and femininity.
- A patient who is told she has type 2 diabetes reacts with a smile. However, the patient is relieved because for weeks she has been worrying that her symptoms were related to terminal cancer.

Many different events, factors, or stimuli can be thought of as stressors. They can be physiological or emotional–psychological (Table 8-1) and positive or negative. The key aspect of stressors is that they require an individual to adapt to a situation (Lazarus & Folkman, 1984). There are differences in the behavioural and physiological adaptive responses to a stressor that are based on the duration of the stressor (acute or chronic) and intensity of the stressor (mild, moderate, or severe). For example, an individual dealing with the chronic stress of caring for a loved one may also be exposed to a multitude of acute episodic stressors (e.g., car accident, influenza).

TABLE 8-1
EXAMPLES OF STRESSORS

Physiological	Emotional–Psychological
• Burns • Chronic pain • Birth of a baby • Infectious diseases • Excessive noise • Inadequate nutrition • Running a marathon	• Diagnosis of cancer • Marital and other family problems • Failing an examination • Inadequate financial resources • Grieving • Prolonged period of caregiving

Daily hassles are experiences and conditions of daily living that are viewed as irritating, frustrating, and distressing. The frequency and intensity of daily hassles have a stronger relationship with somatic illness than do major life events (Lazarus & Folkman, 1984). Examples of daily hassles are traffic, waiting, misplacing or losing things, deadlines, and planning meals. Not all stress is bad. Selye (1983) coined the term **eustress** to refer to stress associated with positive events such as the birth of a baby, going for a run, falling in love, or attending a much-anticipated event. A little stress can motivate and inspire an individual to achieve a goal and become more confident or stronger physically. Uplifts may modify the negative effects of daily hassles. Although studies of the effects of negative experiences (hassles or life events) are more plentiful, it is generally accepted that emotions such as humour and behaviours such as laughter are associated with healthy physiological and psychological functioning (Berk, 2015; Kuiper, 2012).

Work-Related Stress

Work-related stress occurs when there is an imbalance between work demands and a worker's ability to cope with these demands. Nursing-related work demands can include poor working conditions, work overload, shift work, and time pressures. Other demands stem from the individual's role in the organization (e.g., role conflict), career development (e.g., underpromotion), relationships at work (e.g., difficulties in delegating responsibilities), and the organizational climate (e.g., restrictions on behaviour). The extensive research on these factors and their effects validates inclusion of occupation and work experience as essential factors in patient assessment. According to 2010 General Social Survey (Statistics Canada, 2015), 37% of employed Canadians reported that they were experiencing high degrees of stress, citing work as their main source of stress. Decreasing staffing resources for managing increasing workload has been shown to be one of the most significant factors contributing to emotional exhaustion and burnout in nurses (Aiken et al., 2011; Duffield et al., 2011). This burnout is reflective of the nursing attrition rate, which peaked in 2013 at 7.1% and exceeded the number of nurses entering the workforce (Canadian Institute for Health Information, 2016).

Theories of Stress

Three different but complementary stress theories have influenced most contemporary approaches to the study of stress. The current understanding of stress began with Hans Selye, who performed his research at McGill University in Montreal in the late 1930s. He conceptualized stress as a response to a demand or stressor that elicits a series of physiological changes to which the person must adapt. This process is known as *general adaptation syndrome* and is discussed in the next section.

According to a second stress theory, stress is a stimulus that causes a response. This theory originated with Holmes and Masuda (1966) and Miller and Rahe (1997), who developed the Social Readjustment Rating Scale to assess the effects of life changes on health. The major assumption of this theory is that frequent life changes make people more vulnerable to illness. Life changes can range from minor violations of the law to the death of a loved one.

A third stress theory focuses on person–environment interactions and is referred to as the *transaction* or *interaction theory.* Proponents of this theory were Lazarus and Folkman (1984), who emphasized the role of *cognitive appraisal* (Figure 8-1) in assessing stressful situations and selecting coping options. They conceptualized cognitive appraisal as a judgement or evaluative process whereby the individual recognizes the degree of stress and its effect on well-being; as a result of this appraisal, the individual uses coping resources that respond to the demand placed upon them. Cognitive appraisal is divided into two stages: primary and secondary appraisal. Primary appraisal focuses on the influence or effect of the stressor; secondary appraisal involves positive or negative perceptions that the individual holds concerning his or her ability to overcome the stressor.

PATHOPHYSIOLOGY MAP

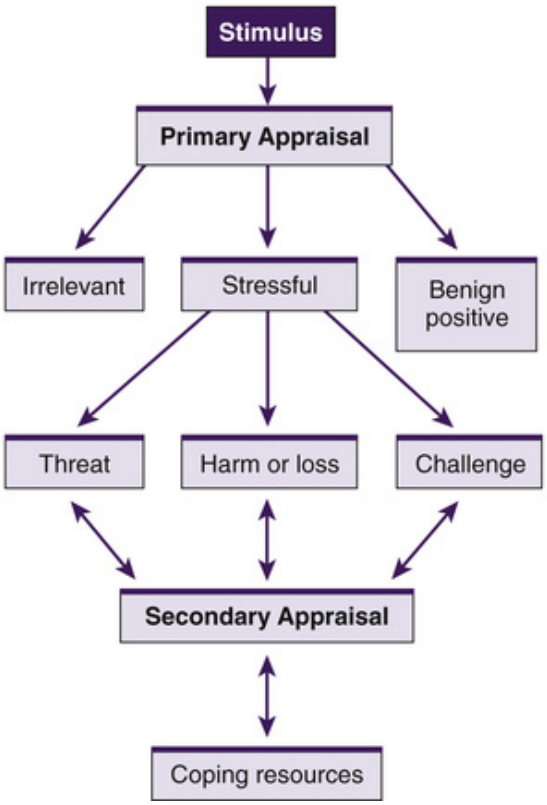

FIGURE 8-1 Cognitive appraisal process.

General Adaptation Syndrome

The **general adaptation syndrome** is composed of three stages: alarm reaction, stage of resistance, and stage of exhaustion. Once the environmental event or stressor stimulates the central nervous system, multiple responses occur because of activation of the hypothalamic–pituitary–adrenal axis and the autonomic nervous system.

The first stage of the stress response is the **alarm reaction**, in which the individual perceives a stressor physically or mentally and the fight-or-flight response is initiated (Figure 8-2). When the stressor is of sufficient intensity to threaten the steady state or homeostasis of the individual, it leads to a series of physiological changes that promote adaptation. This temporarily decreases the individual's resistance and may even result in disease or death if the stress is prolonged and severe.

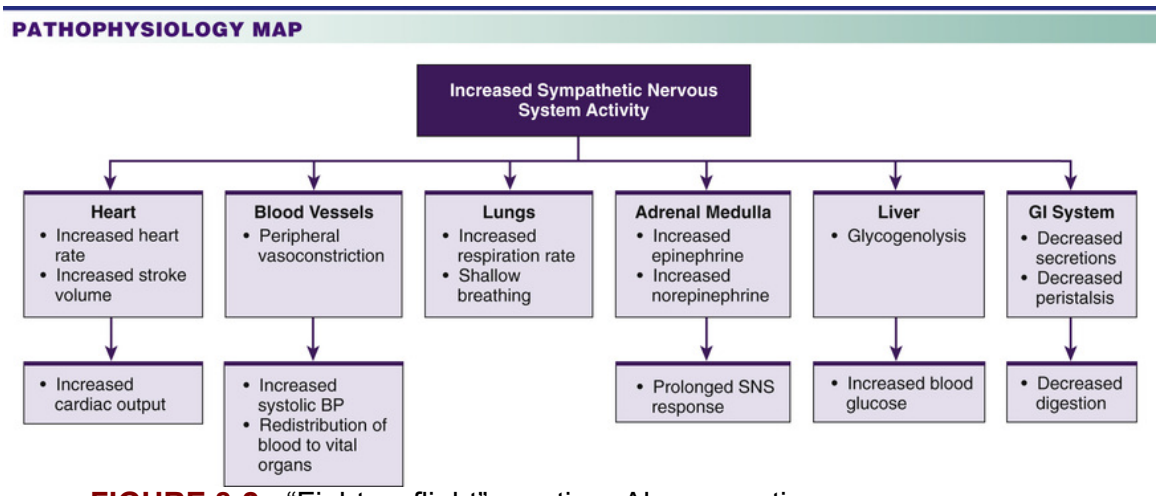

FIGURE 8-2 "Fight-or-flight" reaction. Alarm reaction responses resulting from increased sympathetic nervous system activity. *BP*, blood pressure; *GI*, gastro-intestinal; *SNS*, sympathetic nervous system.

Ideally, the individual quickly moves from the alarm reaction to the **stage of resistance**, in which physiological reserves are mobilized to increase the resistance to stress. At this time, adaptation may occur. The amount of resistance to the stressor varies among individuals, depending on the level of physical functioning, coping abilities, and total number and intensity of stressors experienced. For example, a person who has been exercising regularly and is physically fit has a greater ability to adapt to

the stress of emergency surgery than does a person who is deconditioned and leads a sedentary lifestyle.

Although few overt physical signs and symptoms occur in the resistance stage in comparison with the alarm stage, the person is expending energy in an attempt to adapt. **Allostasis** is the process of achieving homeostasis in the presence of a challenge (Sterling, 1988). When internal and external resources are adequate, the individual may recover successfully from a stressor and return to his or her baseline state. If homeostasis is not achieved, and if these allostatic responses do not terminate, adaptation does not occur, and the person may move to the final phase of the general adaptation syndrome.

The **stage of exhaustion** is that final stage. It occurs when all of the energy for adaptation has been expended. Physical symptoms of the alarm reaction may briefly reappear in a final effort by the body to survive. A terminally ill person who becomes alert and has stronger vital signs shortly before death exemplifies this phenomenon. The individual in the stage of exhaustion usually becomes ill and may die if assistance from outside sources is not available. This stage can often be reversed by external sources of adaptive energy, such as medication or psychotherapy. Selye's research indicated that there is a predictable, uniform pattern in the physiological response to various stressors.

Factors Affecting Response to Stress

Why do people respond differently to stress, and why do some cope better with stress than do others? Factors that affect an individual's response to stress include internal and external influences, a fact that underscores the importance of using a holistic approach in assessing the effect of stress on an individual. See the "Determinants of Health" box for additional factors affecting people's response to stress.

Determinants of Health

Factors Affecting an Individual's Response to Stress

Employment and Working Conditions

- Jobs with high skill utilization, increased psychological demands, job insecurity, and low levels of social support at work are associated with increased levels of psychological distress.*
- Shift work is correlated with poor lifestyle habits such as snacking and decreased physical activity.†
- Shift work is also linked to depression, anxiety, stress-related chronic diseases, and insomnia.†

Health Practices and Coping Skills

Personal Health Practices and Coping Styles

- Individuals who are physically active have lower levels of stress.‡
- Strong support social systems enhance the capacity for an individual to cope with stress.§
- Stress predisposes an individual to emotional eating and impairs sleep hygiene.¶

In attempts to understand why some individuals do not experience negative consequences from stress, researchers have identified key personal characteristics, such as hardiness, sense of coherence, resilience, and attitude as possible factors that buffer the effect of stress. *Hardiness* is a combination of three characteristics: commitment, control, and openness to change. Together they provide protection against stress and depression (Hasel, Besharat, Abdolhoseini, et al., 2013). An *internal locus of control* is the perception that the person's life is self-determined, as opposed to being directed by outside or external events, luck, or chance (an *external locus of control*). Hardiness is discussed in more detail in Chapter 5.

Sense of coherence, first described by Antonovsky (1987), is a concept closely related to hardiness and is thought to be a key determinant of health. Sense of coherence is reflected in an optimistic view of the world and perceived ability to function optimally in that world. An individual with a strong sense of coherence has an enduring tendency to see his or her life as ordered, manageable, and meaningful.

Resilience is another characteristic that is believed to moderate or buffer the negative effects of stress. **Resilience** is defined as the ability to be resourceful, be flexible, and recover from stressful situations and return to

prior levels of functioning. Resilient individuals tend to employ more effective coping and problem-solving strategies, to possess higher self-esteem, and to be less likely to perceive an event as stressful or taxing.

Attitude can also influence the effect of stress on a person. People with positive attitudes view situations differently than do those with negative attitudes. A person's attitude also influences how he or she manages stress. To some extent, positive emotional attitudes can prevent disease and prolong life. Optimistic people tend to recover more quickly, whereas pessimistic people are likely to deny the problem, distance themselves from the stressful event, focus on stressful feelings, or allow the stressor to interfere with achieving a goal (Mayo Clinic, 2015). In addition to personal characteristics, being surrounded by a strong social support system and receiving positive support from friends and family have a significant effect on an individual's ability to cope with stressors.

Physiological Response to Stress

The following discussion is divided into descriptions of the nervous, endocrine, and immune systems. These systems, and thus the physiological stress responses, are interrelated (Figure 8-3). Stress activation of these systems also affects other systems, such as the cardiovascular, respiratory, gastro-intestinal, renal, and reproductive systems.

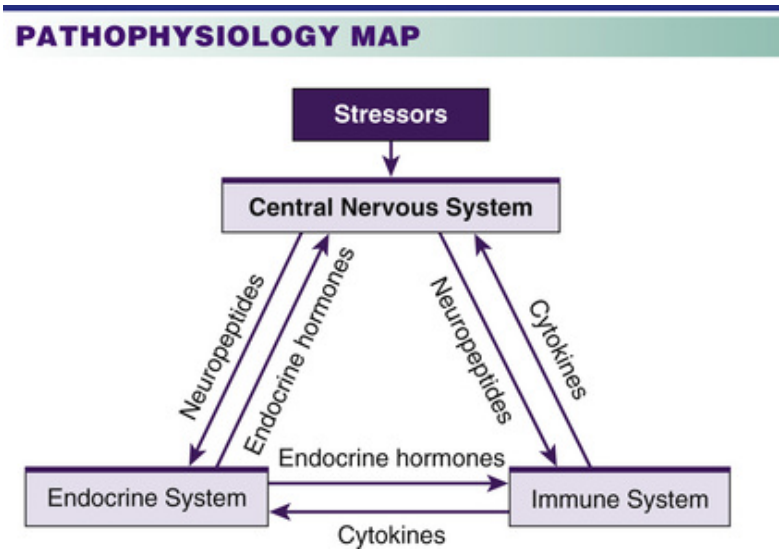

FIGURE 8-3 Neurochemical links among the nervous, endocrine, and immune systems. The communication among these three systems is bidirectional.

The complex process by which an event is perceived as a stressor and the body responds is not fully understood. A person's response to a stressor determines the effect it will have on the body. In addition, the body responds physiologically to both actual (physiological) and perceived (emotional–psychological) stressors.

Nervous System

Cerebral Cortex.

In the cerebral cortex, the emotional–psychological event (stressor) is evaluated with reference to past experiences and future consequences, and

a course of action is planned. These functions are involved in the perception of a stressor.

Limbic System.

The limbic system lies in the inner midportion of the brain near the base of the brain. The limbic system is an important mediator of emotions and behaviour. When the limbic system is stimulated, emotions, feelings, and behaviours that ensure survival and self-preservation may occur.

Reticular Formation.

The reticular formation is located between the lower end of the brainstem and the thalamus. It contains the reticular activating system, which is crucial for the state of wakefulness. When stimulated, the reticular activating system sends impulses to the limbic system and the cerebral cortex, which produce arousal and emotional responses to the stressor. Stress usually increases the degree of wakefulness and can lead to sleep disturbances.

Hypothalamus.

The hypothalamus, which lies at the base of the brain just above the pituitary gland, has many functions that assist in adaptation to stress. It is the central connection between the nervous and endocrine systems in the stress response. Emotional–psychological (perceived) stressors activate the limbic system, which in turn stimulates the hypothalamus. The hypothalamus sends signals via nerve fibres to stimulate the sympathetic nervous system. It also releases hormones that regulate the secretion of adrenocorticotrophic hormone (ACTH) by the anterior pituitary gland (Figure 8-4). Physiological (actual) stressors may originate in the limbic system or in portions of the brain that receive sensory information, which in turn then stimulate the hypothalamus (see Chapter 50).

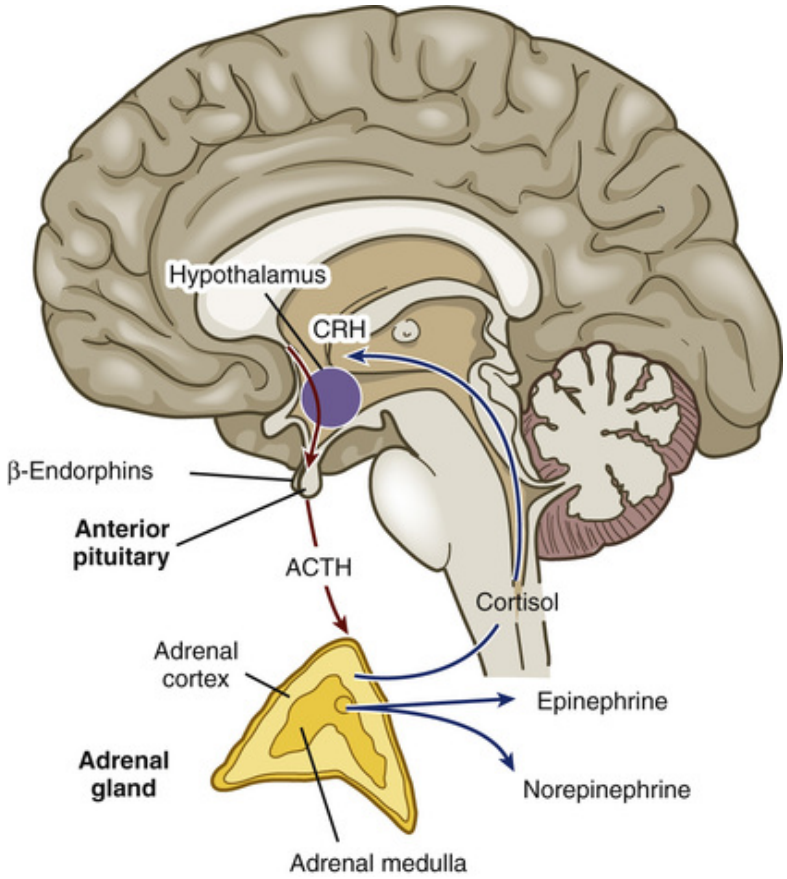

FIGURE 8-4 Hypothalamic-pituitary-adrenal axis. *ACTH,* adrenocorticotrophic hormone; *CRH,* corticotropin-releasing hormone.

Endocrine System

Once the hypothalamus is activated in response to stress, the endocrine system becomes involved. The sympathetic nervous system stimulates the adrenal medulla to release epinephrine and norepinephrine (catecholamines), which initiates a protective reflex called the *fight-or-flight response* (see Figure 8-2). This, along with the actual response of the body to the catecholamines, is referred to as the *sympatho-adrenal response*. Stress activates the hypothalamic–pituitary–adrenal axis (see Figure 8-4). In response to stress, the hypothalamus releases corticotropin-releasing hormone, which stimulates the anterior pituitary to release pro-opiomelanocortin (POMC). Both ACTH (a hormone) and β-endorphin (a neuropeptide) are derived from POMC. Endorphins have analgesic-like effects and blunt pain perception during stress situations involving pain stimuli. ACTH, in turn, stimulates the adrenal cortex to synthesize and

secrete corticosteroids (e.g., cortisol) and, to a lesser degree, aldosterone. The posterior pituitary increases production of antidiuretic hormone, which leads to water retention and a decrease in urine output (Figure 8-5).

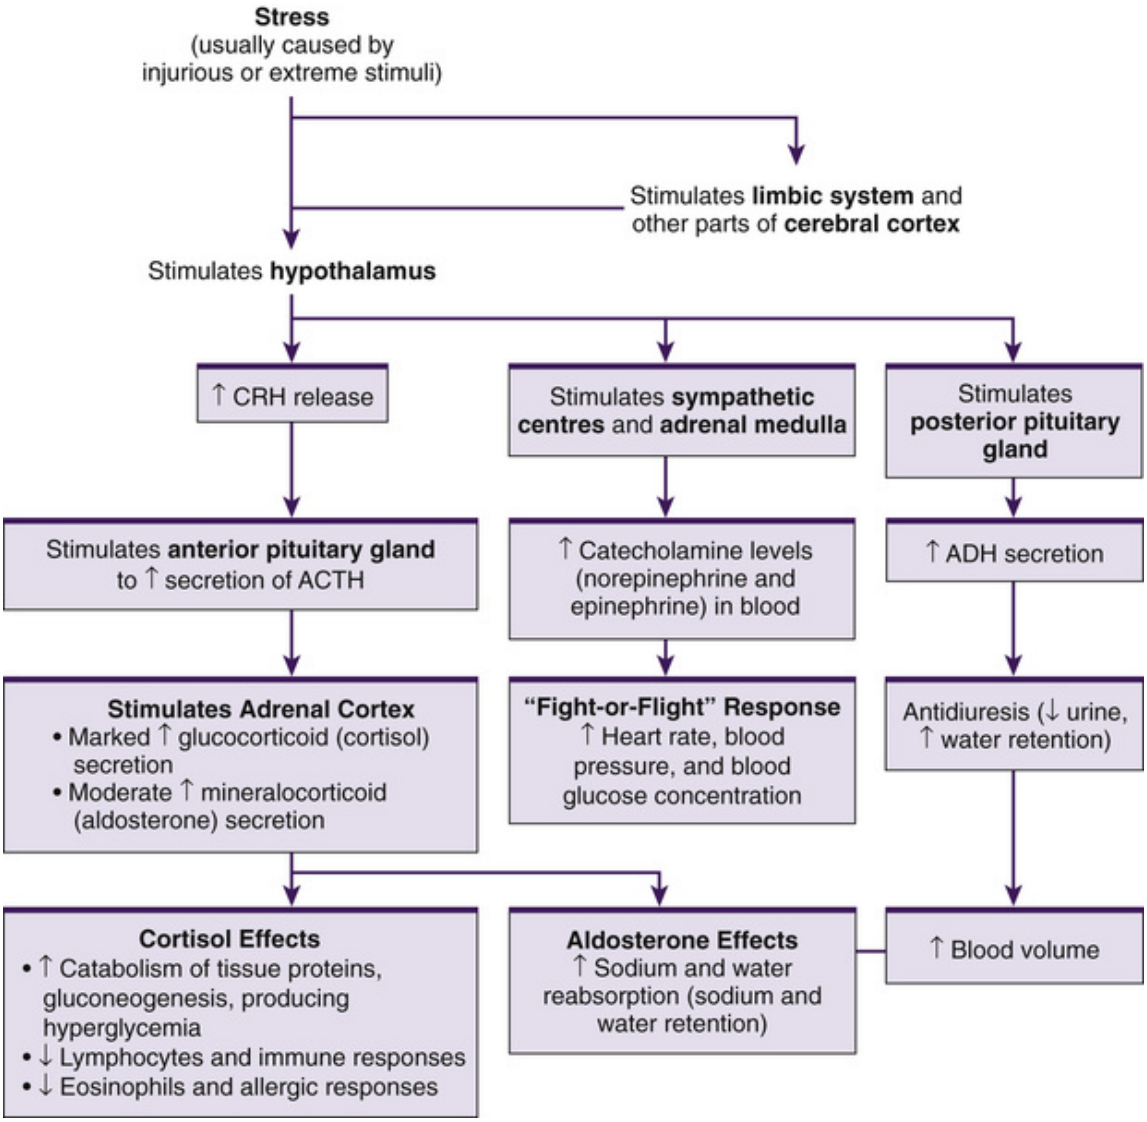

FIGURE 8-5 Current concepts of the stress syndrome. *ADH,* antidiuretic hormone; *ACTH,* adrenocorticotrophic hormone; *ADH,* antidiuretic hormone; *CRH,* corticotropin-releasing hormone.

Corticosteroids are essential for the stress response. Cortisol, a primary corticosteroid, produces a number of physiological effects that potentiate or blunt aspects of the stress response, such as increasing blood glucose levels, potentiating the action of catecholamines (epinephrine, norepinephrine) on blood vessels, and inhibiting the inflammatory

response. The resulting increases in cardiac output, blood glucose levels, oxygen consumption, and metabolic rate enable the fight-or-flight response (see Figure 8-2). Dilation of blood vessels supplying skeletal muscle increases blood supply to the large muscles, which provides for quick movement, and increased cerebral blood flow heightens mental alertness. The increase in blood volume (which results from increases in extracellular fluid and shunting of blood away from the gastro-intestinal system) helps maintain adequate circulation to vital organs in case of traumatic blood loss.

By mediating the inflammatory response, cortisol plays an important role in "turning off" aspects of the stress response, which if uncontrolled can become self-destructive. This is best exemplified by the suppression of proinflammatory mediators, such as the cytokines, tumour necrosis factor, and interleukin-1. The persistent release of such mediators is believed to initiate organ dysfunction in conditions such as sepsis. Thus corticosteroids act not only to support the adaptive response of the body to a stressor but also to suppress an overzealous and potentially self-destructive response.

Summary of Neuroendocrine System Stress Response

In summary, the fight-or-flight response is a very important mechanism of the body for adapting to acute stress. This response is triggered by stressors, regardless of whether they are physiological or emotional–psychological. The acute stress response is a state of physiological and psychological arousal characterized by increased sympathetic nervous system activity that leads to increases in heart and respiratory rate, blood pressure, muscle tension, and brain activity, and to decreases in skin temperature.

Immune System

Psychoneuroimmunology is an interdisciplinary science in which investigators seek to understand the interactions among psychological, neurological, and immune responses (Pariante, 2015). It is now known that the brain is connected to the immune system by neuroanatomical and neuroendocrine pathways; thus stressors have the potential to cause alterations in immune function (Figure 8-6). The network that links the brain and immune system is bidirectional, allowing for back-and-forth

communication among these systems; therefore, not only do emotions modify the immune response but also the products of immune cells send signals back to the brain and alter its activity (see Figure 8-3). Much of the communication from the immune system to the brain is mediated by cytokines, which are crucial in the coordination of the immune response. For example, interleukin-1 (a cytokine made by monocytes) acts on the temperature-regulatory centre of the hypothalamus and initiates the febrile response to infectious pathogens.

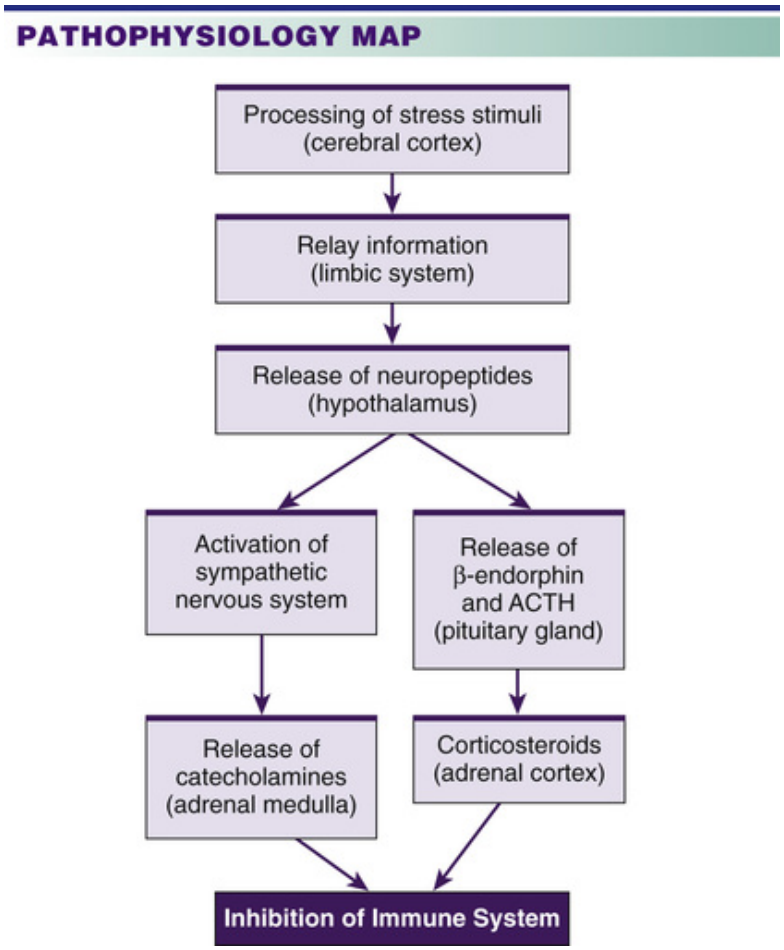

FIGURE 8-6 The psychological and neuroendocrine response to stress alters immune function. *ACTH*, adrenocorticotrophic hormone.

Nerve fibres extend from the nervous system and reach synapses on cells and tissues (i.e., spleen, lymph nodes) of the immune system. In turn, the cells of the immune system have receptors for many neuropeptides and hormones, which enable them to respond to nervous and

neuroendocrine signals. As a result, the mediation of stress by the central nervous system leads to corresponding changes in immune cell activity.

Both acute and chronic stress can affect immune function. Acute stress stimulates increased proliferation of cellular immune components such as neutrophils and natural killer cells, which are the body's first line of defence against infection (Segerstrom, 2012). The stress response is designed to be beneficial, however, only for acute short-term stress. Chronic stress appears to have a negative effect on both the cellular and humoral (antibody) immune systems (Segerstrom, 2012). Immune responses may be either suboptimal and thus ineffective when needed or hypervigilant, leading to chronic inflammatory states that exacerbate chronic stress and predispose affected persons to cardiovascular diseases (Steptoe & Kivimäki, 2012).

Effects of Stress on Health

Acute stress leads to physiological changes that are important to human adaptation and survival. However, if stress is excessive or prolonged, these physiological responses can be maladaptive and lead to harm and disease. When stress is chronic and unrelieved, the body's defences can no longer keep up with the demands. Over time, stress takes a toll (Figure 8-7) and plays a role in the development or progression of conditions related to maladaptation (Table 8-2).

FIGURE 8-7 Chronic stress can take a toll on the body, resulting in poor concentration and memory problems. Source: Syda Productions/Shutterstock.com.

TABLE 8-2
EXAMPLES OF CONDITIONS ASSOCIATED WITH MALADAPTATION TO STRESS

• Angina • Asthma • Depression • Dyspepsia • Eating disorders • Headaches	• Insomnia • Irritable bowel syndrome • Low back pain • Menstrual irregularities • Peptic ulcer disease • Sexual dysfunction

Chronic and intense stress may have profound effects on brain structure and function, especially the hippocampus. The hippocampus plays an important role in long-term memory and other cognitive functions such as spatial learning. Chronic release of corticosteroids in response to stress appears to act in concert with certain neurotransmitters to produce hippocampal damage (Marin, Lord, Andrews, et al., 2011). Studies of

people who have endured traumatic events (e.g., domestic violence, childhood neglect, war) reveal decreased hippocampal volume, activation, and activity. This is thought to explain the memory impairment/fragmentation and dissociation with the traumatic event that are common in post-traumatic stress disorder (Marin, Lord, Andrews, et al., 2011).

Stress can affect cognitive function, causing deterioration in concentration, memory problems, sleep disturbances, and impairment in decision making. In addition, stress can cause a wide variety of changes in behaviour. Such changes include withdrawing from others or becoming unusually talkative, eating disorders, substance abuse, or becoming irritable (Janusek, Cooper, & Matthews, 2012) . Stress can induce fatigue, and the resulting exhaustion limits a person's ability to cope. Fatigue is discussed in more detail in Chapter 5.

Although hypertension in acute stress is thought to be transient, studies demonstrate a strong association between chronic, maladaptive stress and sustained hypertension, which is a major risk factor for cardiovascular disease (Government of Canada, 2015). Other conditions that may be either precipitated or aggravated by stress include obesity, migraine headaches, irritable bowel syndrome, and peptic ulcers (Koenig, Walker, Romeo, et al., 2011). Not only can stress induce immunosuppression, making a person more vulnerable to infectious diseases, but also it may exacerbate or increase the risk of progression of immune-based diseases such as multiple sclerosis, asthma, rheumatoid arthritis, and cancer (Janusek, Cooper, & Matthews, 2012; Koenig, Walker, Romeo, et al., 2011). Many questions about stress and the immune response remain unanswered. For example, it is not known how much stress is needed to cause these changes or how much of an alteration in the immune system is necessary before an affected person becomes susceptible to disease. A current challenge for researchers in the field of psychoneuroimmunology is to study stress-induced immune changes and their relationship to health and to illness outcomes.

Coping

Coping is a person's cognitive and behavioural efforts to manage specific external or internal stressors that seem to exceed available resources (Lazarus & Folkman, 1984). Coping can be either positive or negative. Positive coping includes activities such as exercise and use of social support. Negative coping may include substance abuse and denial. Availability of coping resources affects an individual's ability to cope with stressful situations. **Coping resources** are internal or external assets, characteristics, or actions that a person draws upon to manage stress (Table 8-3).

TABLE 8-3
EXAMPLES OF COPING RESOURCES

Internal Coping Resources	
Health, Energy, Morale	**Problem-Solving Skills**
• Robust health • High energy level • High morale • Positive beliefs • Self-efficacy • Spirituality	• Collection of information • Identification of problem • Generation of alternatives • Social skills • Communication skills • Compatibility
External Coping Resources	
Social Networks	**Utilitarian Resources**
• Family members • Co-workers • Social contacts	• Finances • Self-help books • Social agencies

Coping strategies function broadly in two ways: as emotion-focused or problem-focused efforts (Table 8-4). **Emotion-focused coping** involves managing the emotions that an individual feels when a stressful event occurs. Examples of emotion-focused coping include discussion of feelings with a friend or relaxing in a hot bath. **Problem-focused coping** is a cognitive approach in which the person attempts to find solutions to the problems causing the stress. For example, setting priorities, collecting information, and seeking advice would be considered problem-focused coping. Emotion- and problem-focused strategies can be employed alone or in combination to cope with the same stressor. Although it may not appear to be working toward a solution, emotion-focused coping is a valid and appropriate way to deal with various stressful situations. Two primary purposes of emotion-focused coping are to alleviate negative emotions and to create a sense of well-being. When a situation is

unchangeable or uncontrollable, emotion-focused coping may dominate. If a problem can be changed or controlled, problem-focused cognitive coping may be more effective. Problem-focused coping strategies enable an individual to look at a challenge objectively, take action to address the problem, and thereby reduce the stress.

TABLE 8-4

EXAMPLES OF EMOTION- AND PROBLEM-FOCUSED COPING

Stressor	Emotion-Focused Coping	Problem-Focused Coping
Receiving a diagnosis of terminal cancer	Seeking spiritual guidance from one's place of worship	Preparing advanced health care directives
Exacerbation of chronic obstructive pulmonary disease (COPD)	Joining a support group	Quitting smoking
Renal failure that necessitates frequent travel for dialysis	Enjoying relaxing music and reading during travel time	Arranging for a volunteer driver
Extended hospital stay for stem cell transplantation	Communicating on Skype with family/friends regularly while in hospital	Arranging for child/family care before hospital admission

A key concept to successful coping is *coping flexibility*, which involves the ability to assess the nature of the stressor, determine what aspects can be controlled, and change and adapt coping strategies over time and across different stressful conditions. Stressful situations are best handled when an individual practises flexible coping, inasmuch as certain strategies work more effectively than others, depending on the circumstances, and overreliance on one type of coping strategy can be incapacitating. Regular exercise, especially aerobic movement, results in improved circulation, increased release of endorphins, and an enhanced sense of well-being. Numerous strategies have been shown to prevent or mitigate the effects of stress and are discussed in subsequent sections of this chapter.

Relaxation Strategies

Benson (1975) described *relaxation response* as a state of physiological and psychological deep rest. It is characterized by decreased central nervous system and sympathetic nervous system activity, which leads to decreases in heart and respiratory rates, blood pressure, muscle tension, and brain activity and an increase in skin temperature. The relaxation response can be elicited through a variety of relaxation strategies, including relaxation breathing, meditation, imagery, muscle relaxation, prayer, and physical exercise. It is an effective intervention for stress-related disorders, including chronic pain, insomnia, and hypertension. Individuals who regularly engage in relaxation strategies are able to deal better with their stressors, to increase their sense of control over stressors, and to reduce their tension (Fjorback, Arendt, Ørnbøl, et al., 2011). In addition to common strategies discussed in the following section, the relaxation response can be elicited through methods listed in Table 8-5.

TABLE 8-5

EXAMPLES OF STRESS MANAGEMENT TECHNIQUES

Technique	Description
Thought stopping	A self-directed behavioural approach is used to gain control of self-defeating thoughts. When these thoughts occur, the individual stops the thought process and focuses on conscious relaxation.
Humour	Humour in the form of laughter, cartoons, funny movies, riddles, CDs, comic books, and joke books can be used for both the nurse and the patient.
Assertive behaviour	This behaviour entails open, honest sharing of feelings, desires, and opinions in a controlled way. The individual who has behaves assertively is less subject to stress.
Yoga	This activity incorporates exercise, postures, regulated breathing and meditation to decrease stress and to promote physical and mental well-being.
Social support	This may take the form of organized support and self-help groups, relationships with family and friends, professional help, or some combination.
Journal keeping	The individual expresses self in written form, such as personal events, thoughts, feelings, memories, and perceptions. This may allow the individual to increase self-awareness and coping.
Colouring	Colouring is a relaxation technique that lowers activity of the amygdala, a part of the brain involved in controlling negative emotions that are affected by stress. The colouring and creating of mandalas, a circular design with concentric shapes, embraces creativity and has been shown to decrease negative thoughts (Babouchkina & Robbins, 2015).
Biofeedback	This is a method of monitoring and controlling physiological responses to stressful or challenging events; these responses include skin temperature, muscle tension, heart rate, brain waves, and skin conductance (see Chapter 12).

CD, compact disc.

Relaxation Breathing

Relaxation breathing forms the basis for most relaxation strategies, and an individual can perform it while sitting, standing, or lying down. It is especially useful in reducing stress during a stressful or anxiety-provoking experience. Techniques for relaxation breathing are presented in Table 8-6.

TABLE 8-6
RELAXATION STRATEGIES

Rhythmic Breathing
1. Find a quiet, peaceful environment. 2. Assume a comfortable position, whether sitting or lying down, ensuring that arms and legs are not crossed. 3. Close your eyes, and breathe in and out slowly, saying, "Breathe in, 2, 3, 4; breathe out, 2, 3, 4." The key is a "signal breath" involving deep inhalation through the nose and forceful exhalation through the mouth. The signal breath precedes and follows each repetition of the exercise. 4. Continue to breathe in and out slowly, using abdominal breathing, feeling more relaxed with each breath. As with any breathing exercise, if you begin feeling light-headed, discontinue exercise for 30 seconds and then start again. Initially, relaxation breathing may feel unusual. With practice it becomes easier, and the relaxing benefits are soon obvious. 5. When you are ready to end a breathing relaxation exercise, count silently from 1 to 3; on 1, move your lower body; on 2, move your upper body; on 3, breathe in deeply, open your eyes, and while breathing out slowly, say silently, "I am relaxed and alert." Stretch as if just waking up.
Relaxation by Sensory Pacing
1. Follow steps 1 and 2 of rhythmic breathing. 2. Slowly repeat and finish each of the following sentences: "Now I am aware of seeing…." "Now I am aware of feeling…." "Now I am aware of hearing…." Repeat and complete each sentence four times, then three times, then twice, and finally once. 3. Allow the eyes to close when they feel heavy.
Progressive Relaxation
See the later section "Muscle Relaxation" as well as Table 8-7, for more detail.
1. Follow steps 1, 2, 3, and 4 of rhythmic breathing. 2. Once you are breathing slowly and comfortably, tighten and relax specific muscle groups in ordered succession, concentrating on the feeling of relaxing the muscle. Starting with the feet and moving upward, ending with the face, is an effective technique. 3. Lie still for a few minutes, experiencing the relaxed muscles. Continue to breathe slowly and deeply, feeling tension flow out and relaxation increasing with each breath. 4. When you are ready to get up, count backwards from 4 to 1 and slowly rise.
Modified Autogenic Relaxation
1. Follow steps 1, 2, 3, and 4 of rhythmic breathing. 2. Repeat each of the following phrases to yourself four times, saying the first part of the phrase while breathing in for 2 to 3 seconds, holding the breath for 2 to 3 seconds, and then saying the last part of the phrase while breathing out for 2 to 3 seconds:

Breathing In	**Breathing Out**
I am	relaxed.
My arms and legs	are heavy and warm.
My heartbeat	is calm and regular.
My breathing	is free and easy.
My abdomen	is loose and warm.
My forehead	is cool.
My mind	is quiet and still.

Before a person practises relaxation breathing, it is important to assess his or her normal breathing pattern. To do this, the person begins by placing one hand gently on the abdomen below the waistline and the other hand on the centre of the chest. Without changing the normal breathing pattern, the person takes several breaths. During inhalation, the person takes notice of which hand rises the most. When relaxation breathing is performed properly, the hand on the abdomen should rise more than the hand on the chest. Chest breathing, which involves the upper chest and shoulders, is associated with inefficient breathing, and often occurs during anxiety and distress. Relaxation breathing, which involves the diaphragm, is natural for newborns and sleeping adults and is associated with efficient breathing.

Complementary & Alternative THERAPIES

Stress

In addition to cognitive and behavioural coping strategies, a number of complementary and alternative therapies have been shown to help people to cope with their stress. See Chapter 12 for a discussion of the role of St. John's wort and kava in coping with stress. It is important to read the "Natural Products" section to ensure patient safety when considering herbal preparations in managing any disorders. Chapter 12 also contains discussions of other complementary and alternative therapies that may be used in managing stress, such as yoga, therapeutic and healing touch, massage, and prayer.

Meditation

Meditation is an ancient relaxation strategy used to reduce stress and enhance well-being through focused mindfulness. In people who meditate regularly, the brain is reoriented from a stressful fight-or-flight mode to one of acceptance and contentment (Shonin, Van Gordon, & Griffiths, 2014). Studies have demonstrated possible links between meditation and health. Health benefits include a regeneration of pancreatic cells, which increases the metabolism of glucose in adipose tissue and the liver; a reduction in blood pressure and regression of coronary artery disease; a decline in body mass index; an increased airflow to the lungs; and improved immunity (Ankad, Herur, Patil, et al., 2011; Balaji, Varne, & Ali,

2012). Individuals typically start learning the technique with only 5 to 10 minutes of meditation at a time and increase the time as the practice becomes more comfortable. Table 8-7 is a guide to meditation. It is important to note that meditation takes practice, and people are often not successful at first, and so beginners should not feel discouraged.

TABLE 8-7

BASIC GUIDE TO MEDITATION

- Find a quiet place, with no distractions.
- Sit in a comfortable position, and close your eyes.
- "Shut out the world" so that your brain can stop processing information coming from your senses.
- Pick a word or phrase that means something to you, whose sound or rhythm is soothing when repeated (e.g., "one," "peace," "shalom," "salaam," "The Lord is my shepherd").
- Breathe slowly, and practise relaxation breathing.
- Say the word or phrase again and again, or try saying it silently to yourself with every exhalation.
- The monotony will help you focus.
- Do not be concerned when other thoughts come to mind; just acknowledge them and return calmly to your word or phrase.
- Continue for 10 to 20 minutes, but even 5 minutes can leave you feeling calm and refreshed. Rise slowly.
- Practise once or twice daily.

Imagery

Imagery is the use of the mind to generate images that have a calming effect on the body (Table 8-8; Figure 8-8). It involves the use of mental focus and incorporates all the senses to create physiological and emotional changes. It is a simple relaxation technique that requires no equipment other than an active imagination. Guided imagery is a variation of imagery in which images are suggested by another person (either live or in a recording).

TABLE 8-8
IMAGERY: CREATING A "SPECIAL PLACE"

- Begin by finding a comfortable position, closing your eyes, and taking several slow, deep breaths.
- Imagine a place where you feel completely comfortable and peaceful. It may be a real place or one you imagine; it may be one from your past or some place you have always wanted to go.
- Allow this image to take form, slowly. As it takes form in your imagination, look around, to your left, to your right. Enjoy the scenery: the colours, the texture, and the shapes. Engage all senses: sight, hearing, touch, smell, and taste.
- Listen carefully to the sounds of your place. What do you hear?
- Is there a gentle breeze or sunshine warming your face? Imagine picking up or touching some favourite objects from this special place. Take in a deep breath through your nose, and notice the rich smells around you. Perhaps your favourite flower is in bloom, or you smell the scents of the ocean.
- Take another deep breath and relax. Enjoy the peace, comfort, and safety of this special place.
- This is your special place. You relax and feel thankful that you are here, in your special place.
- You can return to this place any time that you wish.

FIGURE 8-8 Imagery. Creating a "special place" should involve the physical senses, such as a place where rustling leaves can be heard, flowers are smelled, wind is felt, and a colourful landscape is seen. Source: Muriel Lasure/Shutterstock.com.

Imagery can be used in many clinical settings for stress reduction and pain relief. Benefits of imagery include reduction in anxiety, decrease in muscle tension, improvement in comfort during medical procedures, enhancement of immune function, decrease in recovery time after surgery, and improvement in sleep. Health care providers may use imagery in their own lives or may use guided imagery with their patients. Imagery is used to create a safe and special place for mental retreat.

Imagery can also be used to specifically target a disease, problem, or stressor. For example, patients with cancer may imagine sharks gobbling up their cancer cells or radiation and chemotherapy entering the body like healing rays of light that destroy cancer cells. Special images can be created to alleviate symptoms (such as pain) or to treat disorders (such as depression); for example, a person may imagine troubles attached to helium balloons and visualize releasing them into the sky. *Relaxation by colour exchange* is a technique that combines rhythmic breathing and imagery. Patients are instructed to focus on an area of pain or tension and assign a colour to it. While breathing in, they can imagine a warm white light coming into their body and surrounding this area. They then imagine the colour of discomfort leaving their body through their breath as they exhale. It should be noted that relaxation by colour exchange is a very new stress reduction technique that does not yet have an evidence base to support its efficacy.

Music for Relaxation

Music can help achieve relaxation and bring about healthy changes in emotional or physical states. Listening to relaxing music may act as a diversion from a stressful situation. In addition, healing vibrations from music can return the mind and body to better balance.

Music has been used in many clinical settings. In general, music appears to affect functions such as such as heart rate, arterial pressure, gastric and bowel secretions, muscle tone, sweat glands, and temperature regulation (Chan, Wong, & Thayala, 2011). It has been shown to decrease anxiety and pain and to evoke the relaxation response (Bauer, Cutshall, Anderson, et al., 2011). Music with low-pitch tones, without words, and that has approximately 60 to 80 beats per minute is considered to be soothing. Mozart's compositions are the most popular form of music used for relaxation. In contrast, fast-tempo music can stimulate and uplift a person.

Music can be incorporated into clinical practice. It is noninvasive, safe, inexpensive, and easy to use. First, it is important to establish the purpose and benefit of using music with the patients in a given clinical setting and to assess each individual patient's interest and preference in music. The patient should be in a comfortable position, and the possibility of interruptions should minimized: for example, by the use of headphones or earphones. For optimal benefit, music should be played for at least 20 to 30 minutes per day at least twice a day. Patients' responses to the music

should be evaluated through questions about how it sounds and how it makes them feel.

Muscle Relaxation

Muscle tension is a universal reaction to stress. As the stress response sets in, muscles of the entire body tend to tighten. Muscle relaxation is therefore a common method of eliciting the relaxation response. There are two types of muscle relaxation: progressive and passive. *Progressive muscle relaxation* (PMR) involves the tensing and the relaxing of muscles. This method is intended to help patients differentiate between when a muscle is tensed and when it is relaxed. This recognition enables an individual to reduce muscle tension when it occurs during times of stress. PMR is based on the principle that when the muscles are relaxed, the mind relaxes. In a session of PMR, relaxation typically begins at the extremities and gradually moves across the whole body. An example of PMR can be found in Table 8-6. Patients with muscle or connective tissue damage and those with low back pain should not use PMR. In addition, PMR should not be used by patients with increased intracranial pressure, uncontrolled hypertension, or severe coronary artery disease.

In *passive muscle relaxation,* on the other hand, the mind focuses only on relaxation of the muscles. It is performed similarly to PMR, moving from one extremity to the rest of the body, with the exception that the muscles are never tightened. In passive muscle relaxation, the focus is simply on relaxing each muscle group separately. This form of muscle relaxation may be used more frequently by individuals who have chronic pain that may be exacerbated by the tension involved during PMR.

Nursing Management Stress

Nursing Assessment

Patients face an array of potential stressors that can have health consequences. Nurses are well positioned to assess patients and their significant others, to assist them in identifying periods in which they are at high risk for stress, and to implement stress management strategies. Three major areas are important in assessment of stress: demands, human responses to stress, and coping. The Perceived Stress Scale (Roberti, Harrington, & Storch, 2006) is a measure of how stressful a person perceives his or her life to be at that time. Although further research is needed to connect the identification of stressors with managing them, the Distress Thermometer (Snowden, White, Christie, et al., 2011) identifies areas of particular concern to patients. Caregiver stress is a well-identified phenomenon that may occur in a variety of situations, such as caring for a spouse with Alzheimer's disease, an older parent, or a child with cancer, and thus should also be considered in a stress assessment. Communication support, adequate education and resources, social support and a positive approach from nursing staff are shown to improve the quality of life of caregivers (Wittenberg-Lyles, Washington, Demiris, et al., 2014).

Demands.

Stressors, or demands, on the patient may include major life changes, events or situations such as disfiguring or debilitating surgery, or daily hassles. Demands may be categorized as external (e.g., job-related situations, extended hospitalization) or internal (e.g., perception of goals or commitments, physical effects of disease or injury). It is important to keep in mind the many potential stressors that predispose people to stress and take a proactive approach to address them before patients present with stress-related symptoms. The number of simultaneous demands, the duration of these demands, primary appraisal or perception of the demands (see Figure 8-1), previous experience with similar demands, and the patient's family and loved ones' responses to the demands should be considered in the health assessment. Demands may also be categorized as representing harm or loss, threat, or challenge. Eliciting the demand's personal meaning to the patient provides useful insight for planning interventions and self-management strategies with patients. Distinct

groups such as immigrants and Indigenous people may have specific stressors such as language barriers and limited understanding of Western medical practices and available resources that may predispose them to stress, and these stressors should be considered when a nursing assessment is performed.

Human Responses to Stress.

Physiological effects of demands that are appraised as stressful are mediated primarily by the sympathetic nervous system and the hypothalamic–pituitary–adrenal system. Examples of such effects are responses such as increased heart rate, increased blood pressure, loss of appetite, hyperventilation, sweating, and dilated pupils. Symptomatic experiences may include headache, musculo-skeletal pain, gastro-intestinal upset, skin disorders, insomnia, and chronic fatigue. In addition, the patient may exhibit some of the stress-related illnesses or diseases of adaptation (see Table 8-2).

Behavioural manifestations may include accident proneness, anxiety, crying, frustration, and shouting. Behaviour in other aspects of life may include absenteeism or tardiness at work, avoidance of conversations, or procrastination. Observable cognitive responses include self-reports of excessive demand, inability to make decisions, impaired speech, and forgetfulness or inability to concentrate. Some of these responses may also be apparent in stressed caregivers.

Coping.

Secondary appraisal by the patient, or the patient's evaluation of coping resources and options, is important to assess (see Figure 8-1). Resources such as supportive family members, adequate finances, and the ability to solve problems are examples of positive resources (see Table 8-3). Knowledge of the patient's resources assists the nurse in supporting existing resources and developing strategies to expand the patient's sources of support to include family, friends, and community resources. Positive social support and possessing a large social network (relatives, friends, spiritual groups, support groups) have been shown to exert powerful effects on the negative distress associated with illness. Conversely, aversive relationships (punishing, demanding, distancing relationships) may add to life stress and intensify illness-associated pain and distress.

Coping strategies include cognitive and behavioural efforts to meet demands. The use and effectiveness of problem-focused and emotion-focused coping efforts should be addressed (see Table 8-4). These efforts may be categorized as direct action, avoidance of action, seeking information, defence mechanisms, and seeking the assistance of other people. The probability that a certain coping strategy will bring about the desired result is another important aspect to be assessed. Effective coping skills can be taught, and nurses are in a prime position to teach these skills.

Nursing Implementation

The first step in managing stress is to become aware of its presence. The role of the nurse is to facilitate and enhance the processes of coping and adaptation that include identifying and expressing stressful feelings. Nursing interventions depend on the severity of the stress experience or demand. The person with multiple traumas expends energy in an attempt to physically survive. The nurse's efforts are directed to life-supporting interventions and to the inclusion of approaches aimed at the reduction of additional stressors to the patient. The individual who has endured significant trauma is much less likely to adapt or recover if faced with additional stressors such as sleep deprivation or an infection.

The importance of cognitive appraisal in the stress experience should prompt the nurse to assess whether changes in the way a person perceives and labels particular events or situations (cognitive reappraisal) are possible. Some experts also propose that the nurse consider the positive effects that result from successfully meeting stressful demands. Greater emphasis should also be placed on the part that cultural values and beliefs can play to enhance or constrain various coping options.

Because dealing with physical, social, and psychological demands is an integral part of daily experiences, the coping behaviours that are used should be adaptive and should not be a source of additional stress to the individual. Generalizing about which coping strategies are the most adaptive is not possible. However, in evaluating coping behaviours, the nurse should examine the short-term outcomes (i.e., the effect of the strategy on the reduction or mastery of the demands and the regulation of the emotional response) and the long-term outcomes that relate to health, morale, and social and psychological functioning. Nursing students often experience high levels of stress because of the demands of their educational programs; Table 8-9 provides some useful suggestions for coping.

TABLE 8-9
COPING STRATEGIES FOR THE NURSING STUDENT

- Be realistic: do not try to be superhuman.
- Learn to "let go" of things that are outside your control.
- Learn to adapt and to be flexible.
- Learn acceptance of yourself.
- Share your feelings.
- Keep a sense of humour; laugh often.
- Learn and use relaxation breathing, imagery, meditation, or prayer.
- Live a healthy lifestyle (exercise, nutrition, adequate sleep, not smoking, moderate use of alcohol).
- Develop hobbies.
- Take time to relax every day.
- If it is needed, obtain professional counselling.

Various factors affect an individual's response to stressors (see the "Determinants of Health" box earlier in this chapter). Resistance to stress can be increased with a lifestyle that supports optimal health regardless of sex, age, and economic status. Healthy behaviours are also cumulative; that is, the greater the number of these behaviours habitually practised by the individual, the better that person's health is. These behaviours include the following practices.

1. Sleeping regularly 7 to 8 hours per night
2. Eating breakfast
3. Eating regular, well-balanced meals with minimal, healthy snacking
4. Eating moderately to maintain an ideal weight
5. Exercising moderately
6. Enjoying recreational and relaxing activities with friends
7. Drinking alcohol in moderation or not at all
8. Not smoking (best outcome if the person has never smoked)
9. Learning to successfully handle life's stressors and hassles

Good mental health practices are important for good health as well. These practices result primarily in a realistic, positive self-concept and the ability to solve problems. Teaching problem-solving skills can equip individuals to better handle present and future encounters with stressful circumstances.

Stress-reducing activities can be incorporated into nursing practice (Table 8-10). The activities provide mechanisms whereby an individual is able to develop a sense of control of the situation. As stress-reducing practices are incorporated into daily activities, the individual is able to increase his or her confidence and self-reliance and limit the emotional

response to the stressful circumstances. Possessing a sense of control over one's life, believing that one is able to overcome adversity, and being committed to that end are important characteristics that can avert the harmful effects inherent in the stress response.

TABLE 8-10
IMPLEMENTING STRESS MANAGEMENT IN CLINICAL PRACTICE

- Learn relaxation–coping techniques by practising them on your own; then practise teaching them to peers before teaching them to patients. Attend seminars and workshops on stress management to learn more.
- Be aware of potential stressors that the patients face.
- Assess your patients for the demands placed on them, their response to these demands, and coping resources being used or available to them.
- Choose the language you use carefully, and be aware of your nonverbal communication. Words or gestures that express overt alarm or ambiguity may increase the stress experience for the patient.
- Pick coping strategies and stress management strategies that are appropriate for your clinical area.
- Take advantage of opportunities to teach coping and relaxation strategies to patients.
- Anticipate setbacks. They provide feedback about what you are doing wrong. Do *not* quit practising!

The nurse can assume a primary role in planning stress-reducing interventions. Specific relaxation strategies are presented in Table 8-6. Specific stress-reducing activities within the scope of nursing practice (some of which may require additional training) include relaxation training, guided imagery, cognitive reappraisal, music therapy, exercise, time management, decisional control, assertiveness training, massage, meditation, and humour (see Table 8-5). There is ample evidence of the effectiveness of stress management interventions in a variety of illnesses. Nurses are in an ideal situation to take the lead in integrating stress management into their practice. Nurses are also well equipped to develop and test the effectiveness of new approaches to manage stress and promote positive health outcomes. However, it is important for the nurse to recognize when the patient, family, or caregivers need to be referred to a professional with advanced training in counselling.

Case Study

Stress Associated With Cancer Diagnosis and Treatment

Source: Chris from Paris/Shutterstock.com.

Patient Profile

Mrs. Zyskowski, a Polish immigrant, received a diagnosis of stage 2 breast cancer at age 44. Her treatment plan included lumpectomy followed by a regimen of chemotherapy and then radiation therapy. She attributed her breast cancer to her depression, which developed while she cared for her mother, who suffered from Alzheimer's disease. Her mother passed away 6 months before the breast cancer diagnosis.

After completion of her lengthy breast cancer therapy, Mrs. Zyskowski's depression worsened. She no longer had her frequent visits to the breast cancer centre, and she missed the interaction with the nurses and other patients. In addition, Mrs. Zyskowski feared that her cancer would recur, and she worried that she would "pass it on" to her two teenage daughters. She would not discuss her fears with her husband or daughters because she did not want to burden them. She began to lose weight and constantly felt fatigued. She felt "alone" with her cancer and lost interest in other aspects of her life. She thought about joining a cancer support group but was embarrassed by her Polish accent.

Discussion Questions

1. Consider Mrs. Zyskowski's situation, and describe the physiological and psychological stressors that she is dealing with. Describe the possible effects of these stressors on her health status.
2. What are some other potential stressors that Mrs. Zyskowski may be experiencing that the nurse should anticipate and assess further for?
3. What specific nursing interventions can be included in Mrs. Zyskowski's management that will enhance her adaptability?
4. On the basis of Mrs. Zyskowski's profile, what resources are available to Mrs. Zyskowski to help her cope with her cancer diagnosis and treatment?
5. Should Mrs. Zyskowski join a cancer support group? If so, how might this benefit her?

6. ***Priority decision:*** On the basis of the assessment data provided, what are the priority nursing diagnoses? Are there any collaborative problems?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. How does Selye define stress?
   a. Any stimulus that causes a response in an individual
   b. A response of an individual to environmental demands
   c. A physical or psychological adaptation to internal or external demands
   d. The result of a relationship between an individual and the environment that exceeds the individual's resources
2. A client who has undergone extensive surgery for multiple injuries has a period of increasing blood pressure, heart rate, and alertness. Which stage of general adaptation syndrome are these symptoms most characteristic of?
   a. The resistance state of general adaptation syndrome
   b. The alarm reaction of the general adaptation syndrome
   c. The stage of exhaustion of general adaptation syndrome
   d. An individual response stereotype
3. Which of the following actions best demonstrates that a client is using an emotion-focused coping process? *(Select all that apply.)*
   a. Joining a support group for women with breast cancer
   b. Considering the advantages and disadvantages of the various treatment options
   c. Delaying treatment until her family can take a weekend trip together
   d. Telling the nurse that she has a good prognosis because the tumour is small
   e. Engaging in meditation
4. The nurse would expect which of the following findings in a client as a result of the physiological effect of stress on the limbic system?
   a. An episode of diarrhea while awaiting painful dressing changes
   b. Refusing to communicate with nurses while awaiting a cardiac catheterization
   c. Inability to sleep the night before beginning to self-administer insulin injections

d. Increased blood pressure, decreased urine output, and hyperglycemia after a car accident

5. Which of the following best demonstrates that the nurse is applying knowledge of the effects of stress on the immune system?
   a. Encouraging clients to sleep for 10 to 12 hours per day
   b. Encouraging clients to receive regular immunizations when they are stressed
   c. Encouraging clients to use emotion-focused rather than problem-focused coping strategies
   d. Encouraging clients to avoid exposure to upper respiratory infections when physically stressed
6. Chronic stress or daily hassles may place a person at higher risk of developing which of the following conditions? *(Select all that apply.)*
   a. Osteoporosis
   b. Colds and flu
   c. Low blood pressure
   d. Irritable bowel syndrome
   e. Depression
7. During a stressful circumstance that is uncontrollable, which type of coping strategy is the most effective?
   a. Avoidance
   b. Coping flexibility
   c. Emotion-focused coping
   d. Problem-focused coping
8. Which of the following clients is least likely to respond to stress effectively?
   a. One who feels that the situation is directing his or her life
   b. One who sees the situation as a challenge to be addressed
   c. One who has a clear understanding of his or her values and goals
   d. One who uses more problem-focused than emotion-focused coping strategies
9. Which of the following is an appropriate nursing intervention for a client who has a nursing diagnosis of *ineffective coping* related to *inadequate resources*?

a. Controlling the environment to prevent sensory overload and promote sleep

b. Encouraging the client's family to offer emotional support by frequent visiting

c. Arranging for the client to phone family and friends to maintain emotional bonds

d. Asking the client to describe previous stressful situations and how she managed to resolve them

1. d; 2. b; 3. a, e; 4. c; 5. d; 6. b, d, e; 7. c; 8. a; 9. d.

CHAPTER 9

Sleep and Sleep Disorders

Written by, Diana Taibi Buchanan

Adapted by, Holly Symonds-Brown

LEARNING OBJECTIVES

1. Define *sleep.*
2. Describe physiological sleep mechanisms and stages of sleep.
3. Explain the relationship of various diseases/disorders and sleep disorders.
4. Describe the etiology, clinical manifestations, and collaborative and nursing management of insomnia.
5. Describe the etiology, clinical manifestations, and collaborative and nursing management of narcolepsy.
6. Describe the etiology, clinical manifestations, collaborative care, and nursing management of obstructive sleep apnea.
7. Describe parasomnias, including sleepwalking, sleep terrors, and nightmares.
8. Select appropriate strategies for managing sleep problems associated with shift work.

KEY TERMS

cataplexy, p. 132
circadian rhythms, p. 125
circadian rhythm sleep–wake disorders (CRSWDs), p. 132
continuous positive airway pressure (CPAP), p. 134

Sleep

Sleep is a state during which an individual lacks conscious awareness of environmental surroundings and from which the individual can be easily aroused. Sleep is distinct from unconscious states such as coma, from which the individual cannot be aroused. Sleep is a basic, dynamic, highly organized, and complex behaviour that is essential for normal functioning and survival. A third of most humans' lives is spent in sleep (Gamaldo, Chung, Kang, et al., 2014). Both behavioural and physiological functions are influenced by sleep. Some of these include memory, mood, cognitive function, hormone secretion, glucose metabolism, immune function, body temperature, and renal function.

Sleep requirements vary over the lifespan and are affected by health, lifestyle, and gender (Gamaldo, Chung, Kang, et al., 2014; Hirshkowitz, Whiton, Albert, et al., 2015). Most adults require at least 7 to 9 hours of sleep within a 24-hour period (Hirshkowitz, Whiton, Albert, et al., 2015). The term **sleep disturbances** refers broadly to situations of poor quality sleep. *Insufficient sleep* refers to obtaining less sleep than a person requires to be fully awake and alert during the day (Figure 9-1). *Fragmented sleep* is characterized by frequent arousals or actual awakenings that interrupt sleep continuity. Sleep disturbances can be related to a variety of physical, emotional, environmental, and lifestyle factors.

FIGURE 9-1 Sleep disorders are common in our society. Source: Iakov Filimonov/Shutterstock.com.

Sleep disorders are conditions that specifically affect the quality of sleep and wake behaviour. The classification of sleep disorders is complex; 81 different types have been identified. Table 9-1 lists the seven categories of

sleep disorders with some examples based on the International Classification of Sleep Disorders—Third Edition (ICSD-3; Sateia, 2014).

TABLE 9-1

SELECTED SLEEP DISORDERS

Type of Disorder	Characteristics
Insomnia	• Chronic • Short term
Sleep-related breathing disorders	• Obstructive sleep apnea • Central sleep apnea syndromes
Central disorders of hypersomnolence	• Types 1 and 2 narcolepsy • Hypersomnia related to a medical condition • Hypersomnia related to medication or substance
Sleep-related movement disorders	• Periodic limb movement disorder • Restless legs syndrome
Circadian rhythm sleep–wake disorders	• Delayed sleep–wake phase disorder • Shift work sleep disorder
Parasomnias	• Sleepwalking • Sleep terrors • Nightmare disorder
Other sleep disorders	

More than 3 million Canadians have a sleep disorder, and many are unaware that they have a problem (Morin, LeBlanc, Bélanger, et al., 2011; Public Health Agency of Canada, 2009). On average, Canadians sleep approximately 6.5 hours on workdays and 7.5 hours on non-workdays. In one survey, 40.2% of Canadians reported at least one symptom of insomnia for a minimum of 3 nights a week in the previous month, and close to 20% of the survey respondents reported being dissatisfied with the quality of their sleep (Morin, LeBlanc, Bélanger, et al., 2011). People with chronic health problems or physical disability are at greatest risk for sleep disorders (Ahn, Jiang, Smith, et al., 2014).

Untreated sleep disorders pose considerable health and economic consequences. Sleepiness during driving has become a national epidemic. An estimated 20% of fatal driving collisions involve driver fatigue (Transport Canada, 2011). Some work-related accidents have been linked to sleep problems (Uehli, Mehta, Miedinger, et al., 2014). Each year, sleep disorders, sleep loss, and excessive daytime sleepiness add billions of dollars to the cost of health care and to the economic effect of work-related accidents and lost productivity (Knauert, Naik, Gillespie, et al., 2015). Many sleep disorders go untreated because health care providers often do not ask, and patients often do not talk, about sleep problems.

Physiological Sleep Mechanisms

Sleep–Wake Cycle

The nervous system controls the cyclical changes between waking and sleep. No single neuronal structure regulates sleep and waking; rather, a complex arrangement of structures controls these behaviours. Key nuclei in the brain stem, hypothalamus, and thalamus are involved in the regulation of sleep and wake behaviours.

Wake Behaviour.

Wake behaviour is associated with an activated cortical brain wave (electroencephalographic [EEG]) pattern. The reticular activating system in the middle of the brain stem is associated with generalized EEG activation and behavioural arousal. Various neurotransmitters (glutamate, acetylcholine, norepinephrine, dopamine, histamine, serotonin) are involved in wake behaviour. Histamine neurons in the hypothalamus stimulate cortical activation and wake behaviour. The sedating properties of many over-the-counter (OTC) medications result from inhibiting one of these arousal systems (especially acetylcholine and histamine).

Neuropeptides also influence wake behaviour. *Orexin* (also called hypocretin) is found in the lateral hypothalamus. Orexin stimulates wake behaviour through activating the reticular activating system. Decreased levels of orexin or its receptors lead to difficulties staying awake and in the syndrome called *narcolepsy* (Levenson, Kay, & Buysse, 2015). (Narcolepsy is discussed later in this chapter.)

Sleep Behaviour.

Sleep behaviour is regulated by a variety of neurological structures and neurotransmitters. Ventral lateral and median preoptic areas of the brain interact with other areas of the brain such as the hypothalamus and the brain stem to induce sleep by inhibiting the arousal centres. Sleep-promoting neurotransmitters and peptides include melatonin, adenosine, somatostatin, growth hormone–releasing hormone, delta-sleep–inducing peptide, prostaglandins, and proinflammatory cytokines (interleukin-1, tumour necrosis factor α, interleukin-6; Levenson, Kay, & Buysse, 2015). Proinflammatory cytokines are important in mediating sleepiness and lethargy associated with infectious illness. Certain peptides, such as cholecystokinin, released by the gastrointestinal tract after food ingestion, may mediate the sleepiness that follows eating meals *(postprandial sleepiness).*

Circadian Rhythms

Many biological rhythms of behaviour and physiology fluctuate within a 24-hour period. These **circadian rhythms** (from the Latin *circa dies,* "approximately a day") persist when people are placed in isolated environments free of external time cues because the rhythms are controlled by internal (endogenous) clock mechanisms. The suprachiasmatic nucleus in the hypothalamus is the master clock of the body. The 24-hour cycle is synchronized to the environmental light and dark periods through specific light detectors in the retina. Pathways from the suprachiasmatic nucleus innervate sleep-promoting cells in the anterior hypothalamus and wake-promoting cells of the lateral hypothalamus and brain stem.

Light is the strongest time cue for the sleep–wake rhythm. Because of this, light can be used as therapy to shift the timing of the sleep–wake rhythm. For example, bright light used early in the morning causes the sleep–wake rhythm to move to an earlier time; bright light used in the evening causes the sleep–wake rhythm to move to a later time. *Melatonin* is an endogenous hormone produced by the pineal gland in the brain from the amino acid tryptophan. In the central nervous system, melatonin decreases *sleep latency* (time it takes to fall asleep) and increases *sleep efficiency* (time spent asleep in comparison with time spent in bed). The secretion of melatonin is tightly linked to the environmental light–dark cycle. Under normal day–night conditions, more melatonin is released in the evening as it gets dark. Light exposure in the evening hours can suppress the secretion of melatonin (LeGates, Fernandez, & Hattar, 2014.) This can have implications for sleep quality in hospitalized patients, shift workers, and people who are exposed to computer and TV screens in the evening.

Sleep Architecture

On the basis of electrical recordings of brain activity with polysomnography (PSG), sleep can be divided into two major states: *rapid eye movement (REM)* and *non–rapid eye movement (NREM)*. Most adults transition from wake to sleep *(sleep onset latency)* in approximately 10 to 20 minutes. Once asleep, a person goes through sleep cycles. A typical sleep cycle lasts 90 minutes and is repeated throughout the duration of the person's total sleep time. *Sleep architecture* refers to the pattern of a person's sleep stage cycling.

Non–Rapid Eye Movement Sleep.

In healthy adults, the largest percentage of sleep time, approximately 75% to 80%, is spent in NREM sleep. NREM sleep is subdivided into three stages (Scammell, 2015b).

Stage 1 occurs in the beginning of sleep, with slow eye movements, and is a transition phase from wakefulness to sleep. It is short in duration, lasting 1 to 7 minutes, during which the person can be easily awakened. Stage 2 is a period of sound sleep. The heart rate slows down and the body temperature drops. This stage lasts 10 to 25 minutes. Stage 3 is deep sleep, or slow-wave sleep, and is the deepest stage of sleep. During this stage, the sleeper is less responsive to environmental stimuli and unresponsive to sound. This stage lasts 20 to 40 minutes and is most common earlier in a person's total sleep time. Dreaming is more common in this stage than in other stages of NREM sleep, although not as common as in REM sleep.

Rapid Eye Movement Sleep.

REM sleep accounts for 20% to 25% of sleep and occurs more in the later part of a person's total sleep time. REM sleep follows NREM sleep. In a healthy adult, REM sleep occurs four to five times during a period of 7 to 8 hours of sleep. This stage is considered paradoxical because the brain waves resemble wakefulness but movement of the skeletal muscles is inhibited. REM sleep is the period when the most vivid dreaming occurs.

Effects of Sleep Deprivation

Sleep deprivation and poor quality of sleep are associated with changes in body function (Figure 9-2) and health problems (Table 9-2). In patients with chronic illnesses, especially cardiovascular disease and stroke, sleep disorders are directly associated with increased risk for mortality and morbidity (Stopford, Ravi, & Nayar, 2013). Sleep loss is associated with decreases in immune function and body temperature and with endocrine changes, including a decrease in growth hormone levels. Cognitive function and performance on simple behavioural tasks become impaired within 24 hours of sleep loss. The effects of sleep loss are cumulative. Chronic loss of sleep places the individual at risk for a decrease in cognitive function, depression, impaired daytime functioning, social isolation, and overall reduction in quality of life (Sutton, 2014).

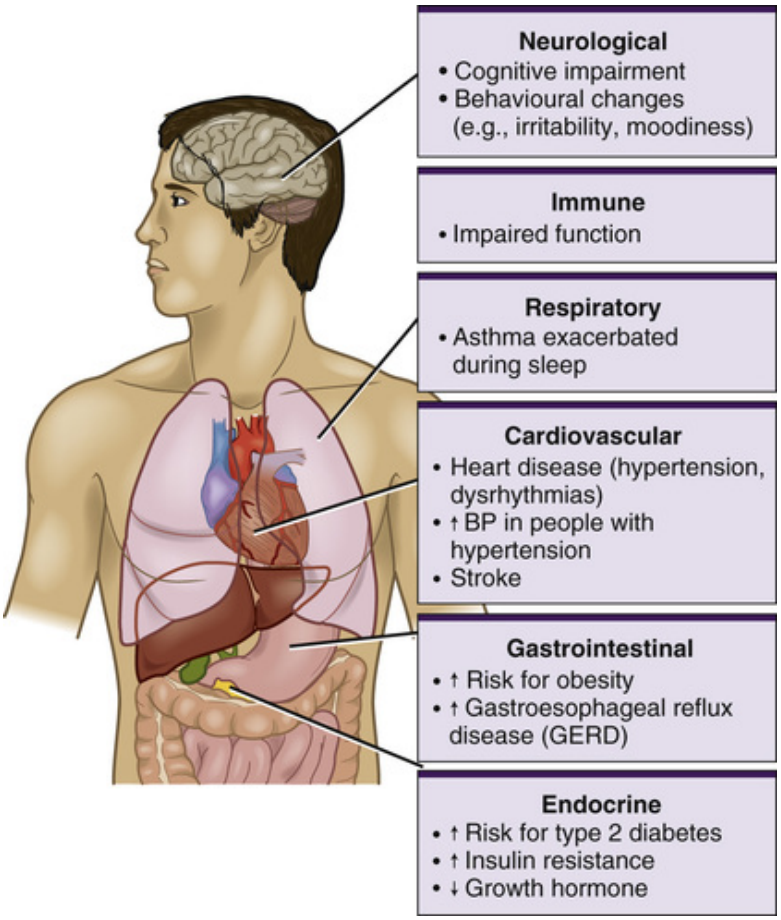

FIGURE 9-2 Effects of sleep deprivation and sleep disorders on the body. *BP,* blood pressure.

TABLE 9-2

RELATIONSHIP OF SLEEP DISTURBANCES TO SELECTED DISEASES AND DISORDERS

Disease/Disorder	Sleep Disturbance
Respiratory	
Asthma	• Exacerbated during sleep • Reports of more insomnia
Chronic obstructive pulmonary disease (COPD)	• Associated with poor sleep quality, nocturnal O_2 desaturation, and coexisting sleep apnea
Obstructive sleep apnea	• Linked to heart disease (hypertension, stroke, coronary artery disease, dysrhythmias) • Impairment of glucose control similar to that occurring in type 2 diabetes • Associated with cancer
Renal	
End-stage renal disease	• Disrupted nocturnal sleep with excessive daytime sleepiness • In patients on dialysis, high incidence of SDB, PLMD, and RLS, which is a significant predictor of mortality in such patients
Immune Disorders	
Human immunodeficiency virus (HIV)	• Sleep disturbances and fatigue highly prevalent and associated with lower rates of survival
Endocrine	
Diabetes	• Insufficient sleep linked to increased risk for type 2 diabetes • Insulin resistance increased in healthy people with sleep deprivation • Sleep duration and quality predictive of Hb A1c levels, an important marker of blood glucose control
Musculoskeletal	
Arthritis	• Increased rates of RLS and SDB; disease activity linked to sleep complaints
Fibromyalgia	• Dysfunctional sleep regulation in relation to altered circadian rhythms and lower concentrations of sleep-dependent hormones (growth hormone, prolactin)
Chronic fatigue syndrome	• Sleep disturbances, including decreases in total sleep time, reported
Cancer	• Higher rates of insomnia reported • Chemotherapy for cancer treatment associated with fragmented sleep
Cardiovascular (CV)	• With sleep apnea/sleep disorders, increased risk for CV disorders, including hypertension, dysrhythmias, and coronary artery disease
Heart failure	• Sleep d0sturbances (insomnia, PLMD, SDB) common • Signs of heart failure exacerbation (Cheyne-Stokes breathing and central apnea) in relation to fluid overload • Central sleep apnea correlated with poor left ventrical function
Central sleep	• In people with hypertension, further elevations in blood pressure as result of inadequate sleep
Gastrointestinal	
Obesity	• Association between short sleep duration and excess body weight; short sleep duration may result in metabolic changes that are linked to obesity. • Higher BMI in people who sleep <6 hr than in people who sleep >8 hr • Poor sleep associated with low levels of leptin and high levels of ghrelin
Gastro-esophageal reflux disease (GERD)	• Reflux of gastric contents into the esophagus during sleep because of incompetent lower esophageal sphincter
Chronic liver disease	• Associated with excessive sleepiness, nocturnal arousal, and incidence of RLS
Bowel disorders	• Associated with increased insomnia
Neurological	
Parkinson's disease	• Associated with difficulty initiating or maintaining sleep, parasomnias, and excessive daytime sleepiness

Disease/Disorder	Sleep Disturbance
Alzheimer's disease	• SDB (frequently sleep apnea) common • Circadian rhythm alterations with nocturnal wandering, daytime sleepiness, and sleep disruption and awakening
Pain (acute and chronic)	• Decreased quantity and quality of sleep; poor sleep can intensify pain
Depression	• Can result in insomnia or hypersomnia • Amount and quality of REM sleep often affected by anti-depressant medication

BMI, Body mass index; *Hb A1c*, hemoglobin A1c; *PLMD*, periodic limb movement disorder; *RLS*, restless legs syndrome; *SDB*, sleep-disordered breathing.

Sources: Centers for Disease Control and Prevention. (2011). *Sleep and chronic disease*. Retrieved from *http://www.cdc.gov/sleep/about_sleep/chronic_disease.html*; and from National Sleep Foundation (2016). *Sleep disorders.* Retrieved from *https://sleepfoundation.org/sleep-disorders-problems*.

An insufficient amount of nighttime sleep has a harmful effect on carbohydrate metabolism and endocrine function. Individuals who report less than 6 hours of sleep a night have a higher body mass index (BMI) and are more likely to be obese. Sleep restriction and sleep fragmentation have been linked to decreased insulin sensitivity and increased risk for diabetes (Reutrakul & Van Cauter, 2014). In women with shortened or disturbed sleep, the risk for heart disease was found to be double that of women with adequate sleep (Rod, Kumari, Lange, et al., 2014).

Sleep Disturbances in the Hospital

Hospitalization, especially in the intensive care unit (ICU), is associated with decreases in total sleep time, sleep efficiency, and REM sleep. Pre-existing sleep disorders may be aggravated or triggered in the hospital. Environmental sleep-disruptive factors, psychoactive medications, and acute and critical illness all contribute to poor sleep. Symptoms such as pain, dyspnea, and nausea can also contribute to sleep loss in acutely ill patients.

Medications commonly used in acutely and critically ill patients can further contribute to sleep loss, by exacerbating sleep disordered breathing (discussed later in this chapter) or by altering sleep architecture. Nightmares can also occur as a result of medication and are commonly reported by patients in the ICU. The longer the stay in the ICU, the more likely the patient is to have nightmares. Drug classes most likely to cause nightmares are sedative–hypnotics, β-adrenergic antagonists, dopamine agonists, and amphetamines.

Hospitalized patients are also at risk for poor sleep partly because of disruptions in circadian rhythm. The hospital or long-term care facility represents a new environment, and thus normal cues linked to sleep may

be absent. Bright lights during the night can also disrupt sleep. The hospital and ICU environmental noise (e.g., staff paging system, respirator alarms, bedside monitors, infusion alarms, staff conversations near patients) during both the day and the night can result in sleep difficulties. In addition, patient care activities (e.g., dressing changes, blood draws, vital sign monitoring) disrupt sleep. Patients in critical care areas have been found to have poor quantity and quality of sleep, with predominantly stage 1 and 2 sleep (Tracy & Chlan, 2011). Sleep can continue being poor after the patient's hospitalization and can affect the long-term recovery and health. Staff prioritization of sleep over other competing critical care demands and the lack of research into sleep promotion within the ICU can affect use of sleep-promoting interventions (Hopper, Fried, & Pisani, 2015).

Decreased sleep duration influences pain perception. Psychological factors, such as anxiety and depression, also modify the sleep–pain relationship. Adequate pain management improves the duration and quality of sleep, but medications commonly used to relieve pain, especially opioids, also alter sleep and place the individual at risk for sleep-disordered breathing. Withdrawal of opioids is associated with rebound effects on sleep architecture.

Nurses have a critical role in creating an environment conducive to sleep. This includes the scheduling of medications and procedures during both day and night. Typical sleep architecture should be considered when interventions and care are planned. When any necessary care episodes are scheduled 90 minutes (or a multiple of that) after a patient has fallen asleep, sleep disruption has been decreased. Reducing light and noise levels or use of earplugs can promote opportunities for sleep.

Sleep Disorders

Insomnia

The most common sleep disorder is insomnia. **Insomnia** is defined as difficulty falling asleep, difficulty staying asleep, waking up too early, or poor quality of sleep. Insomnia is a common problem, affecting approximately one in three adults.

Acute insomnia refers to difficulties falling asleep or remaining asleep and experiencing daytime fatigue for at least 3 nights per week over a 2-week period. *Chronic insomnia* is defined by the same symptoms and a daytime complaint (e.g., fatigue, poor concentration, interference with social or family activities) that occur at least 3 times a week and persist for 3 months or longer. Chronic insomnia occurs in 10% to 15% of Canadians and is more common in women than in men (Morin, LeBlanc, Bélanger, et al., 2011). Chronic insomnia increases in people older than 45 years, and the incidence is higher in divorced, widowed, and separated individuals, as well as in individuals with low socioeconomic status and lower amounts of education (Morin, LeBlanc, Bélanger, et al., 2011).

Etiology and Pathophysiology

Behaviours, maladaptive cognitions, lifestyle, diet, and medications contribute to and perpetuate insomnia. *Inadequate sleep hygiene* refers to practices or behaviours that are inconsistent with quality sleep. Consumption of stimulants (e.g., caffeine, nicotine, methamphetamine, other drugs of abuse), especially before bedtime, results in insomnia. Insomnia is a common adverse effect of many medications (e.g., antidepressants, antihypertensives, corticosteroids, psychostimulants, analgesics). Insomnia can be exacerbated or perpetuated by consumption of alcohol to help induce sleep, smoking close to bedtime, taking long naps in the afternoon, sleeping in until late in the morning, nightmares, exercise near bedtime, and jet lag. *Maladaptive cognitions* concern personal beliefs and interpretations of sleep-related experiences; this is the key area addressed by cognitive–behavioural interventions for sleep (discussed later in this chapter).

Once chronic insomnia is manifested, symptoms are likely to persist over time. Individuals with insomnia may engage in behaviours that perpetuate disturbed sleep by keeping irregular sleep–wake schedules,

using OTC medications or alcohol as sleep aids, and spending more time in bed trying to sleep. Increased attention to one's environment, worry or fear about not obtaining sufficient sleep, and poor sleep habits can lead to a conditioned arousal.

Clinical Manifestations

Manifestations of insomnia include (1) difficulty falling asleep *(long sleep latency),* (2) frequent awakenings *(fragmented sleep),* (3) prolonged nighttime awakenings or awakening too early and not being able to fall back to sleep, and (4) feeling unrefreshed on awakening (as a result of *nonrestorative sleep*). Daytime consequences of insomnia may manifest as tiredness, trouble concentrating at work or school, altered mood, and falling asleep during the day. Behavioural manifestations of poor sleep include irritability, forgetfulness, confusion, difficulty staying awake during the day, and anxiety.

Diagnostic Studies

Self-Report.

The diagnosis of insomnia is based on subjective complaints and on an evaluation of a 1- or 2-week sleep diary completed by the patient. A panel of sleep experts created the Consensus Sleep Diary to standardize the type of information that clinicians collect in sleep diaries (Carney, Buysse, Ancoli-Israel, et al., 2012). In ambulatory care settings, the evaluation of insomnia requires a comprehensive sleep history to establish the type of insomnia and to screen for possible comorbid psychiatric, medical, or sleep disorder conditions that would necessitate specific treatment. Questionnaires such as the Pittsburgh Sleep Quality Index and the Consensus Sleep Diary (see the Resources at the end of this chapter) are examples of questionnaires commonly used to assess sleep quality (Buysse, Reynolds, Monk, et al, 1989; Carney, Buysse, Ancoli-Israel, et al., 2012; Johns, 1991).

Actigraphy.

Actigraphy is a relatively noninvasive method of monitoring rest and activity cycles. A small actigraph watch, which can be worn on the wrist like a watch, is used to measure gross motor activity (Figure 9-3). The watch continually records the movements. After the data are collected, they are downloaded to a computer, and algorithms are used to analyze

the data. Actigraphy is not required to diagnose insomnia but can be used to confirm patient's sleep self-reports and clarify sleep and activity patterns during treatment.

FIGURE 9-3 Actigraph watch worn while the patient is sleeping.
Source: Courtesy Itamar Medical, Inc.

Polysomnography.

A clinical PSG study is not necessary to establish a diagnosis of insomnia. A PSG study is performed only if there are symptoms or signs of a sleep disorder, such as sleep-disordered breathing (discussed later in this chapter). In a PSG study, electrodes simultaneously record physiological measures that define the main stages of sleep and wakefulness. These measures include (a) muscle tone, recorded with electromyography; (b) eye movements, recorded with electro-oculography; and (c) brain activity, recorded through an EEG study. To determine additional characteristics of specific sleep disorders, other measures are made during PSG. These include airflow at the nose and mouth, respiratory effort around the chest and abdomen, heart rate, noninvasive oxygen saturation, and electromyographic study of the anterior tibialis muscles (used to detect periodic leg movements). In addition, a patient's gross body movements are monitored continuously by audiovisual means.

Collaborative Care

Treatments are oriented toward symptom management (Table 9-3). A key to management is to change behaviours that perpetuate insomnia. This often encompasses cognitive–behavioural strategies and education about sleep, including sleep hygiene. **Sleep hygiene** is a variety of different practices that are important for normal, quality nighttime sleep and daytime alertness (Table 9-4).

TABLE 9-4

PATIENT & CAREGIVER TEACHING GUIDE
Sleep Hygiene

The nurse should include the following instructions when teaching a patient who has sleep disturbances/disorders:
• Try to set a bedtime that will allow you adequate sleep hours. • Go to bed only when you are feeling sleepy. • Keep a regular schedule of bedtime and awakening times (including weekends). • Use bedtime routines that help you relax, such as warm baths or listening to music. • Avoid bright light exposure in evenings (screen-time exposure from smart phones, computers, tablets, and TVs should be considered, as well as environmental lighting). • Your bed should be used only for sleep and sex. • Do not have beer, wine, or any other alcohol within 6 hours of your bedtime. • Do not have a cigarette or any other source of nicotine before bedtime. • Do not consume caffeine in late afternoon and evening. • Do not go to bed hungry, but do not eat a big meal near bedtime, either. • Avoid any strenuous exercise close to bedtime. • Avoid sleeping pills, or use them cautiously. • Make your bedroom quiet, dark, and a little bit cool. • Maintain a healthy diet and exercise routine.

Cognitive–Behavioural Therapies.

Cognitive–behavioural therapy for insomnia (CBT-i) is effective in the management of insomnia and should be the first method of therapy (Williams, Roth, Vatthauer, et al., 2013). CBT-i for insomnia includes a structured treatment plan of behavioural routines, relaxation practices, and thought management strategies related to promoting sleep. Examples of strategies that can be included within CBT-i are relaxation training, guided imagery, and cognitive strategies that address dysfunctional ideas about sleep. CBT-i also includes education about good sleep hygiene practices (see Table 9-4). Often a full lifestyle behaviour plan is devised to include regular exercise (performed several hours before bedtime), regular bedtime routines, and time limits for staying in bed. CBTs require individuals to change behaviour and be able to sustain a change in routine. Supporting a patient's behaviour changes requires evaluation of his or her motivation and resources for change before treatments are initiated. Full CBT-i treatment requires providers to have training; it is often delivered by nurses working in primary care and mental health settings. Although not all nurses are trained in CBT-i, they can education people about sleep hygiene and use the principles of CBT-i to help patients set up new routines. For example, individuals with insomnia can be encouraged to avoid watching television, playing video games, or reading in bed. Time in

bed should be limited to the actual time that the individual can sleep. Naps and consumption of large meals, alcohol, and stimulants need to be avoided. Naps are less likely to affect nighttime sleep if they are limited to 20 to 30 minutes.

Drug Therapy.

Despite their perceived usefulness for short-term acute insomnia, medications for sleep are not without risks. Sedatives are linked with increased rates of overall mortality and are linked to adverse events such as falls, motor vehicle accidents, and poisonings. Use of sedatives in Canada has increased sharply in comparison with other prescribed medications (Vozoris & Leung, 2011). The use of sedatives in the management of chronic insomnia, particularly in older adults, is not recommended (American Geriatric Society 2012 Beers Criteria Update Expert Panel, 2012). Many individuals with insomnia become used to taking OTC or prescription medications to treat insomnia and risk becoming dependent on them, both psychologically and physically (Chapter 11 has more information on substance dependence). *Rebound insomnia* is common with abrupt withdrawal of hypnotic medications. The resulting daytime fatigue can negatively influence the patient's efforts to use nondrug approaches.

Classes of medications used to treat insomnia include benzodiazepines and benzodiazepine receptor–like drugs (Table 9-5). Although antidepressants, antihistamines, and antipsychotics are sometimes used as sleep aids, there is actually insufficient evidence to support their use for insomnia (MacFarlane, 2012).

TABLE 9-5
DRUG THERAPY
Insomnia

Drug Class	Specific Drug
Benzodiazepines	• Nitrazepam (Mogadon) • Flurazepam • Temazepam (Restoril) • Triazolam
Benzodiazepine receptor–like drugs	• Zopiclone (Rhovane, Imovane) • Zolpidem
Over-the-counter sleep aids	
Antihistamines	• Diphenhydramine (Benadryl, Nytol, Unisom)
Natural health products	• Melatonin • Valerian

Benzodiazepines.

Benzodiazepines such as diazepam (Valium) work by activating the γ-aminobutyric acid (GABA) receptors to promote sleep. The prolonged half-life of some of these drugs (e.g., flurazepam and nitrazepam) can result in daytime sleepiness, amnesia, dizziness, and rebound insomnia so are not recommended. Temazepam and triazolam are benzodiazepines considered to be suitable for short-term treatment of insomnia because of their fast onset and short half-life, which results in less pronounced daytime effects. None of the benzodiazipines are recommended for use in people older than 65 years (Tanenbaum, 2015). Tolerance to these drugs develops and increases the risk for dependence (see Chapter 11 for more information on benzodiazepine abuse); therefore, it is recommended that the use of benzodiazepines be limited to less than 7 days or to intermittent use of no more than 3 days a week. In addition, benzodiazepines interact with alcohol and other central nervous system depressants.

Benzodiazepine Receptor–like Agents.

Because the safety profile of the so-called Z-drugs (e.g., zolpidem and zopiclone) is better than that of benzodiazepines, Z-drugs are the drug of first choice for insomnia. Adverse effects such as daytime effects, dependence, and motor impairment can still occur; thus close monitoring and short-term use for less than 7 days are recommended (MacFarlane, 2012). Because of the potential delay of activity, these drugs should not be taken with food and should be taken close to bedtime, in combination with other sleep hygiene practices, to enhance sleep.

Antidepressants.

Trazodone, mirtazapine, and amitriptyline are antidepressants with sedating properties. Trazodone is one of the drugs most commonly prescribed in Canada to treat insomnia. However, there is little evidence supporting their use in nondepressed patients, and the potential for adverse effects such as anti-cholinergic effects, dizziness, orthostatic hypotension, and cardiac conduction abnormalities is significant (Davidson, 2012).

Antihistamines.

Many individuals with insomnia self-medicate with OTC sleep aids. Most OTC agents include diphenhydramine (Benadryl, Nytol, Unisom). These agents are less effective than benzodiazepines, and tolerance develops quickly. In addition, they cause adverse effects, including daytime

sedation, impaired cognitive function, blurred vision, urinary retention, and constipation, and they increase the risk for increased intraocular pressure. Agents that contain diphenhydramine are not intended for long-term use and should not be used by older adults.

Complementary and Alternative Therapies.

Many types of complementary therapies and herbal products are used as sleep aids. Common herbal medicines used in Canada are chamomile, melatonin, and valerian root. Other therapies include the use of acupuncture, acupressure, tai chi, and music.

Herbal Supplements.

Chamomile and valerian are herbs that have been used for many years as a sleep aids and to relieve anxiety. Valerian has been found to help with sleep problems related to menopausal symptoms (Taavoni, Ekbatani, & Haghani, 2015). Researchers in only a few small studies have examined chamomile to date, with inconclusive results (Taslaman, 2014). Overall, the current available evidence to support the use of valerian or chamomile to treat insomnia is lacking, and further research is warranted (Leach & Page, 2014).

As noted earlier in the chapter, melatonin is a hormone produced by the pineal gland, which plays an important role in sleep cycle regulation (Lerchl & Reiter, 2012). Melatonin can be somewhat helpful with sleep initiation and efficacy (Costello, Lentino, Boyd, et al., 2014). Although effects on insomnia have been found to be less significant than those of other prescription sleep medications, melatonin is considered much safer (Ferracioli-Oda, Qawasmi, & Bloch, 2013). Melatonin has also been used with sleep phase disorders such as jet lag and shift work disorder, although research evidence for this is weak and further study is required (Costello, Lentino, Boyd, et al., 2014).

Acupuncture.

Acupuncture is an invasive technique that must be performed by a trained provider. Acupuncture has been found in several research trials to improve sleep quality, although due to inconsistent research methods it is not conclusive that it is an effective treatment for insomnia (Cheuk, Yeung, Chung, et al., 2012). Acupressure is a massage technique that can be administered by patients themselves, nursing staff, families, and caregivers. This area of Chinese medicine has been showing promising results with a variety of populations, but continued research is required to

help define the optimum treatment routine and longevity of effect (Simoncini, Gatti, Quirico, et al., 2015).

Other Therapeutic Sleep Aids.

Tai chi is a nonstrenuous exercise and has relaxation effects that have been found to be effective for increasing sleep quality in older adults and people with cardiac disease (Lo & Lee, 2014). Music is another complementary therapy for insomnia (see the following "Complementary & Alternative Therapies" box).

Complementary & Alternative Therapies

Effect of Music on Sleep Quality

Scientific Evidence

Several studies, including randomized control trials, have demonstrated the effectiveness of listening to music as a method to improve sleep quality.

Nursing Implications

- Music is a well-tolerated, nonpharmacological intervention.
- Music is accessible to people in both home and hospital environments.
- Further research on the use of music for sleep may help specify who can benefit the most from the intervention and what factors support its use.

Source: Summarized from Jespersen, K. V., Koenig, J., Jennum, P., et al. (2015). Music for insomnia in adults. *Cochrane Database of Systematic Reviews*, No. 8, Article CD010459. doi:10.1002/14651858.CD010459.pub2.

Nursing Management Insomnia

Nursing Assessment

Nurses are in a key position to assess sleep problems in patients and their family caregivers. Sleep assessment is important in helping patients to identify environmental factors that may contribute to poor sleep. Family caregivers may experience sleep disruptions because of the necessity of providing care to patients in the home. These sleep disruptions can increase the burden of caregiving.

Both subjective and objective methods are used to assess sleep duration and quality. Report of poor sleep is similar to that of pain in that it is a subjective complaint. Many patients may not tell their health care provider about their sleep problems. Therefore, the best way to detect sleep problems is for the nurse to ask about sleep on a regular basis. A sleep history should involve characteristics of sleep, such as the duration and pattern of sleep, and of daytime alertness. Before using any questionnaire, the patient's cognitive function, reading level (if a paper form is used), and language abilities are assessed.

Examples of questions to assess sleep are presented in Table 9-6. The nurse should also assess lifestyle factors that can influence sleep, such as work schedules, diet, and use of caffeine and other stimulants. In asking about how much alcohol is consumed each week, the nurse should find out whether the patient is using alcohol or other substances as sleep aids.

TABLE 9-6

NURSING ASSESSMENT
Sleep

The following questions can serve as an initial assessment regarding sleep:
1. What time do you normally go to bed at night? What time do you normally wake up in the morning?
2. Do you often have trouble falling asleep at night?
3. About how many times do you wake up at night?
4. If you do wake up during the night, do you usually have trouble falling back asleep?
5. Does your bed partner say or are you aware that you frequently snore, gasp for air, or stop breathing?
6. Does your bed partner say or are you aware that you kick or thrash about while asleep?
7. Are you aware that you ever walk, eat, punch, kick, or scream during sleep?
8. Are you sleepy or tired during much of the day?
9. Do you usually take one or more naps during the day?
10. Do you usually doze off without planning to during the day?
11. How much sleep do you need to feel alert and function well?
12. Are you currently taking any type of medication or other preparation to help you sleep?

Source: Harrison G. Bloom, Imran Ahmed, Cathy A. Alessi, Sonia Ancoli-Israel, Daniel J. Buysse, Meir H. Kryger, Barbara A. Phillips, Michael J. Thorpy, Michael V. Vitiello, Phyllis C. Zee. (2009). Evidence-based recommendations for the assessment and management of sleep disorders in older persons. *Journal of the American Geriatrics Society,* 57 (5), 761.

The nurse should ask the patient about sleep aids, both OTC and prescription medications. It is important to note the drug dose and frequency of use, as well as any adverse effects (e.g., daytime drowsiness, dry mouth). Many individuals also consume herbal or dietary supplements to improve sleep. The exact components and concentrations of herbs and supplements often are unknown, and patients may experience adverse effects. Additional sleep aids include white noise devices or relaxation strategies.

The nurse can encourage individuals to keep a sleep diary for 2 weeks. (See the link to the Consensus Sleep Diary in the Resources at the end of this chapter.) Other standardized questionnaires such as the Epworth Sleepiness Scale (see the Resources at the end of this chapter) may be used to assess daytime sleepiness.

The patient's medical history can also provide important information about factors that contribute to poor sleep. For example, men with benign prostatic hyperplasia often report frequent awakenings during the night for voiding. Psychiatric problems such as depression, anxiety, post-traumatic stress disorder, and drug abuse are associated with sleep disturbances. Sleep disturbances often develop as a consequence or complication of a chronic or terminal condition (e.g., heart disease,

dementia, cancer, renal failure). Medical conditions that cause pain such as fibromyalgia or arthritis can also disrupt sleep.

The nurse should ask the patient about work schedules, as well as cross-country and international travel. Shift work can contribute to reduced or poor-quality sleep. Work-related effects of poor sleep may include poor performance, decreased productivity, and job absenteeism.

Nursing Diagnoses

Specific nursing diagnoses related to sleep include *insomnia, sleep deprivation, disturbed sleep pattern,* and *readiness for enhanced sleep.*

Nursing Implementation

Nursing interventions depend on the severity and duration of the sleep problem, as well as on the characteristics of the individual. Occasional difficulty getting to sleep or awakening during the night is not unusual. However, prolonged sleep disruptions become problematic.

The nurse can assume a primary role in teaching about sleep hygiene (see Table 9-4). An important component of sleep hygiene is reducing dietary intake of substances containing caffeine. To reduce caffeine intake, the patient must be aware of the content of caffeine and related stimulants such as guarana and yerba mate in certain foods and beverages (Health Canada, 2012). Table 9-7 provides examples of the caffeine content of beverages and foods. Health Canada recommends no more than 400 mg of caffeine per day for the general adult population and lower amounts for children and women of child-bearing age.

TABLE 9-7

CAFFEINE CONTENT OF SELECTED FOODS AND BEVERAGES

Food/Beverage	Caffeine (mg)
Coffee, brewed (237 mL)	135
Coffee, instant (237 mL)	76–106
Coffee, decaffeinated	5
Black tea, leaf or bag (237 mL)	50
Green tea	30
Herbal tea, all varieties	0
Diet cola (355 mL)	39–50
Cola (355 mL)	36–46
Dr. Pepper (237 mL)	41
Energy drinks (Red Bull, Monster, Rock Star; 237 mL)	80
Chocolate cake (1 piece)	36
Milk chocolate bar (28 g piece)	7
Dark chocolate bar (28 g piece)	19
Hot chocolate (237 mL)	5

Source: Based on Health Canada. (2012). *Caffeine in food*. Retrieved from: *http://www.hc-sc.gc.ca/fn-an/securit/addit/caf/food-caf-aliments-eng.php*.

Nurses are also in an ideal position to take the lead in suggesting and implementing change in patients' homes and institutional environments to enhance sleep. Reducing light and noise levels can enhance sleep. Awareness of time passing and watching the clock can add to anxieties about not falling asleep or returning to sleep.

Patients require education about sleeping medications. With the benzodiazepines and zopiclone (Imovane), the patient is taught to take the drug right before bedtime, to be prepared to get a full night's sleep of at least 6 to 8 hours, and not to plan activities the next morning that require highly skilled psychomotor coordination. The patient should also avoid high-fat foods that can alter drug absorption. To avoid oversedation, these medications should not be taken with alcohol or other central nervous system depressants. Although sleep hygiene education may be helpful, individuals with chronic insomnia require more in-depth training in cognitive–behavioural strategies so referral to a trained provider may be required.

Patient follow-up with regard to medications is important. The nurse should ask the patient about daytime sleepiness, nightmares, and any difficulties in activities of daily living. For patients who have been taking sleeping medications for a period of time, withdrawal of the drug should be tapered.

Narcolepsy

Narcolepsy is a chronic degenerative neurological disorder caused by the brain's inability to regulate sleep–wake cycles normally.

The onset of narcolepsy typically occurs in adolescence (Scammell, 2015a). There are two categories of narcolepsy: type 1 and type 2. With both types of narcolepsy, people experience excessive daytime sleepiness despite adequate sleep. Affected individuals fall asleep for periods lasting from a few seconds to several minutes (Cook, 2013). In significant contrast to people with other sleep disorders, people with narcolepsy awaken refreshed from sleep but become sleepy in a few hours. This excessive sleepiness interferes with sedentary activities and is accompanied by cognitive impairments in attention and working memory (Moraes, Rossini, & Reimão, 2012).

Narcolepsy type 1 is characterized by episodes of **cataplexy**, which is a brief and sudden loss of skeletal muscle tone or muscle weakness. Its manifestations range from a brief episode of muscle weakness to complete postural collapse and falling to the ground. Laughter, anger, or surprise often triggers episodes. Approximately 60% to 70 % of patients with narcolepsy experience cataplexy (Cook, 2013). Patients with narcolepsy, particularly those with cataplexy, have decreased quality of life because of excessive daytime sleepiness. Other common symptoms of narcolepsy are listed in Table 9-8.

TABLE 9-8
COMMON SYMPTOMS OF NARCOLEPSY

Sleep paralysis: a temporary (few seconds to minutes) paralysis of skeletal muscles (except respiratory and extraocular muscles) that occurs in the transition from REM sleep to waking.
Fragmented nighttime sleep
Altered REM sleep regulation (including daytime episodes of REM while awake)
Hypnagogic hallucinations (brief hallucinations that occur at the onset of sleep)
Other sleep disorders such as periodic limb movement disorders, obstructive sleep apnea, REM sleep behaviour disorder
Weight gain
Depression
Anxiety
Chronic pain
Autonomic dysregulation

REM, rapid eye movement.

Sources: Based on Cook, N. (2013). Understanding narcolepsy the wider perspective. *British Journal of Neuroscience Nursing, 9*(2), 76–82; and Scammell, T. E. (2015a). Narcolepsy. *New England Journal of Medicine, 373*(27), 2654–2662. doi:10.1056/NEJMra1500587.

Etiology and Pathophysiology

Type 1 narcolepsy is caused by a loss of hypothalamic neurons that produce orexin (discussed earlier in the chapter; Scammell, 2015a). The cause of type 2 narcolepsy is thought to be similar but remains unknown.

Diagnostic Studies

Narcolepsy is diagnosed on the basis of a history of sleepiness, PSG findings, and daytime *multiple sleep latency tests* (MSLTs). MSLTs are sleep studies in which the patient is encouraged to fall asleep every 2 hours during the day for approximately 20 minutes. Short sleep latencies and onset of REM sleep in more than two MSLTs are diagnostic signs of narcolepsy.

Collaborative Care

Drug Therapy.

Narcolepsy cannot be cured. But excessive daytime sleepiness and cataplexy, the most disabling symptoms of the disorder, can be controlled with drug treatment in most affected patients. Drug management of narcolepsy includes amphetamine-like stimulants to relieve excessive daytime sleepiness and antidepressant drug therapy to control cataplexy (Scammell, 2015a). Sodium oxybate is sometimes used at night to produce a deep non-REM sleep that over time reduces both daytime sleepiness and cataplexy. Because of the significant risk of adverse reactions, this is used only for moderate to severe symptoms of sleepiness and cataplexy.

Behavioural Therapy.

None of the current drug therapies cures narcolepsy or allows patients to consistently maintain a full, normal state of alertness. As a result, drug therapy is combined with various behavioural strategies similar to those for insomnia (discussed earlier in this chapter).

Safety precautions, especially in driving, are crucial for patients with narcolepsy. Excessive daytime sleepiness and cataplexy can result in serious injury or death if not treated. Individuals with untreated narcolepsy symptoms are involved in automobile accidents approximately five times more frequently than is the general population.

Patient support groups are also useful for many patients with narcolepsy and their family members. Social isolation can occur because of

symptoms. Patients with narcolepsy can be stigmatized as being lazy and unproductive because of lack of public and professional understanding about this disorder.

Circadian Rhythm Sleep–Wake Disorders

Circadian rhythm sleep–wake disorders (CRSWDs) are characterized by good quality sleep at the wrong time of day (Gamaldo, Chung, Kang, et al., 2014). This occurs because of lack of synchrony between the circadian time-keeping system and the environment, which disrupts the sleep–wake cycle. **Delayed sleep phase disorder (DSPD)** is the most common CRSWD. With this disorder, people have difficulty falling asleep (staying awake until 0100–0300 hours) and typically sleep later into the morning (waking between 1000 and 1200 hours). Because most people need to get up in the morning for school or work/care responsibilities, chronic sleep restriction and daytime sleepiness result. Typically, DSPD begins in adolescence when there is a normal shift in the sleep–wake drives that then continues into adulthood. Attentional and mood-related issues can result from the chronic sleep restriction and be overlooked as inherent traits. The altered sensitivity of the circadian system is thought to be genetic in origin (Nesbitt & Djik, 2014). People with this disorder are at risk for health sequelae of chronic sleep restriction (see the section "Effects of Sleep Deprivation" later in the chapter).

Shift work disorder is another type of CRSWD and is discussed in the section "Special Sleep Needs of Nurses" later in the chapter.

Sleep-Disordered Breathing

The term **sleep-disordered breathing** indicates abnormal respiratory patterns associated with sleep. These include snoring, apnea, and hypopnea, characterized by increased respiratory effort that leads to frequent arousals. Sleep-disordered breathing results in frequent sleep disruptions and alterations in sleep architecture. Obstructive sleep apnea is the sleep-disordered breathing problem most commonly diagnosed.

Obstructive Sleep Apnea

Obstructive sleep apnea (OSA), also called *obstructive sleep apnea–hypopnea syndrome,* is characterized by partial or complete obstruction of the upper airway during sleep. *Apnea* is the cessation of spontaneous respirations that lasts longer than 10 seconds. *Hypopnea* is a condition characterized by

shallow (30%–90% reduction in airflow) respirations. Airflow obstruction occurs because of narrowing of the air passages with relaxation of muscle tone during sleep, which leads to apnea and hypopnea, or when the tongue and the soft palate fall backward and partially or completely obstruct the pharynx (Figure 9-4).

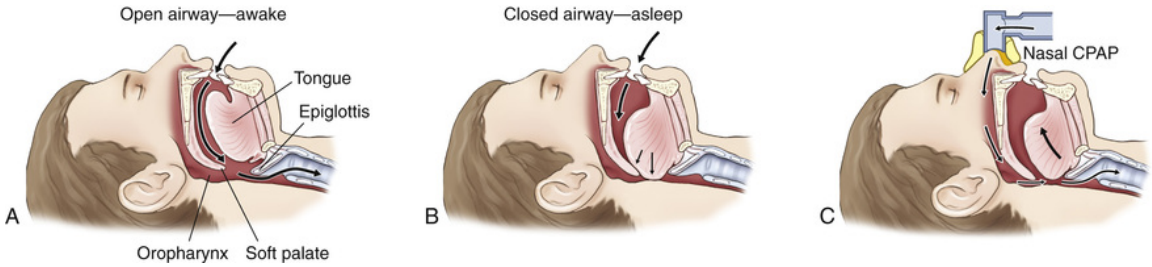

FIGURE 9-4 How sleep apnea occurs. **A,** The patient predisposed to obstructive sleep apnea (OSA) has a small pharyngeal airway. **B,** During sleep, the pharyngeal muscles relax, allowing the airway to close. Lack of airflow results in repeated apneic episodes. **C,** With continuous positive airway pressure (CPAP), the airway is splinted open, which prevents airflow obstruction. Source: Modified from LaFleur Brooks, M. (2012). *Exploring medical language: a student-directed approach* (8th ed.) St. Louis: Mosby.

Each obstruction may last from 10 to 90 seconds. During the apneic period, the patient can experience *hypoxemia* (decreased partial pressure of arterial oxygen or partial oxygen saturation) and *hypercapnia* (increased partial pressure of arterial carbon dioxide). These changes are ventilatory stimulants and cause brief arousals, but the patient may not fully awaken. The patient has a generalized startle response, snorts, and gasps, which cause the tongue and soft palate to move forward and the airway to open. Apnea and arousal cycles occur repeatedly, throughout the night.

Sleep apnea affects 5.4 million Canadians but is considered to be underreported (Public Health Agency of Canada, 2009). The risk increases with obesity (BMI > 35 kg/m^2), age older than 50 years, neck circumference greater than 43 cm (17 inches), craniofacial abnormalities that affect the upper airway, and acromegaly. People who smoke are more likely to have OSA than are those who do not smoke. OSA is twice as common in men as in women until after menopause, when the prevalence is similar.

The STOP-BANG (**s**nore, **t**ired, **o**bstruction, **p**ressure–**B**MI, **a**ge, **n**eck, **g**ender) questionnaire summarizes the key risk factors and is increasingly used as a quick and reliable screening tool for OSA (Nagappa, Liao, Wong, et al., 2015; Table 9-9). In the BANG portion, the more questions that a

patient answers, “Yes,” the greater is the patient's risk of having moderate to severe OSA.

TABLE 9-9

STOP-BANG

STOP		
S (Snore): Have you ever been told that you snore?	Yes	No
T (Tired): Are you often tired during the day?	Yes	No
O (Obstruction): Do you know if you stop breathing, or has anyone witnessed you stop breathing while you are asleep?	Yes	No
P (Pressure): Do you have high blood pressure, or are you on medication to control high blood pressure?	Yes	No
If the person answers “Yes” to two or more of the STOP questions, she or he is at risk for OSA and should contact her or his primary care provider. The second component of this questionnaire (BANG) provides risk assessment of moderate to severe risk of OSA.		
BANG		
B (BMI): Is your body mass index [BMI] greater than 28?	Yes	No
A (Age): Are you 50 years or older?	Yes	No
N (Neck): Are you a male with a neck circumference greater than 43 cm or a female with a neck circumference greater than 41 cm?	Yes	No
G (Gender): Are you a male?	Yes	No

OSA, obstructive sleep apnea.

Source: Chung, F., Yegneswaran, B., Liao, P., et al. (2008). STOP questionnaire: A tool to screen patients for obstructive sleep apnea. *Anesthesiology, 108,* 812–821. doi:10.1097/ALN.0b013e31816d83e4.

Clinical Manifestations and Diagnostic Studies

Clinical manifestations of sleep apnea include frequent arousals during sleep, insomnia, excessive daytime sleepiness, and witnessed apneic episodes. The patient's bed partner may complain about the patient's loud snoring. Other symptoms include morning headaches (from hypercapnia or increased blood pressure that causes vasodilation of cerebral blood vessels), personality changes, and irritability. Women with OSA have higher rates of mortality from the disorder than do men. Hypoxemia associated with OSA is worse in patients with chronic obstructive pulmonary disease (COPD) than in those without COPD.

Complications that can result from untreated sleep apnea include hypertension, right-sided heart failure from pulmonary hypertension caused by chronic nocturnal hypoxemia, and cardiac dysrhythmias, and the risk for stroke is increased. Symptoms of sleep apnea alter many aspects of the patient's life. If problems are identified, appropriate referrals need to be made. Cessation of breathing reported by the bed partner is

usually a source of great anxiety because of the fear that breathing may not resume.

Assessment of the patient with OSA includes thorough documentation of sleep and medical histories. The previously mentioned clinical manifestations of OSA should be assessed, as should less obvious symptoms, which may include cardiovascular symptoms, muscle pain, and mood changes.

A diagnosis of sleep apnea is made on the basis of PSG findings. This diagnosis requires documentation of apneic events (no airflow with respiratory effort) or hypopnea (airflow diminished 30% to 50% with respiratory effort) of at least 10 seconds' duration. OSA is defined as more than five apnea/hypopnea events per hour accompanied by a 3% to 4% decrease in oxygen saturation. In severe cases of apnea, apneic events may number more than 30 to 50 per hour of sleep. Typically, PSG studies are performed in a sleep laboratory with technicians monitoring the patient. In some instances, portable sleep studies are conducted in the home setting (see the "Informatics in Practice" box on sleep apnea diagnosis and monitoring). Overnight pulse oximetry assessment may be an alternative to determine whether nocturnal oxygen supplementation is indicated.

Informatics in Practice

Sleep Apnea Diagnosis and Monitoring

- Home respiratory monitoring is a cost-effective alternative for diagnosing sleep-related breathing disorders that allows some patients the convenience of sleeping in their own home.
- Home respiratory monitoring is used as part of a comprehensive sleep evaluation and in patients likely to have moderate to severe obstructive sleep apnea but who do not have heart failure, obstructive lung disease, or neuromuscular disease.
- Home respiratory monitoring is used to monitor the effectiveness of non-CPAP therapies for patients with sleep-related breathing disorders.
- Wireless monitors can detect changes in vital signs and pulse oximetry, raising an alarm if values fall outside of set parameters.

- A patient may benefit from telehealth to diagnose and monitor for sleep apnea in the home.

CPAP, continuous positive airway pressure.

Nursing and Collaborative Management Sleep Apnea

Mild sleep apnea (5 to 10 apneic/hypopneic events per hour) may respond to simple measures. Conservative treatment at home begins with simply sleeping on the side rather than on the back. The patient is instructed to avoid sedatives and consuming alcoholic beverages for 3 to 4 hours before sleep. Sleep medications often make OSA worse. Because excessive weight worsens and weight loss reduces sleep apnea, referral to a weight loss program may be indicated. Bariatric surgery reduces OSA (Freedman, 2014). It is essential to instruct the patient on the dangers of driving or using heavy equipment (Fleetham, Ayas, Bradley, et al., 2011).

Symptoms may resolve in up to half of patients with OSA who use a special mouth guard, also called an *oral appliance,* during sleep to prevent airflow obstruction. Oral appliances bring the mandible and tongue forward to enlarge the airway space, thereby preventing airway occlusion. Some individuals find beneficial a support group in which concerns and feelings can be expressed and strategies for resolving problems can be discussed.

In patients with more severe symptoms (>15 apneic/hypopneic events per hour), **continuous positive airway pressure (CPAP)** by mask is the treatment of choice. With CPAP, the patient applies a nasal mask that is attached to a high-flow blower (Figure 9-5). The blower is adjusted to maintain sufficient positive pressure (5 to 25 cm H_2O) in the airway during inspiration and expiration to prevent airway collapse. Some patients cannot adjust to wearing a mask over the nose or mouth or to exhaling against the high pressure. With a technologically more sophisticated therapy, bilevel positive airway pressure (BiPAP), a higher inspiration pressure and a lower pressure during expiration can be delivered. With BiPAP, the apnea can be relieved with a lower mean pressure and may be better tolerated.

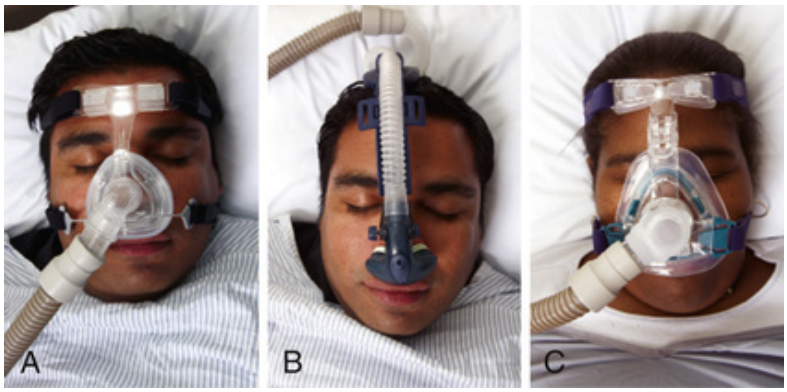

FIGURE 9-5 Examples of positive airwave pressure devices for sleep apnea. **A,** Patient wearing a nasal mask and headgear (positive pressure only to nose). **B,** Patient wearing nasal pillows (positive pressure only to nose). **C,** Patient wearing a full face mask (positive pressure to both nose and mouth). Source: Goldman, I., Schafer, A. I. (2012). *Goldman's Cecil medicine* (24th ed.). Philadelphia: Saunders.

Although CPAP is highly effective in reducing apnea and hypopnea, adherence to the regimen is poor; many people discontinue its use within the first year. Approximately two-thirds of patients using CPAP report adverse effects such as nasal stuffiness. Discomfort, noise, and claustrophobia are other reasons for discontinuation of use. Patient education, including the patient's choice of mask and device and exposure to CPAP before initiation of therapy, and behavioural therapy (e.g., tracking use with a symptom diary) have been shown to be important elements associated with successful adherence to CPAP treatment (Wozniak, Lasserson, & Smith, 2014).

Surgical Interventions

Tonsillectomy (removal of tonsillar glands) is used if a patient with OSA has large tonsils. If other measures fail, surgical interventions may be attempted to help manage the airway. Patients are carefully selected for these surgeries, inasmuch as there has been no conclusive evidence that they are actually beneficial for sleep apnea. The most common procedure is uvulo-palato-pharyngoplasty, which involves excision of the tonsillar pillars, the uvula, and the posterior soft palate with the goal of removing the obstructing tissue.

Special Concerns for Hospitalization With Obstructive Sleep Apnea

CPAP treatment should be maintained throughout hospitalization stay. When patients with a history of OSA are hospitalized, health care staff must be aware that the administration of opioid analgesics and sedating medications (benzodiazepines, barbiturates, hypnotics) may worsen OSA symptoms by depressing respiration. This will necessitate that the patient wear the CPAP or BiPAP when resting or sleeping (Fleetham, Ayas, Bradley, et al., 2011).

Perioperative concerns include an increased risk for difficult endotracheal intubation and a need for increased monitoring the postoperative period. In patients with sleep-disordered breathing, OSA may be exacerbated in the postoperative period in relation to medications they receive during anaesthesia. All patients with OSA should be monitored for pulse oximetry after surgery, and those at increased risk for cardiac events should also receive cardiac monitoring postoperatively (Fleetham, Ayas, Bradley, et al., 2011).

Sleep Movement Disorders

In sleep movement disorders, involuntary movement during sleep disrupts sleep and leads to daytime sleepiness. Periodic limb movement disorder (PLMD) is a type of sleep movement disorder characterized by involuntary, periodic movement of the legs, arms, or both that affects people only during sleep. Sometimes abdominal, oral, and nasal movement accompanies PLMD. Movements typically occur for 0.5 to 10 seconds, in intervals separated by 5 to 90 seconds. PLMD causes poor-quality sleep, which may lead to sleep maintenance insomnia, excessive daytime sleepiness, or both. PLMD and restless legs syndrome often occur simultaneously, but they are distinct disorders. (Restless legs syndrome is discussed in Chapter 61.)

PLMD is diagnosed on the basis of a detailed history from the patient or bed partner, or both, and PSG findings. PLMD is treated by medications aimed at reducing or eliminating the limb movements or the arousals. Dopaminergic drugs (pramipexole [Mirapex] and ropinirole [Requip]) are preferred.

Parasomnias

Parasomnias are defined as unusual and often undesirable behaviours that occur during sleep or during arousal from sleep. They can include abnormal movements and dream-related behaviours, emotions, and

perceptions. They are divided into three clusters: non–rapid eye movement, rapid eye movement, and "other."

Rapid Eye Movement Parasomnias.

Parasomnias that occur during REM sleep include REM sleep behaviour disorder, nightmare disorder, and recurrent isolated sleep paralysis (Sateia, 2014). Parasomnias may result in fragmented sleep and fatigue. *Nightmare disorder* is a parasomnia characterized by recurrent awakening with recall of the frightful or disturbing dream. *Nightmares* are vivid dreams that cause fear and anxiety as they unfold, and they result in a startled awakening (Nadorff, Lambdin, & Germain, 2014). These normally occur during the final third of sleep and in association with REM sleep. The startled awakening differentiates them from bad dreams (Nadorff, Lambdin, & Germain, 2014). Nightmares are more common in childhood but can persist into adulthood. Disturbed sleep, anxiety, sleep avoidance, and increased risk for suicidality are consequences of nightmare disorder. Nightmares are commonly reported by patients in the ICU and are probably adverse effects of medication because REM sleep is often absent in critically ill patients. The longer the stay in the ICU, the more likely the patient is to have nightmares. Drug classes most likely to cause nightmares are sedative–hypnotics, β-adrenergic antagonists, dopamine agonists, and amphetamines.

Treatments for nightmare disorder include prazosin (antihypertensive) and psychological interventions such as imagery rehearsal therapy and exposure treatment (Nadorff, Lambdin, & Germain, 2014). In research studies, nabilone (a synthetic cannaboid) has shown promise in people experiencing nightmares related to post-traumatic stress disorder (Cameron, Watson, & Robinson, 2014; Jetly, Heber, Fraser, et al., 2015).

Non–Rapid Eye Movement Parasomnias.

NREM parasomnias include sleepwalking, sleep terrors, sleep-related eating disorder, and confusional arousal. *Sleepwalking* behaviours can range from sitting up in bed, moving objects, and walking around the room to driving a car. During a sleepwalking event, the affected individual does not speak and may have limited or no awareness of the event. On awakening, the individual does not remember the event. In the ICU, a parasomnia may be misinterpreted as ICU psychosis. In addition, sedated ICU patients can exhibit manifestations of an NREM parasomnia.

Sleep terrors (night terrors) are characterized by a sudden awakening from sleep along with a loud cry and signs of panic. There is an intense

autonomic response, including increased heart rate, increased respiration, and diaphoresis. Factors in the ICU such as sleep disruption and deprivation, fever, stress (physical or emotional), and exposure to noise and light can contribute to sleep terrors.

Age-Related Considerations

Sleep

Sleep, like many physiological functions, change as people age. Even with healthy aging, there are expected changes in sleep patterns, including a decrease in the amount of deep sleep, overall shorter total sleep time at night, decreased sleep efficiency, more awakenings, and increased napping (Gooneratne & Vitiello, 2014). Sleep requirements for older adults are 7 to 8 hours per 24-hour cycle (Hirshkowitz, Whiton, Albert, et al., 2015) (Figure 9-6).

FIGURE 9-6 Many older people have sleep problems. Source: Anneka/Shutterstock.com.

Despite these expected changes, the incidence of sleep disturbances and disorders is also increased in older adults. Insomnia, OSA, PLMD, and REM sleep behaviour disorder in particular are increased in prevalence among older adults (Carrier, Lafortune, & Drapeau, 2012).

A key issue is that multiple factors impair the ability of older adults to obtain quality sleep. Chronic conditions that are more common in older adults—including COPD, diabetes, dementia, chronic pain, and cancer—

can affect sleep quality and increase the prevalence of insomnia (Carrier, Lafortune, & Drapeau, 2012). Prescribed and OTC medications used to treat these conditions can contribute to sleep problems. Daily stress and poor social support have also been linked to insomnia in older adults (Choi, Irwin, & Cho, 2015).

Insomnia may have detrimental effects on cognitive function in healthy older adults. Chronic disturbed sleep in an older adult can result in disorientation, delirium, impairment of intellect, disturbances in cognition, and increased risk of accidents and injury (see precipitating factors for delirium in Chapter 62).

Getting out of bed during the night to use the bathroom increases the risk for falls. Older adults may use OTC medications or alcohol as a sleep aid (see Chapter 11), which can further increase the risk of falls at night.

Because many older adults may not tell their health care providers about their sleep problems, a sleeping assessment (see Table 9-6) can be used to detect sleep disturbances. Napping during the day should not be considered problematic unless the person is complaining of insomnia or excessive daytime sleepiness. In the case of insomnia, daytime napping should be restricted (Carrier, Lafortune, & Drapeau, 2012). Screening for sleep disorders is important because of their higher prevalence among older adults. Sleep hygiene education and CBT-i are useful interventions for insomnia in older adults. Drug therapies are more challenging for older adults. Whenever possible, long-acting benzodiazepines should be avoided (Tanenbaum, 2015). Older adults receiving benzodiazepines are at increased risk of daytime sedation, falls, and cognitive and psychomotor impairment (see Table 62-1). They also have increased sensitivity to hypnotic and sedative medications. For this reason, drug therapies for sleep disturbances are started at low doses and monitored carefully. Hypnotic drugs should be used for as brief a period as possible, in most cases not exceeding 2 to 3 weeks of treatment. OTC sleep medications are not recommended for older adults because of their anticholinergic effects (American Geriatric Society, 2012; Beers Criteria Update Expert Panel, 2012).

Special Sleep Needs of Nurses

Nursing is one of several professions that necessitate night shift and rotating shift schedules. In many acute care and long-term care settings, nurses volunteer or are asked to work a variety of day and night shifts, often alternating and rotating them. Unfortunately, many nurses who do shift work report less job satisfaction and more job-related stress (Matheson, O'Brien, & Reid, 2014) than those who do not.

Nurses on permanent night or rapidly rotating shifts are at increased risk of experiencing **shift work sleep disorder,** characterized by insomnia, sleepiness, and fatigue. Nurses on rotating shifts get the least amount of sleep. With repeated periods of inadequate sleep, the sleep debt grows. Poor sleep is the strongest predictor of chronic fatigue in nurses doing shift work. As a result, rotating and night shift schedules pose specific challenges for the individual nurse's health and for patients' safety.

Shift work alters the synchrony between circadian rhythms and the environment, which leads to sleep disruption. Nurses working the night shift are often too sleepy to be fully alert at work and too alert to sleep soundly the next day. Sustained alterations in circadian rhythms such as that imposed by rotating shift work have been linked to negative health outcomes, including increased risk of morbidity and mortality in association with cardiovascular problems. In addition, mood disorders such as anxiety are more severe in nurses who work rotating shifts. Gastrointestinal disturbances are also more common in nurses who do shift work than in those who do not.

From a patient safety perspective, disturbed sleep and subsequent fatigue can make for a workplace hazard (errors and accidents) for nurses, as well as for their patients (Johnson, Jung, Brown, et al., 2014). Fatigue can result in diminished memory or distortions in perceptual skills, judgement, and decision-making capabilities. Lack of sleep affects the ability to cope and handle stress. Subsequently, the reduced ability to handle stress may result in physical, mental, and emotional exhaustion (Eanes, 2015).

The problem of sleep disruption is one that is critically important in nursing. Workplace policy and nursing education programs have a significant role to play in helping nurses access strategies to ensure adequate sleep. Several strategies may help reduce the distress associated with rotating shift work. These include brief scheduled periods of on-site napping, especially during the night shift, to help with the

chronobiological regulation of sleep (Silva-Costa, Rotenberg, Griep, et al., 2015). Napping during shift has been found to improve recovery time from night shift and to enhance safety on the job of shift workers (Fallis, McMillan, & Edwards, 2011). On-site napping may be beneficial only if the amount of domestic work performed in the daytime hours after night shift is limited (Silva-Costa, Rotenberg, Griep, et al., 2015). Maintaining a consistent sleep–wake schedule even on days off is optimum but perhaps unrealistic. For night shift work, scheduling the sleep period for just before going to work increases alertness and vigilance, improves reaction times, and decreases accidents during night shift work. It is important that nurses self-manage the effect of sleep disruption through the use of sleep hygiene practice. Sleep hygiene skills and self-care practices could be considered as required learning for nursing students because sleep quality has been found to decrease as nurses transition from school to workplace (Ye & Smith, 2015).

Case Study

Insomnia

Source: Blend Images/Shutterstock.com.

Patient Profile

Donna Parsons, a 49-year-old woman, is seen in the preoperative clinic. She is scheduled for a right shoulder (rotator cuff) repair. She tore her rotator cuff while playing tennis 1 year ago. It is no longer painful, but her range of motion is limited. During the preoperative screening, she reports chronic fatigue. She is postmenopausal, according to self-report. In the past year since the end of her periods, she has experienced daily hot

flashes and sleep problems. She denies any other health problems. On a usual workday, she drinks two cups of hot tea and one can of diet cola. Currently, she is taking OTC diphenhydramine for sleep. Her partner, who has accompanied her to the clinic, states that her snoring has gotten worse and it is interfering with his sleep.

Subjective Data

- Complains of hot flashes and nighttime sweating
- Complains of daytime tiredness and fatigue
- States that she has trouble getting to sleep and staying asleep

Objective Data

Physical Examination

- Laboratory evaluations within normal limits
- Overweight (20% over ideal body weight for height)
- Blood pressure (BP): 155/92 mm Hg
- Limited lateral and posterior rotation of right shoulder

Diagnostic Studies

- Nighttime polysomnography study reveals episodes of obstructive sleep apnea

Collaborative Care

- CPAP nightly
- Referred for weight reduction counselling

Discussion Questions

1. What are Ms. Parsons's risk factors for sleep apnea?
2. What specific sleep hygiene practices could Ms. Parsons use to improve the quality of her sleep?
3. How does CPAP work?

4. What are the potential health risks associated with sleep apnea?
5. ***Priority decision:*** According to the assessment data provided, what are the priority nursing diagnoses? Are there any collaborative problems?
6. ***Priority decision:*** For the day of surgery, what are the priority nursing interventions for Ms. Parsons?

Review Questions

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. Sleep is *best* described as a
   a. Loosely organized state similar to coma
   b. State in which pain sensitivity decreases
   c. Quiet state in which there is little brain activity
   d. State in which an individual lacks conscious awareness of the environment
2. Which statement is true regarding rapid eye movement (REM) sleep? *(Select all that apply.*)
   a. The EEG pattern is quiescent.
   b. Muscle tone is greatly reduced.
   c. It only occurs once in the night
   d. It is separated by distinct physiological stages.
   e. The most vivid dreaming occurs during this phase.
3. Sleep loss is associated with which of the following symptoms? *(Select all that apply.)*
   a. Increased body mass index
   b. Increased insulin resistance
   c. Enhanced cognitive functioning
   d. Increased immune responsiveness
4. Which of the following points should the nurse emphasize when providing education to the client with insomnia?
   a. The importance of daytime naps
   b. The need to exercise before bedtime
   c. The need for long-term use of hypnotics
   d. Avoidance of caffeine-containing beverages before bedtime
5. A nurse is establishing a care plan for a client in whom narcolepsy has recently been diagnosed. Which of the following areas would the nurse want to address as a priority?
   a. Risk for injury
   b. Ineffective coping

c. Risk for dehydration

d. Ineffective family coping

6. A client with sleep apnea would like to avoid using a nasal CPAP device if possible. Which of the following suggestions should the nurse make to help him reach his goal?

a. Lose excess weight.

b. Take a nap during the day.

c. Eat a high-protein snack at bedtime.

d. Use mild sedatives or alcohol at bedtime.

7. A client on the surgical unit has a history of parasomnia (sleepwalking). Which of the following is true with regard to parasomnia?

a. Hypnotic medications reduce the risk of sleepwalking.

b. The client is often unaware of the activity on awakening.

c. The client should be restrained at night to prevent personal harm.

d. The potential for sleepwalking is reduced by exercise before sleep.

8. Which of the following strategies would reduce sleepiness during nighttime work?

a. Exercising before work

b. Sleeping for at least 2 hours before work time

c. Taking melatonin before working the night shift

d. Walking for 10 minutes every 4 hours during the night shift

1. d; 2. b, e; 3. a, b; 4. d; 5. a; 6. a; 7. b; 8. b.

CHAPTER 10

Pain

Written by, Rosemary C. Polomano, Mechele Fillman

Adapted by, Michael McGillion, Sheila O'Keefe-McCarthy, Salima S.J. Ladak

LEARNING OBJECTIVES

1. Define pain.
2. Describe the neural mechanisms of pain and pain modulation.
3. Differentiate between nociceptive, neuropathic, somatic, and visceral types of pain.
4. Explain the physical and psychological effects of unrelieved pain.
5. Describe the components of a comprehensive pain assessment.
6. Describe effective pain management techniques used across many professional disciplines.
7. Describe pharmacological and nonpharmacological methods of pain relief.
8. Explain the nurse's role and responsibility in pain management.
9. Discuss ethical issues related to pain and pain management.
10. Evaluate the influence of one's own knowledge, beliefs, and attitudes about pain assessment and management.

breakthrough pain, p. 147
ceiling effect, p. 152
dermatomes, p. 143

Pain

Pain is a complex experience with sensory-discriminative, motivational–affective, and cognitive–evaluative dimensions. For many people, it is a major problem that causes suffering and reduces quality of life. Pain is one of the major reasons that people seek health care, and effective pain relief is a basic human right (Canadian Pain Society [CPS], 2010). A thorough understanding of the multiple dimensions of pain is important for effective assessment and management of patients with pain. Nurses have a central role in pain assessment and management. Components of the nursing role include (a) assessing pain and documenting and communicating this information to other health care providers, (b) ensuring delivery of effective pain relief measures, (c) evaluating the effectiveness of these interventions, (d) monitoring ongoing effectiveness of pain management strategies, and (e) providing education to patients and their families regarding pain management approaches and possible adverse effects. This chapter presents current knowledge about pain and pain management to enable the nurse to assess and manage pain successfully in collaboration with other health care providers.

Magnitude of the Pain Problem

According to Canadian Community Health Survey data from 2007, more than 1.5 million Canadians between 12 and 44 years of age suffer chronic pain, which, for 60%, interferes with daily activities (Ramage-Morin & Gilmour, 2010). Unrelieved, persistent pain is an epidemic in Canada and the United States. More than 50 million people are affected with musculoskeletal pain, such as back pain and arthritis, that goes unrelieved for 5 years or more (American Academy of Pain Management, n.d.). In Canada, pain is the most common cause of disability among working-age adults; up to 60% eventually lose their jobs or incur substantial loss of income (Lynch, 2011). The global prevalence of pain has a major negative economic impact, with estimated annual values of lost productivity ranging from $297.4 billion to $335.5 billion (2010 U.S. dollars). These values include days of work missed (ranging from $11.6 to $12.7 billion); hours of work lost (from $95.2 to $96.5 billion); and reduction in wages (from $190.6 billion to $226.3 billion) (Institutes of Medicine, 2011). Those with chronic pain now gainfully employed are expected to lose up to 28.5 productive working days per year (Lynch, 2011). Unfortunately, cumulative evidence indicates that, across the lifespan, people in a variety of settings continue to experience considerable acute and persistent pain despite the availability of treatment options (Choinière, Watt-Watson, Victor, et al., 2014; Lynch, 2011; McGillion & Watt-Watson, 2015; Watt-Watson & Murinson, 2013). Despite management standards and directives from nongovernmental organizations such as the Canadian Pain Society (2010) and the Registered Nurses' Association of Ontario (RNAO, 2013), more than four decades' worth of evidence documents inadequate pain management practices as the norm across health care settings and patient populations (McGillion & Watt-Watson, 2015; Watt-Watson & Murinson, 2013). For example, alarming numbers of Canadians are still left in pain after surgery, even in our top hospitals. Evidence suggests that up to 50% of patients report pain in the moderate-to-severe range following surgical procedures (Choinière, Watt-Watson, Victor, et al., 2014).

The prevalence of chronic pain increases with age, with estimates that as many as 65% of community-dwelling older adults and up to 80% of older adults in long-term care facilities experience it. Chronic pain in these populations is under-recognized and undertreated (Katz, 2014). People living with cancer—whether the disease is newly diagnosed, is being actively treated, or is in a more advanced stage—also consistently receive

inadequate pain treatment (Lynch, 2011; O'Mara, 2014). The prevalence of moderate to severe pain among people with head and neck cancers, for example, has been reported to be as high as 70% (Chaturvedi, Anderson, Lortet-Tieulent, et al., 2013; O'Mara, 2014). Consequences of untreated pain include unnecessary suffering, physical dysfunction, psychosocial distress (which manifests in such forms as anxiety or depression), impairment in recovery from acute illness and surgery, immuno-suppression, and sleep disturbances (Lynch, 2011; O'Mara, 2014).

In the acutely ill patient, unrelieved pain can result in increased morbidity as a result of respiratory dysfunction, increased heart rate and cardiac workload, increased muscular contraction and spasm, decreased gastro-intestinal (GI) motility, and increased catabolism (Table 10-1). Screening for the presence of pain is recommended to be an institutional priority. In general, it is recommended that pain be assessed—in all clinical care settings for all patients—at least once per day (RNAO, 2013).

TABLE 10-1

CONSEQUENCES OF UNRELIEVED PAIN

System	Responses
Endocrine	↑ Adrenocorticotrophic hormone (ACTH), ↑ cortisol, ↑ antidiuretic hormone (ADH), ↑ epinephrine, ↑ norepinephrine, ↑ growth hormone, ↑ renin, ↑ aldosterone levels; ↓ insulin, ↓ testosterone levels
Metabolic	Gluconeogenesis, glycogenolysis, hyperglycemia, glucose intolerance, insulin resistance, muscle protein catabolism, ↑ lipolysis
Cardiovascular	↑ Heart rate, ↑ cardiac output, ↑ peripheral vascular resistance, hypertension, ↑ myocardial oxygen consumption, ↑ coagulation
Respiratory	↓ Tidal volume, atelectasis, shunting, hypoxemia, ↓ cough, sputum retention, infection
Genitourinary	↓ Urinary output, urinary retention
Gastro-intestinal	↓ Gastric and bowel motility
Musculo-skeletal	Muscle spasm, impaired muscle function, fatigue, immobility
Neurological	↓ Cognitive function; mental confusion
Immunological	↓ Immune response

Source: Adapted from McCaffery, M., & Pasero, C. (1999). *Pain: A clinical manual for nursing practice* (2nd ed.). St. Louis: Mosby.

When left untreated, acute pain can also progress to persistent pain. Common surgical procedures have resulted in patients' experiencing persistent pain after surgery in 5 to 50% of cases; for some (2 to 10%), this pain is moderate to severe (Pergolizzi, Raffa, & Taylor, 2014). Rationales for the undertreatment of pain vary. Among health care providers, frequently cited reasons include a lack of knowledge and skills to adequately assess and treat pain; misconceptions about pain; and

inaccurate and inadequate information regarding addiction, tolerance, respiratory depression, and other adverse effects of opioids (McMillan, Tittle, Hagan, et al., 2000; O'Keefe-McCarthy, McGillion, Clarke, et al., 2015). These reasons are indeed common among nurses, who routinely administer the lowest prescribed analgesic dose when a range of doses is prescribed (McGillion & Watt-Watson, 2015; Voshall, Dunn, & Shelestak, 2013). Such practices do little to provide relief from unremitting pain and are not consistent with current pain management guidelines (RNAO, 2013). The need to improve prelicensure pain education for health care providers in Canada is dire. One national study revealed that students in just one-third of health sciences programs (e.g., dentistry, medicine, nursing, pharmacy, rehabilitation sciences, veterinary medicine) could identify designated, mandatory curricular content dedicated to pain (Watt-Watson, McGillion, Hunter, et al., 2009).

Among patients, misconceptions about pain and opioids also play a major role in the under-reporting and undertreatment of pain (Cogan, Ouimette, Vargas-Schaffer, et al., 2014). Examples include the belief that pain is inevitable and a result of worsening disease and the desire to be a "good" patient who does not complain (Cogan, Ouimette, Vargas-Schaffer, et al., 2014; O'Keefe-McCarthy, McGillion, Nelson, et al., 2014).

Unfortunately, wait times for expert pain-related care in Canada exceed 1 year at more than one-third of publicly funded pain clinics (Lynch, 2011), and many regions have no access to appropriate care.

Definitions of Pain

McCaffery and Pasero's seminal definition that pain is "whatever and whenever the person says it is" changed practice by focusing health care providers' attention on the subjectivity of pain (McCaffery & Pasero, 1999). Patients' self-reports about their pain are key to effective pain management. This definition at the simplest level may cause problems because patients do not always admit to pain or use the word *pain*. The International Association for the Study of Pain (IASP) defined **pain** as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage" (Merskey & Baranowski, 2012).

Pain is multidimensional and subjective, as the IASP definition emphasizes. The patient's self-report, therefore, is the most valid means of assessment. A person's inability to communicate verbally does not negate the possibility of that individual's experiencing pain or the need for appropriate pain-relieving treatment. In the case of patients who are nonverbal or cognitively unable to rate pain, gathering nonverbal information is critical for pain assessment.

The IASP definition of pain underlines the fact that pain can be experienced in the absence of identifiable tissue damage. It is important to differentiate pain that involves perception of a noxious (tissue-damaging) stimulus from pain involving nociception, which may not be perceived as painful. **Nociception** is the activation of the primary afferent nociceptors (PANs) with peripheral terminals (free nerve endings) that respond differently to noxious stimuli. Nociceptors function primarily to sense and transmit pain signals. If nociceptive stimuli are blocked, pain is not perceived.

Pain is not synonymous with *suffering,* although pain can cause substantial suffering. **Suffering** has been defined as "the state of severe distress associated with events that threaten the intactness (biopsychosocial integrity) of the person" (Cassell, 1982, p. 32). Suffering can occur in the presence or absence of pain, and pain can occur with or without suffering. For example, the woman awaiting breast biopsy may suffer emotionally because of anticipated loss of her breast. She may have acute pain in the breast after the biopsy (due to the procedure itself) without emotional suffering if the biopsy result is negative for malignancy. Conversely, she may have biopsy-related pain with emotional suffering if the biopsy result is positive for malignancy.

Dimensions of Pain and the Pain Process

Pain is a complex experience involving several dimensions: *physiological, sensory-discriminative* (i.e., the perception of pain by the individual that addresses the pain location, intensity, pattern, and quality), *motivational–affective*, *behavioural*, *cognitive–evaluative*, and *sociocultural* (Figure 10-1). In 1965, Melzack and Wall built on prior understanding of pain mechanisms in order to develop their gate control theory of pain (Melzack & Wall, 1987). Although the gate control theory is limited to providing a basic understanding of acute pain mechanisms, it is seminal work that remains critical to the understanding of the pain process, including transduction, transmission, perception, and modulation of pain. Pain experience and response result from complex interactions among these dimensions. In the following discussion, each dimension and the ways in which different dimensions influence pain are described.

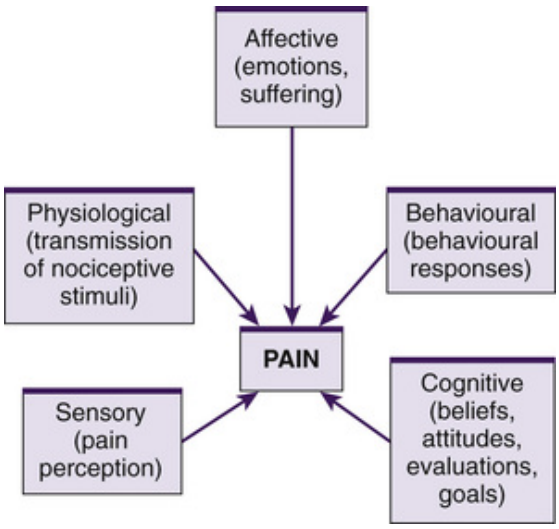

FIGURE 10-1 Multidimensional nature of pain. Developed by M. McCaffery, C. Pasero, and J. A. Paice. Modified from McCaffery, M., & Pasero, C. (1999). *Pain: A clinical manual for nursing practice* (2nd ed.). St. Louis: Mosby.

Physiological Dimension of Pain

Understanding the physiological dimension of pain requires knowledge of neural anatomy and physiology. The neural mechanism by which pain is perceived consists of four major steps: transduction, transmission,

perception, and modulation (Fields, 1987). Figure 10-2 outlines these four steps.

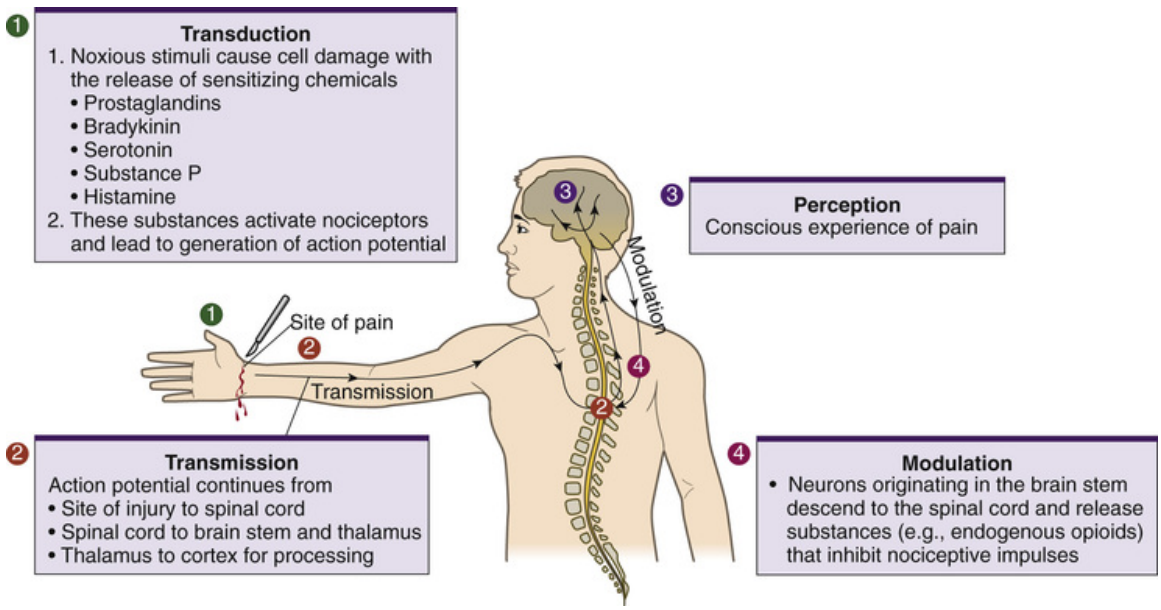

FIGURE 10-2 Nociceptive pain originates when the tissue is injured. Transduction *(1)* occurs when chemical mediators are released. Transmission *(2)* involves the conduct of the action potential (short-term change in the electrical potential travelling along a cell) from the periphery (injury site) to the spinal cord and then to the brain stem, thalamus, and cerebral cortex. Perception *(3)* is the conscious awareness of pain. Modulation *(4)* involves signals from the brain going back down the spinal cord to modify incoming impulses. Source: Developed by M. McCaffery, C. Pasero, & J. A. Paice. Modified from McCaffery, M., & Pasero, C. (1999). *Pain: clinical manual* (2nd ed.). St. Louis: Mosby.

Transduction.

Transduction is the conversion of a mechanical, thermal, or chemical stimulus to a neuronal action potential. Transduction occurs at the level of the peripheral nerves, particularly the free nerve endings, or PANs. Noxious (tissue-damaging) stimuli can include thermal damage (e.g., sunburn), mechanical damage (e.g., surgical incision, pressure from swelling), or chemical damage (e.g., from toxic substances). These stimuli cause the release of numerous chemicals into the peripheral microenvironment of the PAN. Some of these chemicals—such as histamines, bradykinin, prostaglandins, nerve growth factor, and

arachidonic acid—activate or sensitize the PAN to excitation (Mogil, 2012; Mifflin & Kerr, 2014). If the PAN is activated or excited, it fires an action potential to the spinal cord.

An action potential is necessary to convert the noxious stimulus to an impulse and move the impulse from the periphery to the spinal cord. A pain action potential can result from two sources: (a) a release of the sensitizing and activating chemicals *(nociceptive pain)* or (b) abnormal processing of stimuli by the nervous system *(neuropathic pain);* both of these sources produce a change in the charge along the neuronal membrane (Kerstman, Ahn, Battu, et al., 2013; Mifflin & Kerr, 2014). In other words, when the PAN terminal is transduced, the PAN membrane becomes depolarized. Sodium enters the cell, and potassium exits the cell, thereby generating an action potential. The action potential is then transmitted along the entire length of the neuron to cells in the spinal cord.

Inflammation and the subsequent release of the chemical mediators listed above lower the excitation threshold of PANs and increase the likelihood of transduction. This increased susceptibility is called *sensitization.* Several chemicals, such as leukotrienes, prostaglandins, and substance P, are probably involved in this process of sensitization. It is known that the release of substance P, a chemical stored in the distal terminals of the PAN, sensitizes the PAN and dilates nearby blood vessels, resulting in subsequent development of edema and release of histamine from mast cells (Mogil, 2012; Pelletier, Higgins, Bourbonnais, 2015).

Therapies directed at altering either the PAN environment or the sensitivity of the PAN are used to prevent the transduction and initiation of an action potential. Decreasing the effects of chemicals released at the periphery is the basis of several pharmacological approaches to pain relief. For example, nonsteroidal anti-inflammatory drugs (NSAIDs), such as ibuprofen (Advil, Motrin) and naproxen (Naprosyn, Aleve), and corticosteroids, such as dexamethasone (Decadron), exert their analgesic effects by blocking pain-producing chemicals. NSAIDs block the action of cyclo-oxygenase, and corticosteroids block the action of phospholipase, thereby interfering with the production of prostaglandins.

Transmission.

Transmission is the movement of pain impulses from the site of transduction to the brain (see Figure 10-2) (Fields, 1987). Three segments are involved in nociceptive signal transmission: (a) transmission along the nociceptor fibres to the level of the spinal cord, (b) processing in the dorsal

horn, and (c) transmission to the thalamus and the cortex. Each step in the transmission process is important in pain perception.

Transmission to the Spinal Cord.

One nerve cell extends the entire distance from the periphery to the dorsal horn of the spinal cord with no synapses. For example, an afferent fibre from the great toe travels from the toe through the fifth lumbar nerve root into the spinal cord; it is one cell. Once generated, an action potential travels all the way to the spinal cord unless it is blocked by a sodium channel inhibitor or disrupted by a lesion at the central terminal of the fibre (e.g., by a dorsal root entry zone lesion) (Fields, 1987).

Two types of peripheral nerve fibres are responsible for the transmission of pain impulses from the site of transduction to the level of the spinal cord: the A fibres (A-alpha, A-beta, and A-delta) and the C fibres. Neurons that project from the periphery to the spinal cord are also referred to as *first-order neurons.* Each type of fibre has different characteristics that determine its conduction rate (Table 10-2). A-alpha and A-beta fibres are large fibres enclosed within myelin sheaths that allow them to conduct impulses at a rapid rate. A-delta fibres are smaller with thinly myelinated sheaths. Because of their smaller size, however, they conduct at a slower rate than the larger A-alpha and A-beta fibres. C fibres are the smallest fibres and are unmyelinated. They conduct at the slowest rate. The conduction rates have important implications for the modulation of noxious information from A-delta and C fibres (Fields, 1987).

TABLE 10-2

CHARACTERISTICS OF PERIPHERAL NERVE FIBRES

Type of Fibre	Size	Myelinization	Conduction Velocity*
A-alpha	Large	Myelinated	Rapid
A-beta	Large	Myelinated	Rapid
A-delta	Small	Myelinated	Medium
C	Smallest	Not myelinated	Slow

*The conduction rates are important because information carried to the spinal cord by the more rapidly conducting nerve fibres reaches dorsal horn cells sooner than does information carried by the fibres that conduct more slowly.

Stimulation of different fibres results in different sensations. Stimulation of A-delta fibres results in pain described as pricking, sharp, well localized, and short in duration. C-fibre activation pain is described as a dull, aching, burning sensation and is characterized by its diffuse nature,

slow onset, and relatively long duration. The A-alpha (sensory muscle) and A-beta (sensory skin) fibres typically transmit nonpainful sensations such as light pressure to deep muscles, soft touch to skin, and vibration. All of these fibres extend from the peripheral tissues through the dorsal root ganglia to the dorsal horn of the spinal cord. The manner in which nerve fibres enter the spinal cord is central to the notion of spinal dermatomes. **Dermatomes** are areas on the skin that are innervated primarily by a single spinal cord segment. Figure 10-3 illustrates different dermatomes and their innervations.

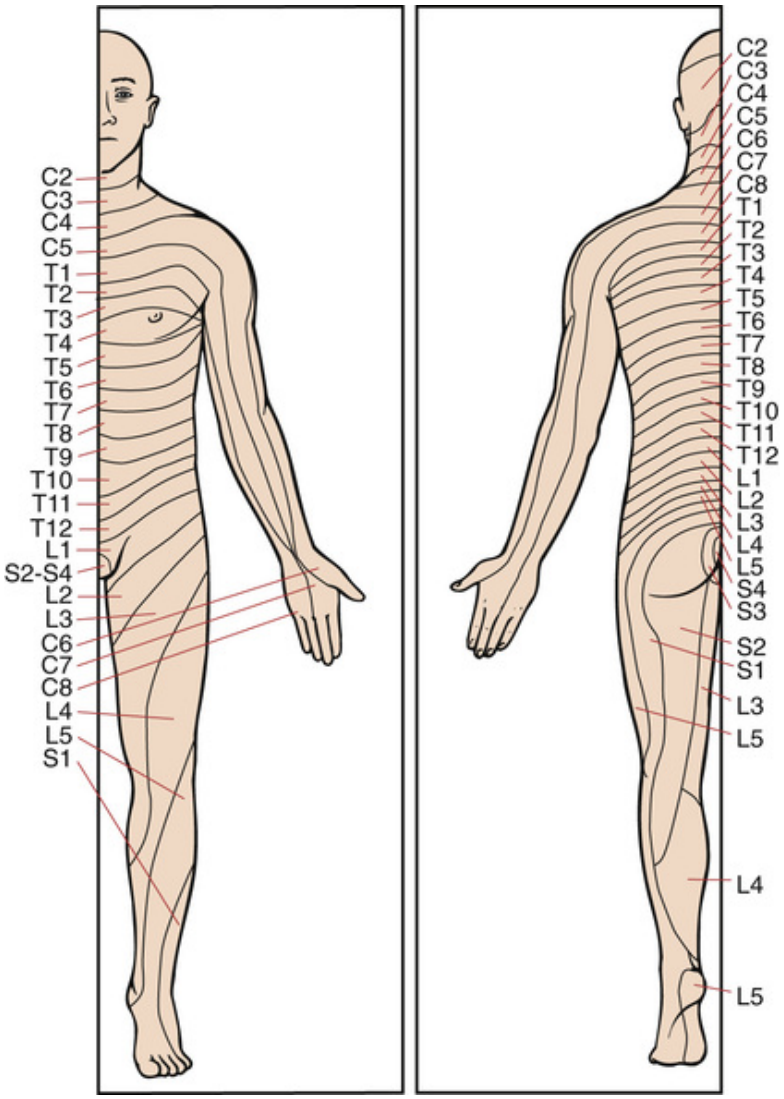

FIGURE 10-3 Spinal dermatomes representing organized sensory input carried via specific spinal nerve roots. *C,* cervical; *L,* lumbar; *S,* sacral; *T,* thoracic.

Dorsal Horn Processing.

Once the nociceptive signal arrives in the central nervous system (CNS), it is processed within the dorsal horn of the spinal cord. This processing includes the release of neurotransmitters from the afferent fibre into the synaptic cleft. These neurotransmitters bind to receptors on nearby cell bodies and dendrites of cells that may be located elsewhere in the dorsal horn. Some of these neurotransmitters (e.g., aspartate, glutamate, substance P) produce activation of nearby cells, whereas others (e.g., γ-aminobutyric acid, serotonin, norepinephrine) inhibit such activation. In turn, these nearby cells release other neurotransmitters. The effects of the

complex neurochemistry can facilitate or modulate (i.e., inhibit) transmission of noxious stimuli. In this area, exogenous and endogenous opioids also play an important role by binding to opioid receptors and blocking the release of neurotransmitters, particularly substance P. Endogenous opioids, which include enkephalins and β-endorphins, are chemicals that are synthesized and secreted by the body. They are capable of producing effects that are similar to those of exogenous opioids such as morphine.

The dorsal horn of the spinal cord contains specialized cells called *wide dynamic range neurons*. These neurons receive input from noxious stimuli primarily carried by A-delta and C-fibre afferent pathways (especially from viscera) and from non-noxious stimuli from A-beta fibres; they also receive indirect input from dendritic projections (Mogil, 2012; Kerstman, Ahn, Battu, et al., 2013; Mifflin & Kerr, 2014). These stimuli come from distant areas, providing a neural explanation for referred pain. Inputs from both nociceptive fibres and A-beta fibres converge on the wide dynamic range neuron, and when the message is transmitted to the brain, pain in the originating area of the body becomes poorly localized. The concept of referred pain must be considered when a person with injury to or disease involving visceral organs reports pain in a certain location. The location of a tumour, for instance, may be distant from the pain location reported by the patient (Figure 10-4). For example, liver disease is located in the right upper abdominal quadrant, but pain frequently is referred to the anterior and posterior neck region and to a posterior flank area. If referred pain is not considered in the evaluation of a pain location report, diagnostic tests and therapy could be misdirected.

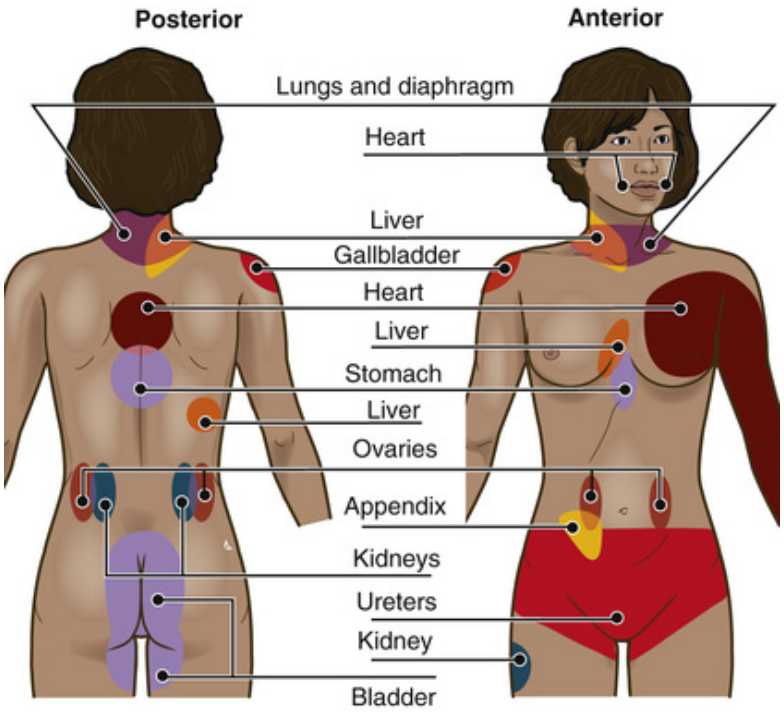

FIGURE 10-4 Typical areas of referred pain.

Sensitization, or enhanced excitability, can also occur at the level of the spinal neurons, known as *central sensitization* (Mifflin & Kerr, 2014; Kerstman, Ahn, Battu, et al., 2013; Pelletier, Higgins, & Bourbonnais, 2015). Peripheral tissue damage or nerve injury can cause central sensitization, and continued nociceptive input from the periphery is necessary to maintain it (Mifflin & Kerr, 2014; Kerstman, Ahn, Battu, et al., 2013; Pelletier, Higgins, & Bourbonnais, 2015). With ongoing stimulation of the slowly conducting unmyelinated C-fibre nociceptors, firing of specialized dorsal horn neurons gradually increases. This process is known as **windup** and is dependent on the activation of *N*-methyl-D-aspartate (NMDA) receptors. NMDA receptors produce alterations in neural processing of afferent stimuli that can persist for long periods. For this reason, an important goal of therapy is to prevent persistent pain by avoiding central sensitization. Currently, the NMDA antagonist most commonly used is the anaesthetic medication ketamine (Ketalar). Unfortunately, intolerable adverse effects, such as hallucinations, limit its usefulness. Development of newer NMDA-antagonist drugs is ongoing and shows promise for potentially blocking central sensitization with fewer adverse effects.

Transmission to the Thalamus and the Cortex.

From the dorsal horn, nociceptive stimuli are communicated to the *third-order neurons,* primarily in the thalamus, and several other areas of the brain. Fibres of dorsal horn projection cells enter the brain through several pathways, including the spinothalamic tract and the spinoreticular tract. Distinct thalamic nuclei receive nociceptive input from the spinal cord and have projections to several regions in the cerebral cortex, where the perception of pain is believed to occur.

Perception.

Pain perception is the recognition of, definition of, and response to pain by the individual experiencing it. In the brain, nociceptive input is perceived as pain. There is no single, precise location where pain perception occurs. Instead, pain perception involves several brain structures. For example, it is believed that the reticular activating system is responsible for the autonomic response of warning the individual to attend to the pain stimulus; the somatosensory system is responsible for localization and characterization of pain; and the limbic system is responsible for the emotional and behavioural responses to pain. Cortical structures are also thought to be crucial to constructing the meaning of the pain. Therefore, behavioural strategies such as distraction, relaxation, and imagery (distraction and relaxation are discussed later in this chapter; imagery is discussed in Chapter 8) are effective pain-reducing therapies for many people. By directing attention away from the pain sensation, patients can reduce the sensory and affective components of pain. For example, blood flow to the anterior central gyrus, an area intimately involved with the perception of the unpleasantness of pain, can be altered by hypnosis.

Modulation.

Modulation involves the activation of descending pathways that exert inhibitory or facilitatory effects on the transmission of pain. Depending on the type and degree of modulation, the nociceptive stimuli may or may not be perceived as pain. Modulation of pain signals can occur at the level of the periphery, the spinal cord, the brain stem, and the cerebral cortex. Centrally, modulation of nociceptive impulses occurs via descending fibres that influence dorsal horn neuronal activity. Complex neurochemistry involving excitatory and inhibitory neurotransmitters such as enkephalin, γ-aminobutyric acid, serotonin, and norepinephrine is involved in this nociceptive modulation; as a result, pain transmission is

inhibited (Salter, 2014). A number of pain management medications exert their effects through the modulatory systems. For example, tricyclic antidepressants, such as amitriptyline (Elavil), are used in the management of persistent noncancer pain and cancer pain. These medications interfere with the reuptake of serotonin and norepinephrine, thereby increasing their availability to inhibit noxious stimuli and produce analgesia. Baclofen (Lioresal), an analogue of the inhibitory neurotransmitter γ-aminobutyric acid, can interfere with the transmission of nociceptive impulses and thus produce analgesia for many chronic conditions, particularly those accompanied by muscle spasms. Table 10-3 briefly summarizes how pain-relieving medications can affect pain transduction, transmission, perception, and modulation.

TABLE 10-3

DRUG THERAPY
Interrupting the Pain Pathway

Pain Mechanism	Mechanism of Action
Transduction	
NSAIDs	Block prostaglandin production
Local anaesthetics	Block action potential initiation
Antiseizure drugs (e.g., gabapentin [Neurontin])	Block action potential initiation
Corticosteroids	Block action potential initiation
Transmission	
Opioids	Block release of substance P
Cannabinoids	Inhibit mast cell degranulation and response of nociceptive neurons
Perception	
Opioids	Decrease conscious experience of pain
NSAIDs	Inhibit cyclo-oxygenase action
Adjuvants (e.g., antidepressants)	Dependent on specific adjuvant
Modulation	
Tricyclic antidepressants (e.g., amitriptyline [Elavil])	Interfere with reuptake of serotonin and norepinephrine

NSAIDs, nonsteroidal anti-inflammatory drugs.

Sensory-Discriminative, Motivational–Affective, Behavioural, Cognitive–Evaluative, and Sociocultural Dimensions of Pain

Pain is subjective; the experience of pain and related responses vary from person to person. Because of the complex neural mechanisms of nociceptive processing, pain is a multidimensional sensory and affective experience that has cognitive, behavioural, and sociocultural aspects.

The *sensory-discriminative* component of pain is the recognition of the sensation as painful. Elements of sensory pain include pattern, area, intensity, and nature (PAIN). Information about these elements and knowledge about the pain process are indispensable to clinical decision making and appropriate pain therapy.

The *motivational–affective* component of pain encompasses the emotional responses to the pain experience. These affective responses include anger, fear, depression, and anxiety, negative emotions that impair the patient's quality of life. They become part of a vicious cycle in which pain leads to negative emotions such as depression, which in turn intensifies pain perception, leading to more depression and impairment of function. It is important for nurses to recognize this cycle and intervene appropriately (Richardson, 2014).

The *behavioural* component of pain comprises the observable actions used to express or control the pain. For example, facial expressions such as grimacing may reflect pain or discomfort. Posturing may be used to decrease pain associated with specific movements. A person often adjusts his or her daily physical and social activities in response to the pain. In this way, pain, especially persistent pain, has profound effects on functioning (RNAO, 2013).

The *cognitive–evaluative* component of pain consists of beliefs, attitudes, memories, and the meaning of the pain for the individual. The meaning of the pain stimulus can contribute to the pain experience. For example, a woman in labour may experience severe pain, but for her it is associated with a joyful event; moreover, she may feel control over her pain because of training she received in prenatal classes and the knowledge that the pain is self-limited. In contrast, a woman with persistent, nonspecific musculo-skeletal pain may be plagued by thoughts that the pain is "not real." Many people with persistent pain like this experience challenges from health care providers and others who question whether their pain is a legitimate experience (McGillion & Watt-Watson, 2015).

Such anxieties, fears, and stressors have been identified as potential intensifiers of perceived pain and related burden (O'Keefe-McCarthy, McGillion, Clarke, et al., 2015). The meaning of pain and related responses are critical aspects of nursing pain assessment. The *cognitive* dimension also includes pain-related beliefs and the cognitive coping strategies that people use. For example, some people cope with pain by distracting themselves, whereas others struggle with feelings that the pain is untreatable and overwhelming. Cognitions about the pain contribute to patients' goals for and expectations of pain relief and treatment outcomes.

The *sociocultural* dimension of pain encompasses factors such as demographic features (e.g., age, sex, education, socioeconomic status), support systems, social roles, past pain experiences, and cultural aspects that contribute to the pain experience (Sturgeon & Zautra, 2013). Female sex, for example, has been found to influence nociceptive processes and the acceptability and usage of and response to analgesics such as NSAIDs and opioids (McGillion, Arthur, Cook, et al., 2012a; O'Keefe-McCarthy, McGillion, Clarke, et al., 2015).

Causes and Types of Pain

Pain is generally classified as nociceptive, neuropathic, or both, according to the underlying pathological process. Nociceptive pain and neuropathic pain have different characteristics (Table 10-4). Because of its temporal nature, pain may be acute or persistent; some people may experience both, depending on the problem (Table 10-5).

TABLE 10-4
COMPARISON OF NOCICEPTIVE AND NEUROPATHIC PAIN

Nociceptive Pain	Neuropathic Pain
Definition	
Processing of noxious stimuli by an intact nervous system; usually responsive to analgesics (e.g., opioids, NSAIDs) or physical modalities	Abnormal processing of sensory input as a result of injury of the peripheral or central nervous system; treatment includes a variety of analgesics (e.g., antidepressants, opioids, antiseizure drugs)
Types	
Somatic Pain Arises from bone, joint, muscle, skin, or connective tissue; usually aching or throbbing in quality and well localized ***Visceral Pain*** Arises from organs, such as the gastrointestinal tract and bladder. Can be further subdivided as follows: • Tumour involvement of the organ capsule that causes aching and fairly well-localized pain • Obstruction of hollow organ that causes intermittent cramping and poorly localized pain	***Centrally Generated Pain*** • Deafferentation pain, caused by injury to either the peripheral or central nervous system (e.g., phantom pain may reflect injury to peripheral nerve) • Sympathetically maintained pain, associated with dysregulation of the autonomic nervous system (e.g., reflex sympathetic dystrophy) ***Peripherally Generated Pain*** • Painful polyneuropathies, in which pain is felt along the distribution of many peripheral nerves (e.g., diabetic neuropathy, alcohol-nutritional neuropathy, Guillain-Barré syndrome) • Painful mononeuropathies, usually associated with a known peripheral nerve injury and in which pain is felt at least partly along the distribution of the damaged nerve (e.g., nerve root compression, trigeminal neuralgia)

NSAIDs, nonsteroidal anti-inflammatory drugs.

TABLE 10-5
DIFFERENCES BETWEEN ACUTE AND PERSISTENT PAIN

Characteristic	Acute Pain	Persistent Pain
Onset	Sudden	Gradual or sudden
Duration	Usually within the normal time for healing	May start as acute injury but continues past the normal time for healing to occur
Severity	Mild to severe	Mild to severe
Cause of pain	In general, a precipitating illness or event (e.g., surgery) can be identified	May not be known; original cause of pain may differ from mechanisms that maintain the pain
Course of pain	↓ Over time and goes away as recovery occurs	Typically, pain persists and may be ongoing, episodic, or both
Typical physical and behavioural manifestations	Manifestations reflect sympathetic nervous system activation: • ↑ Heart rate • ↑ Respiratory rate • ↑ Blood pressure • Diaphoresis, pallor • Anxiety, agitation, confusion NOTE: Responses normalize quickly owing to adaptation	Predominantly behavioural manifestations: • Changes in affect • ↓ Physical movement and activity • Fatigue • Withdrawal from other people and social interaction
Usual goals of treatment	Pain control with eventual elimination	Minimizing pain to the extent possible; focusing on enhancing function and quality of life

Nociceptive Pain

Nociceptive pain is caused by damage to somatic or visceral tissue. *Somatic pain,* characterized as aching or throbbing that is well localized, arises from bone, joint, muscle, skin, or connective tissue. *Visceral pain,* which may result from stimuli such as tumour involvement or obstruction, arises from internal organs such as the intestines and the bladder. Examples of nociceptive pain include pain from a surgical incision or a broken bone, arthritis, or cardiac ischemia. Nociceptive pain is usually responsive to both nonopioid and opioid medications.

Neuropathic Pain

Neuropathic pain is caused by damage to nerve cells or changes in spinal cord processing. Typically described as burning, shooting, stabbing, or electrical in nature, neuropathic pain can be sudden, intense, short-lived, or lingering. Neuropathic pain is difficult to treat, and management includes opioids, antiseizure drugs, and antidepressants. Neuropathic pain can be either central or peripheral in origin.

Table 10-5 lists the classification of pain as acute or persistent. Acute pain and persistent pain have different causes, courses, manifestations,

and treatment. Examples of acute pain include postoperative pain, labour pain, pain from trauma (e.g., lacerations, fractures, sprains) and infection (e.g., dysuria), and angina. For acute pain, treatment includes analgesics for symptom control treatment of the underlying cause (e.g., splinting for a fracture, antibiotic therapy for an infection). Normally, acute pain diminishes over time as healing occurs. Persistent pain continues beyond the normal time expected for healing. Persistent pain is often disabling and accompanied by anxiety and depression. Sometimes, persistent pain is further classified as cancer and noncancer pain. Persistent cancer-related pain arises from many causes, including disease progression, diagnostic procedures, anticancer therapies, and infection (von Gunten, 2011).

Cancer pain often is considered separately because its cause can be determined, its course differs from that of nonmalignant pain (cancer pain often worsens with documented disease progression), and the use of opioids in its treatment is more widely accepted than in the treatment of noncancer pain (von Gunten, 2011).

Pain Assessment

The goals of a nursing pain assessment are (a) to describe the patient's sensory, affective, behavioural, and sociocultural pain experience for the purpose of implementing pain management techniques and (b) to identify the patient's goal for therapy and resources and strategies for effective self-management. The nurse is responsible for gathering and documenting assessment data and for making collaborative decisions with the patient and other health care providers about pain management. The following sections describe key components in pain assessment.

Sensory-Discriminative Component

Every pain assessment should include evaluation of the sensory-discriminative component: pattern, area, intensity, and nature (PAIN) of the pain. Information about these elements is essential to identifying appropriate therapy for the type and severity of the pain (RNAO, 2013).

Before beginning any assessment, the nurse must recognize that patients may use words other than *pain*. For example, older adults may deny that they have pain but respond positively when asked if they have discomfort, soreness, or aching (Tracy & Morrison, 2013). For these patients, repeatedly using open-ended questions including descriptors to understand pain may elicit more information than close-ended questions. The words that the patient uses in describing pain must be documented, and when the patient is asked about pain, the patient's words should be used consistently.

Pattern of Pain.

Pain onset (when it starts) and duration (how long it lasts) are components of the pain pattern. Acute pain typically increases during wound care, ambulation, coughing, and deep breathing. Acute pain associated with surgery or injury tends to diminish over time, with recovery as tissues heal. In contrast, persistent pain may be ongoing, episodic, or both. For example, a person with persistent osteoarthritis pain may experience increased stiffness and pain on arising in the morning. As the joint is gently mobilized, the pain often decreases.

A patient may have constant, round-the-clock pain or discrete periods of intermittent pain. **Breakthrough pain** is moderate to severe pain that

occurs despite treatment. Many patients with cancer experience breakthrough pain. It is usually rapid in onset and brief in duration, with highly variable intensity and frequency of occurrence. *Episodic, procedural,* or *incident pain* is a transient increase in pain that is caused by a specific activity or event that precipitates the pain (e.g., dressing changes, movement, eating, position changes, and certain procedures such as catheterization).

Figure 10-5 shows one method for the patient to document the pain pattern so as to report how the intensity of the pain changes with time. A similar method could be used to document the changes in the area or the nature of the pain.

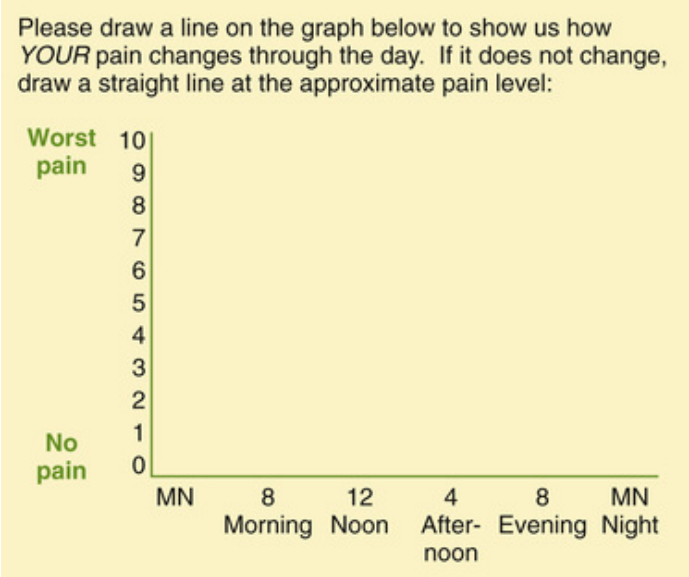

FIGURE 10-5 A method of tracking pain over time.

Area of Pain.

The area or location of pain assists in identifying possible causes of the pain and in determining treatment. Some patients may be able to specify one or more precise locations of their pain, whereas others may describe very general areas or comment that they "hurt all over." The location of the pain may also be *referred* from its origin to another site (see Figure 10-4), as described earlier in the chapter. Pain may also *radiate* from its origin to another site. For example, angina pectoris is known to radiate from the chest to the jaw, to the shoulders, or down the left arm. Sciatica is pain that originates from compression or damage to the sciatic nerve or its roots

within the spinal cord. The pain is projected along the course of the peripheral nerve, causing painful shooting sensations down the back of the thigh and the inside of the leg.

Typically, information about the location of pain is elicited by asking the patient to (a) describe the site or sites of pain, (b) point to painful areas on the body, or (c) mark painful areas on a body diagram (Figure 10-6). Because many patients have more than one site of pain, it is important to make certain that the patient describes every location and identifies which one is most problematic.

Initial Pain Assessment Tool

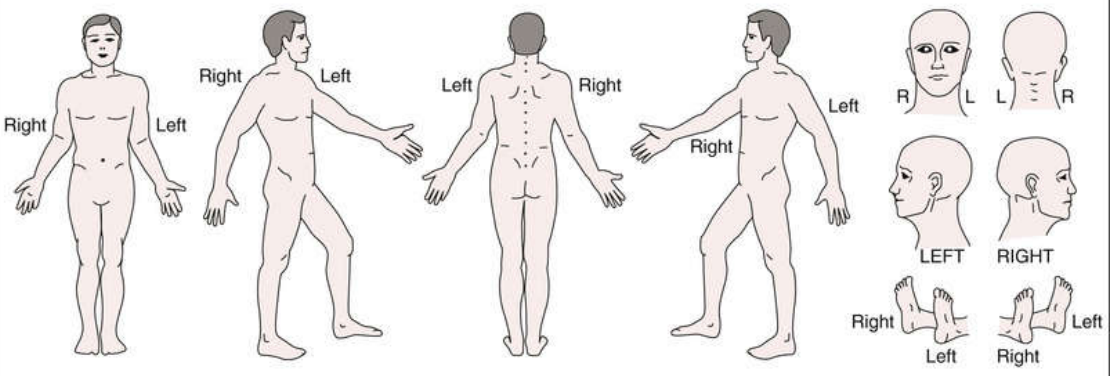
Date _____

Client's Name _____ Age _____ Room _____

Diagnosis _____ Physician _____

Nurse _____

1. LOCATION: Patient or nurse marks drawing.



2. INTENSITY: Client rates the pain. Scale used: _____

Present: _____

Worst pain gets: _____

Best pain gets: _____

Acceptable level of pain: _____

3. QUALITY: (Use client's own words, e.g., prick, ache, burn, throb, pull, sharp) _____

_____

4. ONSET, DURATION, VARIATIONS, RHYTHMS: _____

_____

5. MANNER OF EXPRESSING PAIN: _____

_____

_____

6. WHAT RELIEVES THE PAIN? _____

_____

_____

7. WHAT CAUSES OR INCREASES THE PAIN? _____

_____

_____

8. EFFECTS OF PAIN: (Note decreased function, decreased quality of life)

Accompanying symptoms (e.g., nausea) _____

Sleep _____

Intensity of Pain.

An assessment of the severity, or intensity, of pain provides a reliable measurement for determining the type of treatment as well as for evaluating the effectiveness of therapy. Pain scales are useful in helping the patient communicate the intensity of pain and in guiding treatment. Scales must be adjusted to age and level of cognitive development. Numerical scales (e.g., 0 = "no pain" and 10 = "the worst pain"), verbal descriptor scales (e.g., none, a little [1–3], moderate [4–6], and severe [7–10]), or visual analogue scales (a 10-cm line with one end labelled "no pain" and the other end labelled "worst possible pain") can be used by most adults to rate the intensity of their pain (Figure 10-7). For patients who are unable to respond to other pain intensity scales, a series of faces ranging from "smiling" to "crying" can be used. These scales have been investigated for use in a variety of patient populations, including young children and older adults. Results indicate that they provide valid and reliable assessment data (Craig, Prkachin, & Grunau, 2011).

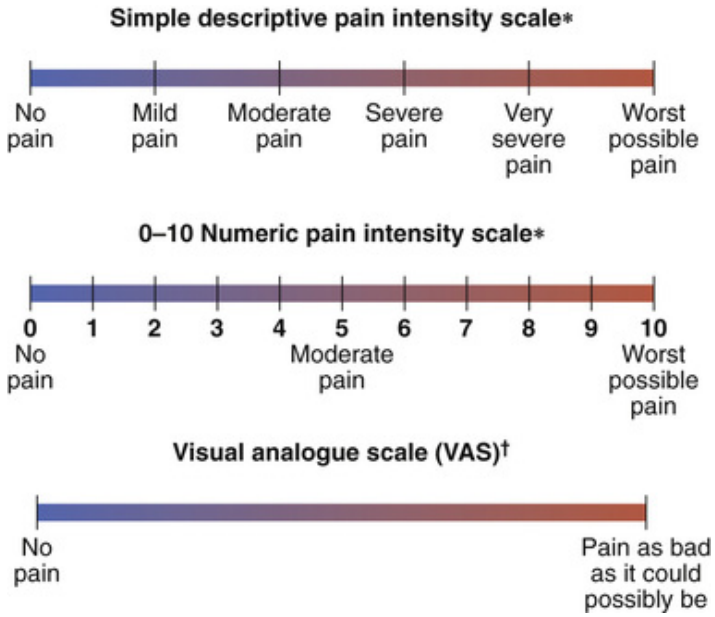

FIGURE 10-7 Simple descriptive word tool and visual analogue scale (VAS) used to assess a patient's pain. *If used as a graphic rating scale, a 10-cm baseline is recommended. †A 10-cm baseline is recommended for VAS scales. Source: McCormack, H. M., Horne, D. J., & Sheather, S. (1988). Clinical applications of visual analogue scales: A critical review. *Psychological Medicine, 18*(4), 1007–1019. Reproduced with permission.

Nature of Pain.

The *nature* of pain refers to the quality or characteristics of the pain. Many commonly used words to describe the nature of pain are included in the McGill Pain Questionnaire (MPQ; see the Resources at the end of this chapter). The MPQ is a widely used measure of subjective pain experience with well-established reliability, validity, sensitivity, and discriminative capacity in divergent acute and chronic pain populations (Katz & Melzack, 2011). Two major strengths of the MPQ are that (a) it provides a comprehensive assessment of the nature of pain problems in a short time frame (5 to 10 minutes) and (b) it includes subsets of verbal pain descriptors associated with both nociceptive and neuropathic pain (Katz & Melzack, 2011).

For example, patients may describe neuropathic pain as burning, cold, shooting, stabbing, or itchy. Nociceptive pain may be described as sharp, aching, throbbing, or cramping.

Motivational–Affective, Behavioural, Cognitive–Evaluative, and Sociocultural Components

Comprehensive pain assessment includes evaluation of all pain dimensions and should be completed upon a patient's admission to a facility and repeated at regular intervals in order to evaluate response to treatment. In an acute care setting, time limitations may dictate an abbreviated assessment of the affective, behavioural, cognitive, and sociocultural dimensions of pain. At a bare minimum, patients' expression of pain and the effect of pain on sleep, daily activities, relationships, physical activity, and emotional well-being should be assessed. Strategies that the patient has used or tried to control the pain (effective or not) should also be documented.

When possible and relevant, assessment should also include examination of the psychological and social factors associated with patients' subjective experience of pain and, in particular, the meaning of the pain experience; *pain* meaning may often feature prominently in patients' treatment progress (O'Keefe-McCarthy, McGillion, Clarke, et al., 2015). Data related to meaning may be particularly useful in care planning for patients who exhibit high levels of pain-related behaviour, functional impairment, or pain-related distress. Such responses, for example, may be found in patients suffering moderate to severe persistent cardiac pain (McGillion, Arthur, Cook, et al., 2012a; O'Keefe-McCarthy, McGillion, Clarke, et al., 2015).

Measurement of beliefs related to the meaning of pain is complex. For clinical assessment purposes, key areas of inquiry with patients about the meaning of pain and related beliefs should include effective pain control in relation to current intervention strategies, pain-related disability, value placed on comfort and solace from other people, and the effect of emotions on the experience of pain.

Comprehensive assessment information is necessary to ensure effective treatment, as shown in Table 10-6.

TABLE 10-6

NURSING ASSESSMENT
Pain Data

Subjective Data
Important Health Information
Past health history: Includes onset, location, intensity, quality, patterns, and expression of pain; coping strategies; past pain experiences (e.g., in childhood, in family members, other pain problems, pain relief measures used in the past and their effectiveness); pain triggers; effect of pain on emotions, relationships, sleep, work and school, family routines, leisure, and other activities; interviews with family members; meaning of pain to patient; records from any psychiatric treatment related to the pain; review of the use of health care services in relation to the pain problem (e.g., emergency department visits, treatment at pain clinics, visits to primary health care providers and specialists); influence of cultural, ethnic, or religious factors on pain intensity, interpretation of the pain, and pain management strategies *Medications:* Use of any prescription, over-the-counter, or herbal products or other medications for pain relief; alcohol use
Symptoms
Fatigue; limitations in activities; pain related to muscle use; decreased libido; constipation related to opioid or tricyclic medication use (or both); depression; anxiety; mood or self-image problems
Objective Data
Complete physical examination, including evaluation of functional limitations Psychosocial evaluation

Advances in Pain Assessment Research

Optimal ways to assess pain continue to be examined in several populations. The Postoperative Pain Assessment Skills Tool (PAST), for example, was developed by McGillion, Dubrowski, Stremler, and colleagues (2011) as a tool to develop health care providers' pain assessment skills. The PAST is divided into two components: a pain assessment checklist and a global rating scale. The assessment checklist examines pain sensory characteristics; treatment history; impact of pain on functional status, perception of self, and relationships; and past pain experiences. The global rating scale uses a series of scales to evaluate the health care provider's interpersonal skills and empathy while conducting a pain assessment, degree of coherence during the pain assessment interview, and skillful use of verbal and nonverbal expression (McGillion, Dubrowski, Stremler, et al., 2011). The PAST has been found to be a reliable tool for providing real-time feedback to nurses and other health care providers while conducting comprehensive pain assessments under time-constrained conditions (in keeping with the realities of institutional clinical settings). Results also suggest that this tool can be used effectively by novice and experienced nurses who wish to advance their pain assessment skills (McGillion, Dubrowski, Stremler, et al., 2011).

Pain Treatment

Basic Principles

All pain treatment is guided by the same underlying principles. Although treatment regimens range from short-term management to multimodal, long-term therapy for many persistent pain problems, all treatment should follow the same basic standards, as stated by the CPS (2010) and the RNAO 2013 Pain Assessment and Management Best Practice Guidelines:

- Routine assessment is essential for effective management. Pain is a subjective experience involving multiple characteristics including biological and psychosocial factors, all of which must be considered for comprehensive assessment and management.
- Unrelieved acute pain complicates recovery. Unrelieved pain after surgery or injury results in more complications, longer hospital stays, greater disability, and potentially long-term pain.
- Patients' self-report of pain should be used whenever possible. For patients unable to report pain, a nonverbal assessment method must be used.
- Health care providers have a responsibility to assess pain routinely, to accept patients' pain reports and document them, and to intervene in order to manage pain.
- The best approach to pain management involves patients, families, and health care providers. Patients and families must be informed of their right to the best pain care possible and encouraged to communicate the severity of their pain.

• Many patients—in particular, vulnerable populations; ethnic minorities including infants, children, and adolescents; older adults, adults, and children with limited ability to communicate; and patients with past or current substance use problems —are at high risk for suboptimal or inappropriate pain management. Health care providers must understand that adequate pain relief is a basic human right, must be aware of their own biases and misinformation, and must ensure that all patients are treated respectfully. Patients with a history of opioid tolerance or addiction may have higher opioid requirements following a new episode of acute pain. Care should be taken that these patients do not experience withdrawal due to undermedication.
• Treatment must be based on the patient's and family's goals for pain treatment, which should be discussed upon initial pain assessment. Sometimes these goals can be described in terms of pain intensity (e.g., the desire for pain intensity to decrease from an “8 out of 10” to a “3 out of 10”). Other patients may express a functional goal (e.g., a person may want the pain to be relieved to an extent that allows him or her to perform daily activities). Over the course of prolonged therapy, these goals should be reassessed, and progress should be documented. If the patient has unrealistic goals for therapy, such as wanting to be completely rid of all persistent arthritis pain, the nurse should work with the patient to establish a more realistic goal.

• Treatment plans should involve a combination of pharmacological and nonpharmacological therapies. Although medications are often considered the mainstay of therapy, particularly for moderate to severe pain, nonpharmacological strategies should be incorporated to increase the overall effectiveness of the treatment plan and to allow for the reduction of medication dosages to minimize adverse effects. Examples of therapies are discussed later in the chapter.
• A multidimensional and interdisciplinary approach is necessary for optimal pain management; multiple perspectives, from all members of the interprofessional team, should be incorporated.
• All therapies must be evaluated to ensure that they are meeting the patient's goals. Therapy must be individualized for each patient, and, often, achieving an effective treatment plan requires trial and error. Medications, dosages, and routes are commonly adjusted to achieve maximal benefit while minimizing adverse effects. This trial-and-error process can become frustrating for the patient and family. They need to be reassured that pain relief is possible and that the health care team will continue to work with them to achieve adequate pain relief.
• Adverse effects of medications must be prevented or managed. Adverse effects are a major reason for treatment failure and nonadherence despite the fact that most patients' pain can be effectively managed (RNAO, 2013). Adverse effects are managed in one of several ways, described in Table 10-7. The nurse plays

a key role in monitoring for and treating adverse effects, as well as in teaching the patient and family how to minimize adverse effects.

TABLE 10-7

DRUG THERAPY
Examples of Ways to Manage Adverse Effects of Opioids

• Ensuring a schedule for the dosing regimen to maintain blood levels • Using stool softeners and stimulant laxatives to prevent constipation • Using an antiemetic to prevent nausea • Changing to a different medication in the same class • Using an administration route that minimizes drug concentrations at the site of the adverse effect (e.g., intraspinal administration of opioids is sometimes used to minimize high drug levels that produce sedation, nausea, and vomiting)

- Patient and caregiver teaching should be a cornerstone of the treatment plan. Content should include information about the cause or causes of the pain, pain assessment methods, treatment goals and options, expectations for pain management, instruction regarding the proper use of drugs, management of adverse effects, and nonpharmacological and self-help measures for pain relief (RNAO, 2013). Teaching should be documented, and the patient's and caregiver's comprehension of this teaching should be evaluated.

Drug Therapy for Pain

Although a physician or nurse practitioner prescribes the medications, it is the nurse's responsibility to evaluate the effectiveness and adverse effects of what is prescribed. It is also a nursing responsibility to document and communicate the outcomes of analgesic therapy and to suggest changes when appropriate, using knowledge and skills related to several pharmacological and pain management concepts. These include calculating equianalgesic doses, scheduling analgesic doses, titrating opioids, and selecting from the prescribed analgesic drugs.

Equianalgesic Dose.

The term **equianalgesic dose** refers to a dose of one analgesic that produces pain-relieving effects equivalent to those of another analgesic. The concept of equivalence is important when substituting one analgesic for another in the event that a particular medication is ineffective or causes intolerable adverse effects and when the administration route of opioids is changed (e.g., from parenteral to oral). In general, opioids are administered in equianalgesic doses—important to know because no upper dosage limit has been established for many of these drugs. Equianalgesic charts and conversion programs are widely available in textbooks, in clinical guidelines, in health care facility pain protocols, and on the Internet. Table 10-8 provides an example of common equianalgesic dosages compared with 10 mg of parenteral morphine, which is the standard basis for comparison. Although equianalgesic charts are useful tools, health care providers must understand their limitations: Equianalgesic dosages are approximate, and individual patient response must be routinely assessed. In addition, discrepancies exist among different published equianalgesic charts. All changes in opioid therapy must be carefully monitored and adjusted for the individual patient. When possible, health care providers should use equianalgesic conversions that have been approved for their facility or clinic and should consult a pharmacist before making changes.

TABLE 10-8
EXAMPLES OF COMMON EQUIANALGESIC DOSES

Drug	Approximate Equianalgesic Parenteral Dosage	Approximate Equianalgesic Oral Dosage	Alert/Special Considerations
Morphine	10 mg	30 mg	
Hydromorphone (Dilaudid)	4 mg	2 mg	
Oxycodone	Not available	20 mg	
Codeine	120 mg	200 mg	
Methadone and tramadol	—	—	Methadone and tramadol conversion morphine dose equivalents have not been reliably established. Methadone conversion requires a licensed expert's assessment based on the patient's history of opioid consumption.
Meperidine (Demerol)	75 mg	300 mg	Prolonged use may increase risk of toxicity (e.g. seizures) from accumulation of the meperidine metabolite, normeperidine.

In *Canadian guideline for safe and effective use of opioids for chronic non-cancer pain* (p. 75). Retrieved from *http://nationalpaincentre.mcmaster.ca/documents/opioid_guideline_part_b_v5_6.pdf*.

Scheduling Analgesics.

Appropriate analgesic scheduling should focus on prevention or ongoing control of pain rather than on providing analgesics only after the patient's pain has become moderate to severe. A patient should receive medication before procedures and activities that are expected to produce pain. Similarly, a patient with constant pain should receive analgesics around the clock rather than on an as-needed basis. These strategies control pain before it starts and usually result in lower analgesic requirements. Fast-acting drugs should be used for incident or breakthrough pain, whereas long-acting analgesics are more effective for constant pain. Examples of fast-acting and sustained-release analgesics are described later in this section.

Titration.

Analgesic **titration** is dosage adjustment that is based on assessment of the adequacy of analgesic effect versus the adverse effects produced. The amount of analgesic needed to manage pain varies widely, and titration is an important strategy in addressing this variability. An analgesic dosage

can be titrated upward or downward, depending on the situation. For example, in a postoperative patient, the dosage of analgesic generally decreases over time as the acute pain resolves. On the other hand, opioids for persistent, severe chronic noncancer pain may be titrated upward over the course of therapy to maintain adequate pain control; this titration requires expert specialty care according to Canadian guidelines for chronic opioid therapy (National Opioid Use Guideline Group [NOUGG], 2010). The goal of titration is to use the lowest dosage of opioid that provides effective pain control with the fewest adverse effects.

Analgesic Ladder.

Several national and international groups have published practice guidelines recommending a systematic plan for using analgesic drugs. One widely used system is the analgesic ladder proposed by the World Health Organization (WHO) (Figure 10-8). The WHO treatment plan emphasizes that different medications are administered, depending on the severity of pain, by means of a three-step ladder approach. Step 1 medications are used for mild pain; step 2, for mild to moderate pain; and step 3, for moderate to severe pain. If pain persists or increases, medications from the next higher step are introduced to control the pain. The steps are not meant to be sequential if someone has moderate to severe pain: for this person, the analgesics given would be the stronger analgesics listed in steps 2 and 3.

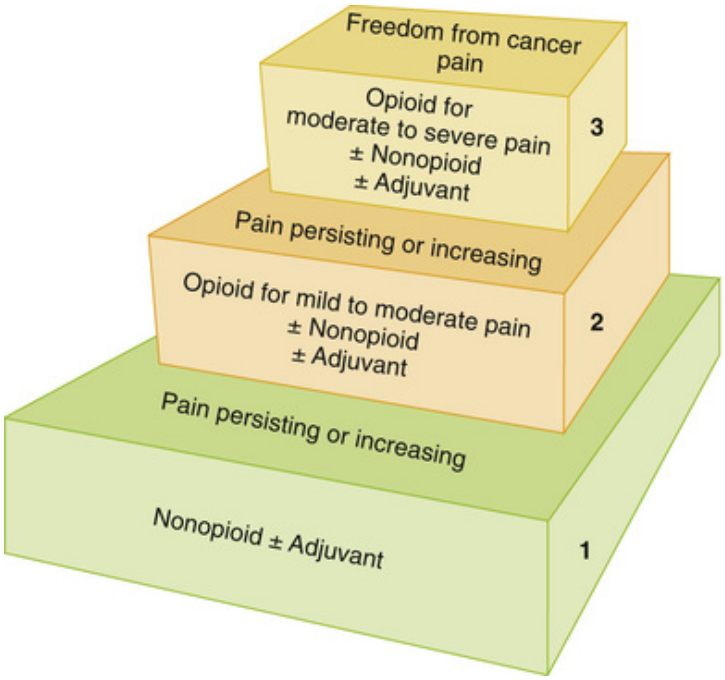

FIGURE 10-8 The analgesic ladder proposed by the World Health Organization. Source: Reprinted from *Cancer,* WHO, WHO analgesic ladder, WHO, Copyright 2018.

Drug Therapy for Mild Pain.

When pain is mild (1 to 3 on a scale of 0 to 10), nonopioid analgesics (Aspirin and other salicylates, other NSAIDs, and acetaminophen) may be used (Table 10-9). These medications are characterized by the following: (a) their analgesic properties have a **ceiling effect**: that is, increasing the dose beyond an upper limit provides no greater analgesia; (b) they do not produce tolerance or physical dependence; and (c) many are available without a prescription. It is important to monitor over-the-counter analgesic use to avoid serious problems related to medication interactions, adverse effects, and overdosage.

TABLE 10-9

DRUG THERAPY
Comparison of Select Nonopioid Analgesics

Drug	Analgesic Efficacy in Comparison to Standards	Nursing Considerations
Acetaminophen (Tylenol)	Comparable to Aspirin	Rectal suppository available; sustained-release preparations available; maximum daily dosage of 4 g
Salicylates		
Acetylsalicylic acid (Aspirin)	Standard for comparison	Rectal suppository available; sustained-release preparations available Possibility of upper GI bleeding
Nonsteroidal Anti-Inflammatory Drugs (NSAIDs)		
Ibuprofen (Motrin, Advil)	Superior at 200–650 mg of aspirin	Usually well tolerated despite the potential for upper GI bleeding
Indomethacin	25 mg comparable with 650 mg of Aspirin	Not routinely used because of high incidence of adverse effects; rectal, intravenous, and sustained-release oral forms available
Ketorolac (Toradol)	30–60 mg equivalent to 6–12 mg of morphine	Treatment should be limited to maximum of 7 days; may precipitate renal failure in dehydrated patients
Diclofenac (Voltaren)	25–50 mg BID to TID; has a longer duration than 650 mg of aspirin	Available in oral, ophthalmic, and topical preparations
Cyclo-oxygenase-2 (COX-2) inhibitors (Celecoxib)	Similar to NSAIDs	Fewer GI complaints, including bleeding; more costly than other NSAIDs
Meloxicam (Mobicox)	Similar to other NSAIDs	May cause fewer GI adverse effects, including bleeding, than do other NSAIDs, but risk is still present; is more costly than other NSAIDs

BID, twice per day; *GI*, gastro-intestinal; *TID*, three times per day.

Drug Alert: NSAIDs

- NSAIDs (except Aspirin) have been linked to a higher risk for cardiovascular events such as myocardial infarction, stroke, and heart failure.
- Patients who have just had heart surgery should not take NSAIDs.

A number of nonopioid analgesics such as acetylsalicylic acid (ASA, Aspirin) and NSAIDs inhibit the chemicals that activate the PAN (Figure 10-9). Thus when these medications are used, the PAN is transduced less often, or a larger stimulus is needed to produce transduction.

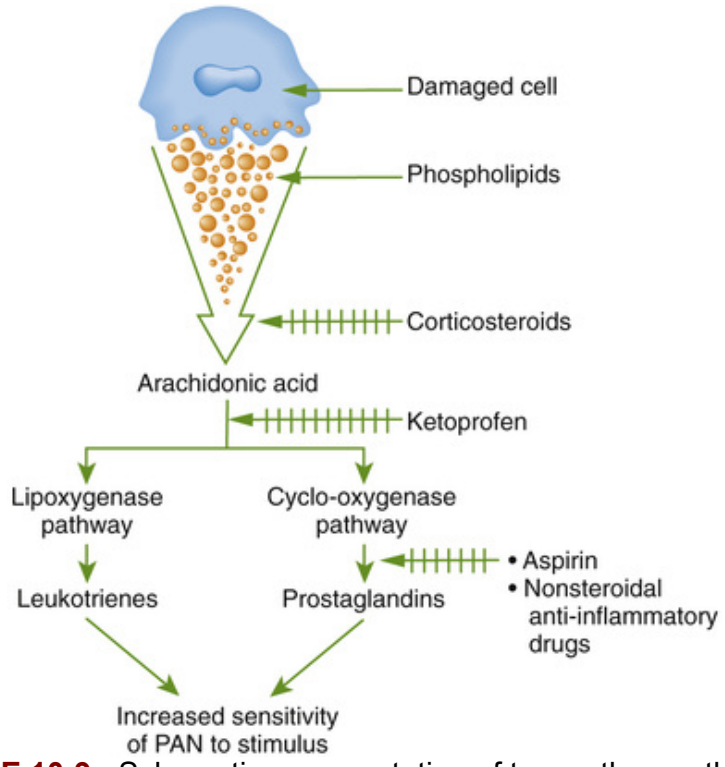

FIGURE 10-9 Schematic representation of two pathways that lead to the production of chemicals that cause the primary afferent nociceptor (PAN) to be more easily excited. Medications that block the synthesis of these chemicals are also shown.

Aspirin is effective for mild pain, but its use is limited by its common adverse effects, including gastric upset and bleeding. Other salicylates such as choline magnesium trisalicylate cause fewer GI disturbances and bleeding abnormalities. Similarly to Aspirin, acetaminophen (Tylenol) has analgesic and antipyretic effects, but it has no antiplatelet or anti-inflammatory effects. Acetaminophen is well tolerated; however, dosages higher than 4 000 mg per day, acute overdosage, or use by patients with alcoholism or liver disease can result in severe hepatotoxicity.

The NSAIDs represent a broad class of medications with varying efficacy and adverse effects. Some NSAIDs possess analgesic efficacy equal to that of Aspirin, whereas others have somewhat higher efficacy. Patients vary greatly in their responses to a specific NSAID, so when one NSAID does not provide relief, another should be tried. NSAIDs inhibit the cyclo-oxygenase-1 (COX-1) and -2 (COX-2) enzymes, which produce prostaglandins involved in inflammation. Because prostaglandins also play a key role in protecting the lining of the stomach from acids, adverse effects of NSAIDs can be serious and include bleeding tendencies secondary to decreased platelet aggregation, GI problems ranging from

dyspepsia to ulceration and hemorrhage, renal insufficiency, and, on occasion, CNS dysfunction. For certain chronic conditions, such as rheumatoid arthritis and osteoarthritis, NSAIDs that more selectively inhibit cyclo-oxygenase-2 (COX-2) only are used. The COX-2 enzyme does not play a role in protecting the stomach or intestinal tract, and therefore its selective inhibition is not associated with the same risk for injury to these organs as is the inhibition of COX-1. A common example of a COX-2 inhibitor is meloxicam (Mobicox). Cautious use of anti-inflammatory medications, long-term, has been recommended due to increased risk for cardiovascular accidents (Sanchez, Tenias, Arias, et al., 2015).

Drug Therapy for Mild to Moderate Pain.

When pain is moderate in intensity (4 to 6 on a scale of 0 to 10) or mild but persistent despite nonopioid therapy, step 2 medications are indicated. Medications commonly used for mild to moderate pain are listed in Table 10-10.

TABLE 10-10
DRUG THERAPY
Opioid Analgesics Commonly Used for Mild to Moderate Pain

Drug	Comments	Nursing Considerations
Morphine-Like Agonists		
Codeine	Weak opioid: Many preparations are combinations with nonopioid analgesics; codeine is a prodrug and metabolized to morphine; 1–30% of people metabolize too efficiently and 10–20% are unable to metabolize it	For mild to moderate pain, preparations of codeine and other opioids are limited by the dosage of nonopioid analgesic (e.g., the maximum dosage of acetaminophen is 44 g in 24 hours)
Tramadol (Ultram)	Maximum dosage: 400 mg in 24 hours	May cause seizures, although rarely
Mixed Agonist–Antagonists		
Pentazocine (Talwin)	*Not recommended*	Can precipitate withdrawal in people taking opioids on a regular basis; frequently causes psychotomimetic effects
Butorphanol	Not available orally; not scheduled under *Controlled Drugs and Substances Act*; butorphanol nasal spray is used to treat migraine headaches	May precipitate withdrawal in people taking opioids on a regular basis; may cause psychotomimetic effects; reacts with many other medications; not widely prescribed

Source: Adapted from Inturrisi, C., & Lipman, A. (2010). Opioid analgesics. In S. M. Fishman, J. C. Ballantyne, & J. P. Rathmell (Eds.), *Bonica's management of pain* (4th ed., pp. 1174–1175). London, UK: Wolters-Kluwer/Lippincott Williams & Wilkins.

One class of step 2 medications is opioids. Opioids include many drugs (Table 10-11; also see Table 10-10) that produce their effects by binding to receptors. Opioid receptors are found in the CNS, on the terminals of sensory nerves, and on the surface of immune cells. There are three major

opioid receptors, traditionally referred to as *mu*, *kappa,* and *delta.* The receptors have been reclassified as OP1 (delta), OP2 (kappa), and OP3 (mu). Most clinically useful opioids bind to the mu receptors. Mu agonists include morphine, oxycodone, hydromorphone (Dilaudid), and methadone. Opioid *agonists* (e.g., morphine) bind to the receptors and cause analgesia. *Antagonists* (e.g., naloxone) bind to the receptors but do not produce analgesia; they also block other effects of opioid receptor activation, such as sedation and respiratory depression. Mixed *agonists naloxone,* such as pentazocine (Talwin) and butorphanol, should not be used because they bind as agonists on the kappa receptor and, as weak antagonists or partial agonists, on the mu receptor (Figure 10-10). When a mixed agonist–antagonist is given to someone taking an agonist (e.g., morphine), it will act like an agonist–antagonist, such as naloxone, and reverse any analgesic effect. These opioid agonist–antagonists also cause more dysphoria and agitation. In addition, they have an **analgesic ceiling** (a dosage at which no additional analgesia is produced regardless of further dosage increases) and can precipitate withdrawal in a patient who is physically dependent on agonist drugs.

TABLE 10-11

DRUG THERAPY
Opioids Commonly Used for Severe Pain

Drug	Comments	Nursing Considerations
Morphine	Standard comparison for opioid analgesics; sustained-release preparation (MS Contin) available	For all opioids: use with caution in people with impaired ventilation, bronchial asthma, increased intracranial pressure, liver failure; in some people, the metabolite M6G may cause excessive vomiting and hallucinations, necessitating a change of opioid
Morphine-Like Agonists		
Hydromorphone (Dilaudid)	—	Well tolerated; also available in elixir form for patients unable to swallow tablets
Oxycodone (slow-release formulation is OxyNeo)	May be given alone or combined with acetaminophen; immediate- and slow-release preparations are available; formulated to deter potential misuse	For moderate to severe pain; usually well tolerated
Methadone	Good oral potency; 24- to 36-hour half-life, which necessitates careful monitoring	Licence required to prescribe; accumulates with repeated doses; on days 2–5, dosage size and frequency must be reduced
Fentanyl	Available as sublingual tablet, as injection, or, for persistent pain, as transdermal preparation (Duragesic)	Immediate onset after administration by intravenous route; within 7–8 min. after intramuscular route; onset after transdermal route may take several hours; not recommended for acute pain management
Meperidine (Demerol)	Not recommended as first-line treatment for acute pain and should not be used for persistent pain management	Not well absorbed through oral route and should not be used; normeperidine (toxic metabolite with half-life of 14–21 hours) accumulates with repetitive dosing, causing CNS excitation and seizures; naloxone potentiates excitation and must not be used; avoid in patients taking monoamine oxidase inhibitors (e.g., selegiline)
Mixed Agonist–Antagonists		
Butorphanol	Not available orally; not scheduled under *Controlled Drugs and Substances Act*	May precipitate withdrawal in opioid-dependent patients

CNS, central nervous system.

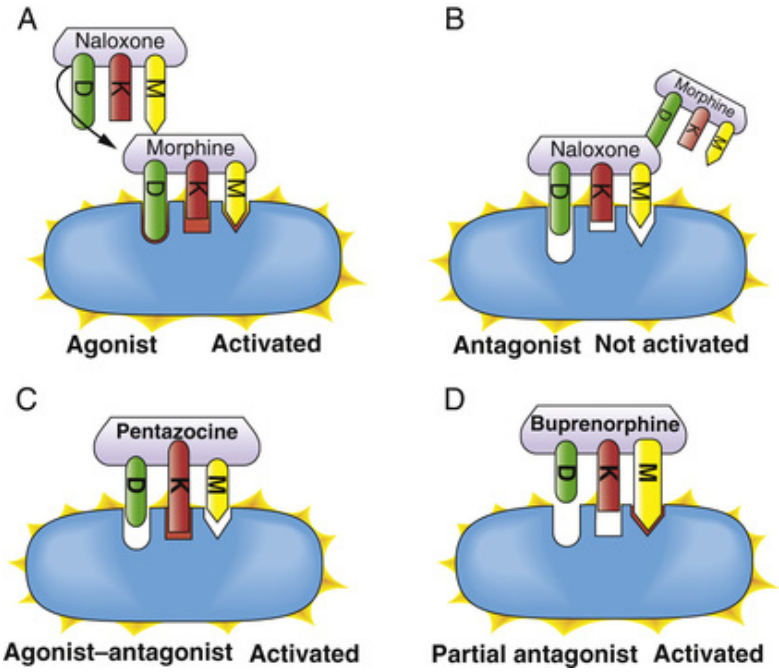

FIGURE 10-10 Opioid receptor subtypes. **A,** Agonist action. **B,** Antagonist action. **C,** Agonist–antagonist action. **D,** Partial antagonist action. *M,* mu receptor; *K,* kappa receptor; *D,* delta receptor.

At step 2, prescriptions for commonly used opioids are often for products combining an opioid with a nonopioid analgesic (e.g., oxycodone [Oxycontin] or codeine plus acetaminophen [Tylenol No. 3]), which may limit the opioid dose that can be given. Oxycodone is now administered for severe pain as well. Although propoxyphene (Darvon) is classified as a step 2 drug, it is not recommended in analgesia guidelines because its effectiveness is limited and its toxic metabolite can cause seizures. Propoxyphene is not approved for use in Canada. A third type of medication available for mild to moderate pain is tramadol (Ultram). Tramadol is a weak mu-receptor agonist and is thought to inhibit the reuptake of norepinephrine and serotonin. It has approximately the same efficacy as acetaminophen plus codeine. The most common adverse effects, which are similar to those of other opioids, include nausea, constipation, dizziness, and sedation.

Drug Therapy for Moderate to Severe Pain.

Step 3 drugs are recommended for moderate to severe pain (4 to 10 on a scale of 0 to 10) or when step 2 drugs do not produce effective pain relief. Most commonly used step 3 analgesics are mu-receptor agonists, although these medications also bind with the other receptors. These medications

are effective for moderate to severe pain because they are potent, have no analgesic ceiling, and can be delivered via many routes of administration. Step 3 drugs are listed in Table 10-11.

Morphine is one of the opioids most commonly prescribed for moderate to severe pain, although fentanyl (Duragesic), hydromorphone (Dilaudid), methadone (Metadol), and oxycodone also are used extensively. A long-acting morphine formulation (MS Contin) is available to treat moderate to severe persistent pain in patients who require continuous, round-the-clock therapy for an extended period. Meperidine (Demerol), a mu-receptor agonist, is no longer recommended for acute or persistent pain because of the high incidence of neurotoxicity (e.g., seizures) associated with the accumulation of its neurotoxic metabolite, normeperidine. Moreover, any adverse effect cannot be reversed by naloxone, which potentiates the effect of normeperidine. In addition, a hyperpyrexic syndrome with delirium, which can cause death, can occur if meperidine is given to patients taking monoamine oxidase inhibitors. Although step 3 opioids have no analgesic ceiling, people can experience dose-limiting adverse effects. In opioid-naive patients, adverse effects include constipation, nausea and vomiting, sedation, respiratory depression, and pruritus. With continued use, most adverse effects diminish; the exception is constipation. Less common adverse effects include urinary retention, myoclonus, dizziness, confusion, and hallucinations.

Drug Alert: Opioids

- Opioids may cause respiratory depression.
- If respirations are 12 or fewer breaths per minute, withhold medication and contact the health care provider.
- Methadone may cause respiratory depression.
- In increased doses, methadone can cause cardiac toxicity, specifically QT prolongation.
- Transdermal fentanyl should not be used for management of acute pain.

Constipation is the most common opioid adverse effect. Because tolerance to opioid-induced constipation does not occur, a bowel regimen should be instituted at the beginning of opioid therapy and should

continue for as long as the person takes opioids. Although dietary roughage, fluids, and exercise should be encouraged to the extent possible, these measures rarely are sufficient by themselves. Thus most affected patients should immediately begin taking a gentle stimulant laxative (e.g., senna [Senokot]) plus a stool softener (e.g., docusate sodium [Colace]). Other agents (e.g., milk of magnesia, bisacodyl [Dulcolax], lactulose) can be added if necessary. Left untreated, constipation can lead to fecal impaction and paralytic ileus that can be difficult to differentiate from obstruction.

Nausea often is a problem in opioid-naive patients. The use of antiemetics such as ondansetron (Zofran), metoclopramide, hydroxyzine (Atarax), or a prochlorperazine can prevent or minimize opioid-related nausea and vomiting until tolerance develops, which usually occurs within 1 week. Metoclopramide is particularly effective when a patient complains of gastric fullness. Opioids delay gastric emptying, and this effect can be reversed by metoclopramide. If nausea and vomiting are severe and persistent, as with morphine because of the metabolite M6G, changing to a different opioid such as oxycodone or hydromorphone may be necessary.

Two of the most common concerns associated with opioids are sedation and respiratory depression. Sedation may occur initially in opioid-naive patients, although patients handling pain without relief may be sleep deprived. Respiratory depression is rare in opioid-tolerant patients when opioids are titrated to analgesic effect. Individuals at risk for respiratory depression include opioid-naive patients, older-adult patients, and patients with underlying lung disease. If respiratory depression occurs and stimulating the patient (e.g., calling and shaking patient) does not reverse the somnolence or increase the respiratory rate and depth, naloxone (0.4 mg in 10 mL saline), an opioid antagonist, can be administered intravenously or subcutaneously in 0.5 mL increments every 2 minutes. However, if the patient has been taking opioids regularly for more than a few days, naloxone should be used judiciously and titrated carefully because its use can precipitate severe, agonizing pain, profound withdrawal symptoms, and seizures. Because the half-life (60 to 90 minutes) of naloxone is shorter than that of most opioids, nurses should monitor the patient's respiratory rate because it can drop again 1 to 2 hours after naloxone administration.

Itching may occur with opioids, most frequently when they are administered via intraspinal routes. An antihistamine such as diphenhydramine (Benadryl) often is effective. If measures are ineffective,

a low-dose opioid antagonist (e.g., naloxone) or a mixed agonist–antagonist can be used, but the patient must be carefully assessed for reversal of analgesia and withdrawal.

Safety Alert

- The most appropriate opioid depends on the patient's clinical profile and the nature of the pain problem (e.g., mild to moderate, severe).
- Patients should be advised that opioids can cause cognitive effects, impairing their ability to drive.
- It is important to recognize that some women rapidly metabolize codeine to morphine. In the case of postoperative patients who are breastfeeding, the infant may be at risk for fatal opioid toxicity. If codeine is prescribed to breastfeeding mothers, consultation with the physician and other health care team members is crucial to ensure careful monitoring (NOUGG, 2010). The patient should be advised to monitor the infant for signs of CNS depression, including poor feeding and limpness, and to contact the health care provider immediately if any such signs are noted.

Adjuvant Analgesic Therapy.

Adjuvant analgesic therapies are medications used in conjunction with opioid and nonopioid analgesics. Adjuvants are sometimes referred to as *coanalgesics*. They include medications that enhance pain therapy through one of three mechanisms: (a) enhancing the effects of opioids and nonopioids, (b) possessing analgesic properties of their own, or (c) counteracting the adverse effects of other analgesics. Commonly used analgesic adjuvants are listed in Table 10-12. Figure 10-11 shows the sites of actions of pharmacological and nonpharmacological therapies for pain. Adjuvant drugs are used at every step in the WHO ladder.

TABLE 10-12

DRUG THERAPY
Adjuvant Drugs Used for Pain Management

Drug	Specific Indication	Nursing Considerations
Corticosteroids	Inflammation	Avoid high dosage for long-term use
Antidepressants		
Amitriptyline (Elavil) Bupropion Duloxetine (Cymbalta) Desipramine Doxepin (Sinequan) Imipramine Maprotiline Nortriptyline (Aventyl) Venlafaxine	Neuropathic pain	Monitor for anticholinergic adverse effects
Antiseizure Drugs		
Carbamazepine (Tegretol) Clonazepam (Rivotril) Gabapentin (Neurontin) Pregabalin (Lyrica) Oxcarbazepine (Trileptal) Topiramate (Topamax) Valproic acid (Epival, Depakene)	Neuropathic pain	Start with low dosages, increase slowly to appropriate level for effect Clonazepam and carbamazepine: Check liver function, renal function, electrolytes, and blood cell counts at baseline, at 2 wks. and at 6 wks. Gabapentin: Monitor for idiosyncratic adverse effects (e.g., ankle swelling, ataxia, sedation)
Muscle Relaxant		
Baclofen (Lioresal)	Neuropathic pain (e.g., trigeminal neuralgia, muscle spasms)	Monitor for weakness, urinary dysfunction; avoid abrupt discontinuation because of CNS irritability
Anaesthetics: Systemic or Oral		
Mexiletine	Diabetic neuropathy; neuropathic pain	Monitor for adverse effects, including dizziness, perioral numbness, paresthesias, tremor; can cause seizures, dysrhythmias, and myocardial depression at high dosages; avoid in patients with pre-existing cardiac disease
Anaesthetics: Local		
Topical EMLA: lidocaine 2.5% + prilocaine 2.5%	Local skin analgesic before venipuncture, incision; possibly effective for postherpetic neuralgia	Must be applied under an occlusive dressing (e.g., Tegaderm, DuoDerm) or on an anaesthetic disc; absorption from the genital mucosa is more rapid and onset time is shorter (5–10 min.) than after application to intact skin; common adverse effects include mild erythema, edema, skin blanching
Capsaicin	Pain associated with arthritis, postherpetic neuralgia, diabetic neuropathy	Apply sparingly, rub well into affected area; wash hands with soap and water after application; adverse effects include skin irritation (burning, stinging) at the application site and cough

Drug	Specific Indication	Nursing Considerations
Psychostimulants		
Dextroamphetamine (Dexedrine) Methylphenidate (Ritalin)	Managing opioid-induced sedation	Adverse effect is insomnia; avoid administering late in the day; usually well tolerated at low dosages
Cannabinoids		
Nabilone	Neuropathic pain	Recommended as an adjuvant for neuropathic pain in cases where therapeutic effect is not achieved via gabapentin

EMLA, eutectic mixture of local anaesthetics.

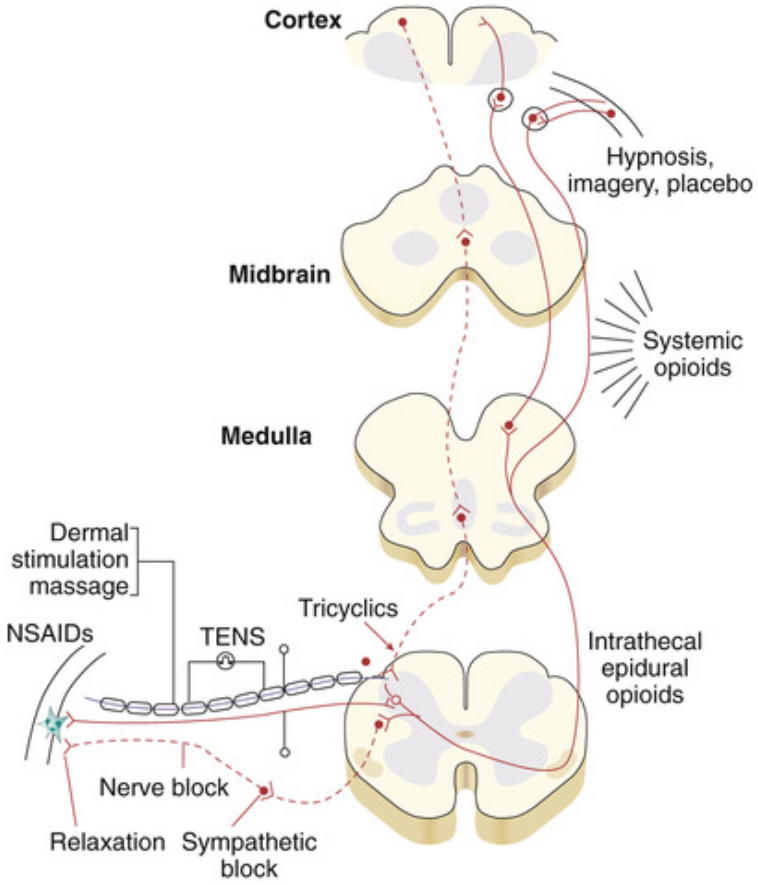

FIGURE 10-11 The sites of commonly used pharmacological and nonpharmacological analgesic therapies. *NSAIDs,* nonsteroidal anti-inflammatory drugs; *TENS,* transcutaneous electrical nerve stimulation.

Antidepressants.

Tricyclic antidepressants have analgesic properties at dosages lower than those effective for depression. They enhance the descending inhibitory

system by preventing synaptic reuptake of serotonin and norepinephrine. Higher levels of serotonin and norepinephrine in the synaptic cleft inhibit the transmission of nociceptive signals in the CNS. Tricyclic antidepressants have been shown to be effective for a variety of pain syndromes, especially those involving neuropathic pain. Anticholinergic effects such as dry mouth, urinary retention, sedation, and orthostatic hypotension may lessen patients' acceptance of using the drug and adherence to the regimen.

Drug Alert: Tricyclic Antidepressants

- Tricyclic antidepressants have been implicated in prolonged QT intervals.

Antiseizure Drugs.

Antiseizure drugs such as gabapentin (Neurontin), carbamazepine (Tegretol), and clonazepam (Rivotril) stabilize the membrane of the neuron and prevent transmission. These medications are effective for some neuropathic pain and for prophylactic treatment of headaches.

Corticosteroids.

Corticosteroid medications, which include dexamethasone and methylprednisolone (Medrol), are used to treat several types of pain, including acute and persistent cancer pain, pain secondary to spinal cord or brain compression, and some neuropathic pain syndromes. Mechanisms of action are unknown but may involve the ability of corticosteroids to decrease edema and inflammation and, in some cases, to shrink tumours. Corticosteroids have many adverse effects, especially when used chronically in high dosages. Adverse effects include hyperglycemia, fluid retention, dyspepsia and GI bleeding, impairment in healing, muscle wasting, osteoporosis, and susceptibility to infection.

Local Anaesthetics.

Oral, parenteral, and topical applications of local anaesthetics are used to interrupt transmission of pain signals to the brain. Local anaesthetics are given for acute pain resulting from surgery or trauma. Persistent neuropathic pain also may be controlled with local anaesthetics. Adverse effects can include dizziness, paresthesias, and seizures (at high dosages).

Incidence and severity of adverse effects depend on dosage and route of administration. These medications also affect cardiac conductivity and may cause dysrhythmias and myocardial depression.

Administration Routes.

Opioids and other analgesic medications can be delivered via many routes. This flexibility allows the health care provider to (a) target a particular anatomical source of the pain, (b) achieve therapeutic blood levels rapidly when necessary, (c) avoid certain adverse effects through localized administration, and (d) provide analgesia when patients are unable to swallow. The following discussion highlights the uses and nursing considerations for analgesics delivered through a variety of routes.

Oral.

In general, oral administration is the route of choice for the patient with a functioning GI system. Oral medications are usually less expensive than those delivered by other routes. Many opioids are available in oral preparations, such as liquid and tablet formulations. To obtain analgesia equivalent to that provided by doses administered intramuscularly or intravenously, oral doses must be higher. For example, 10 mg of parenteral morphine is equivalent to approximately 30 mg of orally administered morphine. Generally, oral administration is the route required for opioid-naive patients because of the first-pass effect of hepatic metabolism. This means that oral opioids initially are absorbed from the GI tract into the portal circulation and shunted to the liver. Partial metabolism in the liver occurs before the medication enters systemic circulation and becomes available to peripheral receptors or before it can cross the blood–brain barrier and access CNS opioid receptors, a process necessary to produce analgesia. Many opioids are available in oral preparations, such as liquid and tablet form. Oral opioids are as effective as parenteral opioids if the dose administered is large enough to compensate for the first-pass metabolism.

Oral preparations also are available in immediate-release and sustained-release preparations. For example, morphine is available in immediate-release solutions or tablets. These products are effective in providing rapid, short-term pain relief; concentration in the blood typically peaks within 30 to 60 minutes. Sustained-release oral morphine tablets are administered every 8 to 12 hours; the most common preparation is morphine ER (MS Contin). As with other sustained-release preparations, this product should not be crushed, broken, or chewed. Oxycodone also

comes in a sustained-release capsule (OxyNeo). Other opioids with sustained-release formulations include hydromorphone and tramadol. The time to maximum blood plasma dose concentration typically ranges from 30 to 60 minutes and from 2 to 4 hours for immediate-release and sustained-release formulations, respectively.

Sublingual and Buccal.

Opioids administered under the tongue or held in the mouth and absorbed into systemic circulation are exempt from the first-pass effect.

Intranasal.

Intranasal administration allows delivery of medication to highly vascular mucosa and avoids the first-pass effect. Butorphanol is one of the few intranasal analgesics available. This medication is most commonly indicated for migraine headaches. Several intranasal opioids such as fentanyl drugs are being investigated (Dale, 2010).

Rectal.

The rectal route is often overlooked but is particularly useful when the patient cannot take an analgesic by mouth. Rectal suppositories that are effective for pain relief include hydromorphone (Dilaudid) and morphine.

Transdermal.

Fentanyl (Duragesic) is available as a transdermal patch system for application to nonhairy skin. This delivery system is useful for the patient who cannot tolerate oral analgesic drugs. Absorption from the patch is slow. Therefore, transdermal fentanyl is not suitable for rapid dosage titration but can be effective if the patient's pain is stable and the dosage required to control it is known. Patches may have to be changed every 48 hours rather than the recommended 72 hours, depending on individual patient responses.

Currently, creams and lotions containing 10% trolamine salicylate (e.g., Aspercreme, Myoflex) are available. These medications have been recommended by the manufacturers for joint and muscle pain. This Aspirin-like substance is absorbed locally. The topical route of administration precludes gastric irritation, but the other adverse effects of high-dosage salicylate are not necessarily prevented.

Ointments, lotions, gels, liniments, and balms (most of which are over-the-counter products) are sometimes applied topically to achieve pain relief. Common ingredients include methyl salicylate combined with

camphor, menthol, or both. On application, these medications usually produce a strong hot or cold sensation and should not be used after massage or a heat treatment, when blood vessels are already dilated. Skin testing is advisable when the patient has not used the particular medication before because the strengths of the medications vary and different intensities of sensation are produced. These products are indicated for arthralgia, bursitis, myalgia, and tendinitis.

Other topical analgesic medications, such as capsaicin (e.g., Flex-ol) and prilocaine plus lidocaine (eutectic mixture of local anaesthetics [EMLA]), and anti-inflammatory medications such as Voltaren (1% diclofenac) also provide analgesia. Derived from red chili pepper, capsaicin depletes and prevents reaccumulation of substance P in the peripheral sensory neurons. It can control pain associated with postherpetic neuralgia, diabetic neuropathy, and arthritis. EMLA is useful for control of pain associated with venipunctures, ulcer debridement, and possibly postherpetic neuralgia. The area to which EMLA is applied should be covered with a plastic wrap for 30 to 60 minutes before a painful procedure begins.

Parenteral Routes.

The parenteral route includes subcutaneous and intravenous administration. The only opioid that must be injected intramuscularly is meperidine, and this drug is not recommended because its toxic metabolite, normeperidine, can accumulate with repeated administration, causing CNS excitation. Single-dose administration (subcutaneous or intravenous) is possible via parenteral routes. The intramuscular route, although frequently used, is not recommended because these injections cause significant pain, result in unreliable absorption, and, with chronic use, can result in abscesses and fibrosis. Onset of analgesia after subcutaneous administration is slow, and thus the subcutaneous route is rarely used for acute pain management. However, continuous subcutaneous infusions are effective for persistent cancer pain. This route is especially helpful for people with abnormal GI function and limited venous access. Intravenous administration is the best option when immediate analgesia and rapid titration are necessary. Continuous intravenous infusions provide excellent steady-state analgesia through stable blood levels.

Intraspinal Delivery.

Intraspinal (epidural or intrathecal) opioid therapy involves inserting a catheter into the subarachnoid space (for intrathecal delivery) or the

epidural space (for epidural delivery) and injecting an analgesic, by either intermittent bolus doses or continuous infusion. Percutaneously placed temporary catheters are used for short-term therapy (2 to 4 days), and surgically implanted catheters are used for long-term therapy. Although the lumbar region is the most common site of placement, epidural catheters may be placed at any point along the neuroaxis (cervical, thoracic, lumbar, or caudal). Intraspinally administered analgesics are highly potent because they are delivered close to the receptors in the dorsal horn of the spinal cord. Thus much lower doses of analgesics are needed for intraspinal delivery in comparison with other routes, including intravenous. Drugs that are delivered intraspinally include morphine, fentanyl, and hydromorphone. Nausea, itching, and urinary retention are common adverse effects of intraspinal opioids.

Complications of intraspinal analgesia include catheter displacement and migration, neurotoxicity (especially of certain medications when infused intraspinally), and infection. Clinical manifestations of catheter displacement or migration depend on catheter location. Movement of a catheter out of the intrathecal or epidural space causes a decrease in pain relief with no improvement even when additional analgesic is administered. Correct placement of an intrathecal catheter can be checked by aspirating cerebrospinal fluid. Migration of a catheter into a blood vessel causes an increase in adverse effects because of systemic medication distribution. A number of medications and chemicals are highly neurotoxic when administered intraspinally. These include many substances, such as preservatives (e.g., alcohol and phenol), antibiotics, potassium, and total parenteral nutrition supplements. To avoid inadvertent injection of intravenous medications into an intraspinal catheter, the catheter should be clearly marked as an intraspinal access device, and only preservative-free medications should be injected.

Infection rarely occurs with intraspinal analgesia. However, it is a serious complication that can be difficult to detect. The skin around the exit site should be carefully assessed for inflammation, drainage, or pain. Signs and symptoms of an intraspinal infection include diffuse back pain, pain or paresthesias during bolus injection, and unexplained sensory or motor deficits. Fever may or may not be present. Acute bacterial infection (meningitis) is manifested by fever, headache, and altered mental status. Infection is avoided with regular, meticulous wound care and with the use of sterile technique in caring for the catheter and injecting drugs.

Patient-Controlled Analgesia.

A specific type of subcutaneous, intravenous, or intraspinal delivery system is **patient-controlled analgesia (PCA)**, or *demand analgesia.* PCA is an infusion system that allows the patient to self-administer a dose of opioid through a pump when needed: The patient pushes a button to receive a bolus infusion of an analgesic within preprogrammed intervals. PCA is used widely for the management of acute pain, including postoperative pain and cancer pain. Often, the patient also receives an additional continuous basal infusion (known as *PCA plus basal*) at a preset dose and rate. The addition of a continuous basal infusion to a PCA regimen improves nighttime pain relief and promotes better sleep postoperatively. Common opioids used in the PCA administration method include morphine, fentanyl, and hydromorphone (Dilaudid).

Use of PCA begins with patient teaching. The patient needs to understand the benefits and principles of PCA therapy, the mechanics of obtaining a medication dose (i.e., the operation of the pump and button), and how to titrate the medication to achieve good pain relief. The patient should be encouraged to use the PCA pump prophylactically by self-administering the analgesic before ambulation, physiotherapy, and dressing changes. The patient also needs to be reminded that apart from the involved health care providers, he or she is the only person who should press the button. The patient should also be assured—for safety reasons and to avoid excessive sedation or respiratory depression—that the pump is programmed to deliver a maximum number of doses per hour; pressing the button after the maximum dose is administered will not result in additional analgesic. If the maximum doses are inadequate to relieve pain, by order of a physician or nurse practitioner, the pump can be reprogrammed to increase the amount or frequency of administration. In addition, bolus doses can be given by the nurse if they are included in the physician's orders. The patient should also be encouraged to report adverse effects such as nausea and vomiting or pruritus so that they can be managed effectively. To make a smooth transition from infusion PCA to oral therapy, the dosage of oral medication should be increased (as ordered) as the PCA analgesic is tapered.

Surgical Therapy for Pain

Nerve Blocks.

Nerve blocks are used to reduce pain by temporarily or permanently interrupting transmission of nociceptive input. This is achieved with local anaesthetics or neurolytic drugs (e.g., alcohol, phenol). Neural blockade

with local anaesthetics is sometimes used for perioperative pain. For intractable persistent pain, nerve blocks are used when more conservative therapies fail. Nerve blocks have been a successful pain management technique for more localized persistent pain states, such as peripheral vascular disease, trigeminal neuralgia, causalgia, and some cancer pain. A nerve block may be considered advantageous for managing localized pain caused by malignancy and in debilitated patients who could not otherwise withstand a surgical procedure for pain relief.

Interventional Therapy

Therapeutic Nerve Blocks.

Nerve blocks generally involve one-time or continuous infusion of local anaesthetics into a particular area to produce pain relief. Such relief is also referred to as *regional anaesthesia.* Nerve blocks interrupt all afferent and efferent transmission to the area and thus are not specific to nociceptive pathways. They include local infiltration of anaesthetics into a surgical area (e.g., for excision of a breast lump, inguinal hernia surgery, intra-articular infiltration after joint surgery, amputation, subcostal incisions) and injection of anaesthetics into a specific nerve (e.g., occipital or pudendal nerve) or nerve plexus (e.g., brachial or celiac plexus). Nerve blocks often are used during and after surgery to manage pain. For longer-term relief of chronic pain problems, local anaesthetics can be administered via a continuous infusion.

For intractable persistent pain, neuroablative nerve blocks (see next section) with phenol or alcohol may be used. For example, a neurolytic celiac plexus block may be induced for pain caused by pancreatic cancer, or an intercostal neurolytic block may be induced for post-thoracotomy pain. Heat and microwaves, used in many neurolytic procedures, produce nerve tissue destruction.

Neuroablative Techniques.

Neuroablative interventions are performed for severe pain that is unresponsive to all other therapies. Neuroablative techniques destroy nerves, thereby interrupting pain transmission. Destruction is accomplished by surgical resection or thermocoagulation, including radiofrequency coagulation. Neuroablative interventions that destroy the sensory division of a peripheral or spinal nerve are classified as neurectomies, rhizotomies, and sympathectomies. Neurosurgical procedures that ablate the lateral spinothalamic tract are classified as

cordotomies if the tract is interrupted in the spinal cord or as tractotomies if the interruption is in the medulla or the midbrain of the brain stem. Figure 10-12 depicts the sites of neurosurgical procedures for pain relief. Both cordotomy and tractotomy can be performed with the aid of local anaesthesia by a percutaneous technique.

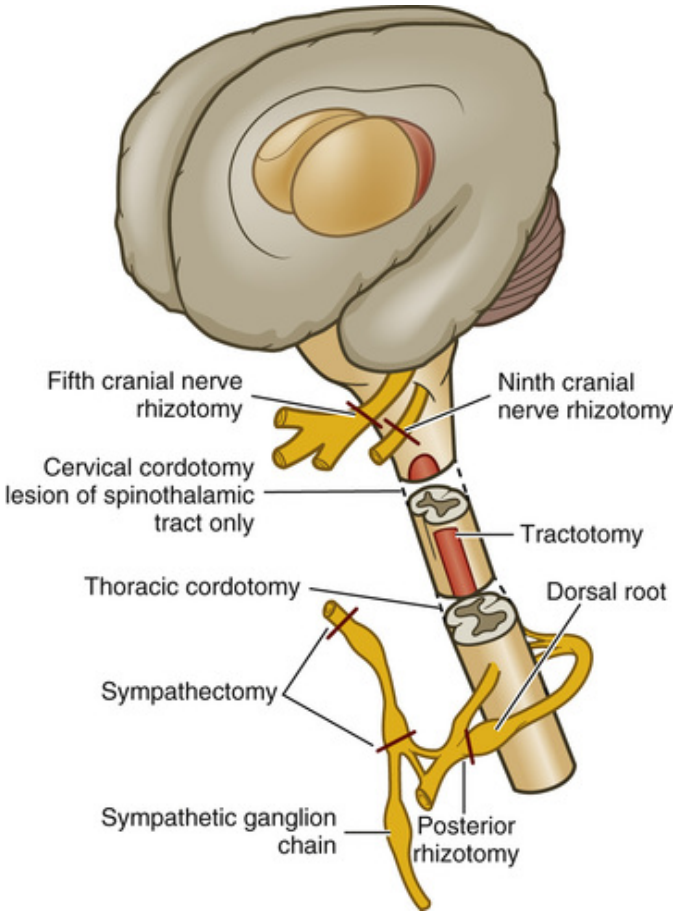

FIGURE 10-12 Sites of neurosurgical procedures for pain relief.

Neuroaugmentation.

Neuroaugmentation involves electrical stimulation of the brain and the spinal cord. Spinal cord stimulation is performed much more often than deep brain stimulation. Technological advances have enabled the use of multiple leads and multiple electrode terminals so as to stimulate large areas. In Canada and the United States, common uses of spinal cord stimulation are for chronic back pain secondary to nerve damage that is

unresponsive to other therapies (van Tulder & Koes, 2013) and chronic refractory angina (McGillion, Arthur, Cook, et al., 2012b).

Potential complications include those related to the surgery (bleeding and infection), migration of the pulse generator (which usually is implanted in the subcutaneous tissues of the upper gluteal or pectoralis area), and nerve damage.

Nonpharmacological Therapy for Pain

Nonpharmacological pain management strategies can reduce the dose of an analgesic required to control pain and thereby minimize adverse effects of drug therapy. Some strategies are believed to alter ascending nociceptive input or stimulate descending pain modulation mechanisms. Nonpharmacological pain relief methods can be categorized as physical or cognitive strategies (Table 10-13).

TABLE 10-13
NONPHARMACOLOGICAL THERAPIES FOR PAIN

Physical Therapies	Cognitive Therapies
• Acupuncture • Application of heat and cold • Exercise • Massage • Percutaneous electrical nerve stimulation (PENS) • Transcutaneous electrical nerve stimulation (TENS)	• Distraction • Hypnosis • Imagery • Relaxation strategies • Self-management

Physical Pain Relief Strategies

Massage.

Massage is a common therapy for pain, and many massage techniques exist. Examples include moving the hands or fingers over the skin slowly or briskly with long strokes or in circles (superficial massage) or applying firm pressure to the skin to maintain contact while massaging the underlying tissues (deep massage). Specific massage techniques include acupressure and trigger-point massage. A **trigger point** is a circumscribed hypersensitive area within a tight band of muscle that is the result of acute or persistent muscle strain. Several common trigger points have been identified on the neck, back, and arms. Trigger-point massage is performed by either application of strong, sustained digital pressure, deep

massage, or gentler massage with ice followed by muscle heating. (Massage is discussed further in Chapter 12).

Exercise.

Exercise is a critical part of the treatment plan for patients with persistent pain, particularly those with musculo-skeletal pain. Many patients become physically deconditioned as a result of their pain, which in turn can exacerbate pain. Exercise acts through many mechanisms to relieve pain: it enhances circulation and cardiovascular fitness, reduces edema, increases muscle strength and flexibility, and enhances physical and psychosocial functioning. A safe exercise program should be tailored to the physical needs and lifestyle of the patient and should include mild to moderate aerobic exercise, stretching, and strengthening exercises. The program also should be supervised by trained personnel (e.g., physiologist, physiatrist, registered nurse with specialty training, exercise physiologist, physiotherapist).

Transcutaneous Electrical Nerve Stimulation.

Transcutaneous electrical nerve stimulation (TENS) delivers an electric current through electrodes applied to the skin surface over the painful region, at trigger points, or over a peripheral nerve. A TENS system consists of two or more electrodes connected by lead wires to a small, battery-operated stimulator (Figure 10-13). Usually, a physiotherapist is responsible for administering TENS therapy, although nurses also can be trained in the technique.

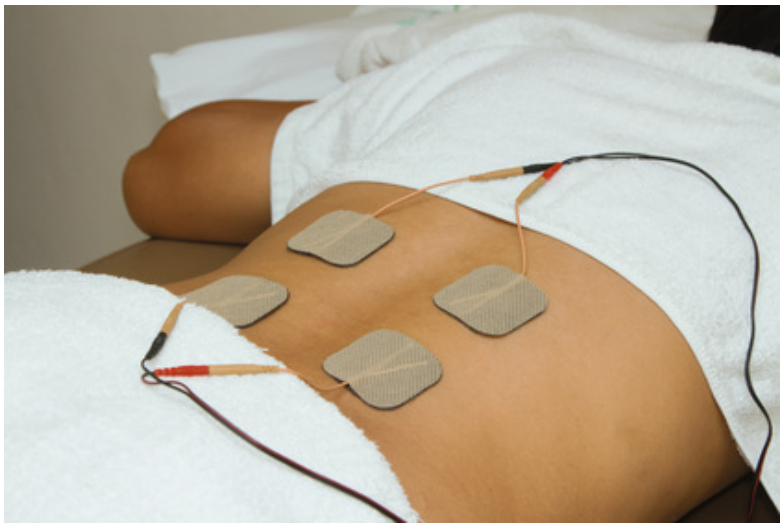

FIGURE 10-13 Transcutaneous electrical nerve stimulation (TENS). Source: Praisaeng/Shutterstock.com.

TENS may be used for acute pain, including postoperative pain, visceral pain, and pain associated with physical trauma. Although the effect of TENS on persistent pain is less clear, it may be effective in such cases (Song, Popescu, & Bell, 2014).

Application of Heat.

Application of heat for pain management has been used for centuries. The premise is that applying heat to skin will increase blood flow and reduce pain-related neurotransmitter activity (RNAO, 2013). Heat therapy includes application of either moist or dry heat to the skin and can be superficial or deep. Superficial heat can be applied through an electric heating pad (dry or moist), a hot pack, hot moist compresses, or a hot water bottle. For exposure to large areas of the body, patients can immerse themselves in a hot bath, shower, or whirlpool. Physical therapy departments provide deep-heat therapy through such techniques as shortwave diathermy, microwave diathermy, and ultrasound therapy. Patient teaching regarding heat therapy is described in Table 10-14.

TABLE 10-14

PATIENT & CAREGIVER TEACHING GUIDE
Application of Heat and Cold

When patients use superficial heating techniques, they should be taught the following:
• Do not use heat on an area that is being treated with radiation therapy, is bleeding, has decreased sensation, or has been injured in the past 24 hours. • Do not use any menthol-containing products (e.g., Vicks VapoRub) with heat applications because this combination may cause burns. • Cover the heat source with a towel or cloth to prevent burns. • Do not apply heat directly to transdermal analgesic preparations, such as fentanyl, as heat application may alter drug bioavailability.
When patients use superficial cold techniques, they should be taught the following:
• Cover the cold source with a cloth or towel. • Do not apply cold to areas that are being treated with radiation therapy, have open wounds, or have poor circulation. • If it is not possible to apply the cold directly to the painful site, try applying it directly above or below the painful site or on the opposite side of the body on the corresponding site (e.g., left elbow if the right elbow hurts).

Application of Cold.

Like heat therapy, application of cold therapy has long been used for pain relief. Cold therapy competes for nerve transmission and reduces sensation, effects that can be especially helpful for pain that resembles a burning sensation (RNAO, 2013). Cold therapy involves the application of either moist or dry cold to the skin. Dry cold can be applied by means of an ice bag, and moist cold by means of towels soaked in ice water, cold hydrocollator packs, or immersion in a cold bath or under running cold water. Icing with ice cubes or blocks of ice made to resemble popsicles is another technique used for pain relief. Cold therapy is believed to be more effective than heat for a variety of painful conditions, including acute pain from trauma or surgery, acute flares of arthritis, muscle spasms, and headache. Patient teaching regarding cold therapy is described in Table 10-14.

Cognitive Techniques.

A variety of cognitive strategies and behavioural approaches can alter the affective, cognitive, and behavioural components of pain. Some of these techniques require little training and often are adopted independently by the patient. For others, a trained therapist must administer therapy.

Distraction.

The redirection of attention on something other than the pain is a simple but powerful strategy to relieve pain. Distraction-induced analgesia involves introducing competition for attention between a highly salient sensation (pain) and some other information-processing activity. Distraction can be achieved by engaging the patient in any activity that can hold his or her attention (e.g., watching TV, conversing, listening to music, playing a game). Recent evidence suggests that distraction may be most effective in those who exhibit persistent pain–related catastrophizing behaviours due to great attention to pain overall (Schreiber, Campbell, Martel, et al., 2014).

Relaxation Strategies.

Relaxation strategies reduce stress, decrease acute anxiety, distract from pain, alleviate muscle tension, combat fatigue, facilitate sleep, and enhance the effectiveness of other pain relief measures (Shengelia, Parker, Ballin, et al., 2013). Elicitation of the relaxation response requires a quiet environment, a comfortable position, and a mental device as a focus of concentration (e.g., a word, a sound, or the breath). Relaxation strategies include relaxation breathing, music, imagery, meditation, and progressive muscle relaxation (Crawford, Lee, & Bingham, 2014). (See Chapters 8 and 12 for additional information.)

Self-Management.

Self-management training is now in widespread use in Canada as an effective, adjunctive strategy for managing the effect of chronic pain on day-to-day functioning and quality of life (McGillion, O'Keefe-McCarthy, Carroll, et al., 2014; McGillion, LeFort, Webber, et al., 2011). By structured rehearsal of various cognitive and behavioural self-management techniques (e.g., energy conservation, pacing, sleep promotion, relaxation, communication skills, safe exercise), patients and family members learn to set realistic weekly goals that are directed at increasing overall functional capacity and emotional well-being. Strong evidence supports the effectiveness of self-management training for (a) improving participants' perceived self-efficacy or ability to achieve selected goals, (b) reducing pain, and (c) improving perceived quality of life (McGillion, O'Keefe-McCarthy, Carroll, et al., 2014; McGillion, LeFort, Webber, et al., 2011).

Nursing and Collaborative Management Pain

The nurse is an important member of the interprofessional pain management team. The nurse acts as planner, educator, patient advocate, interpreter, and supporter of the patient in pain and of the patient's family or caregivers. Because any patient in a wide variety of care settings (e.g., home, hospital, clinic) can be in pain, the nurse must be knowledgeable about current therapies and flexible in trying new approaches to pain management. The extent of the nurse's involvement depends on the unique factors associated with the patient, the setting, and the cause of the pain. Many nursing roles were described earlier in this chapter: conducting pain assessments, administering therapies, monitoring for adverse effects, and teaching patients and caregivers. However, the success of these actions depends on the nurse's ability to establish a trusting relationship with the patient and caregivers and to address the concerns that they have regarding pain and its treatment.

Effective Communication

Patients need to feel confident that their reporting of pain will be believed and will not be perceived as "complaining." The patient and family also need to know that the nurse considers the pain significant and is committed to helping the patient obtain pain relief and cope with any unrelieved pain. Pharmacological and nonpharmacological interventions should be incorporated into the treatment plan, and the patient should be supported through the period of trial and error that may be necessary to implement an effective therapeutic plan. It also is important to clarify responsibilities of pain relief. The nurse should help the patient understand the roles of the interprofessional health care team members, as well as the roles and expectations of the patient.

In addition to addressing specific aspects of pain assessment and treatment, the nurse evaluates the total effect that the pain may have on the lives of the patient and family. Thus, other possible nursing diagnoses must also be considered. Table 10-15 lists possible nursing diagnoses that may be appropriate for assessing and managing pain. Table 10-16 addresses teaching needs of patients and caregivers in relation to pain management.

TABLE 10-15

NURSING ASSESSMENT
Pain-Related Nursing Diagnoses

• Activity intolerance • Acute pain • Anxiety • Chronic pain • Constipation • Disturbed sleep pattern • Fatigue • Fear	• Hopelessness • Ineffective coping • Ineffective role performance • Interrupted family processes • Powerlessness • Risk for self-mutilation • Social isolation • Acute confusion

TABLE 10-16

PATIENT & CAREGIVER TEACHING GUIDE
Pain Management: Teaching Needs

The goals of teaching related to pain management include the expectation that the patient and the caregivers understand the following:
• The need to maintain a record of pain intensity and effectiveness of treatment • No need to wait until pain becomes severe to take medications or use nonpharmacological therapies for pain relief • The possibility that the dosage of medication will have to be adjusted over time to maximize long-term effectiveness • The potential adverse effects (e.g., nausea and vomiting, constipation, sedation and drowsiness, itching, urinary retention, sweating) and complications associated with opioid therapy or other pain relief therapies • The need to report when pain is not relieved to tolerable levels

Barriers to Effective Pain Management

Pain is a complex, multidimensional, and subjective experience, and its management is influenced greatly by psychosocial, sociocultural, and legal and ethical factors. These factors include emotions, behaviours, misconceptions, and attitudes of patients and family members about pain and the use of pain therapies. Achieving effective pain management requires careful consideration of these factors.

Concerns regarding tolerance, dependence, and addiction are common barriers to effective pain management, inasmuch as these phenomena are often misunderstood. Patients, family members, and health care providers often share these concerns. It is important for the nurse to understand and be able to explain the differences among these various concepts (RNAO, 2013).

Tolerance.

Tolerance is "a state of adaptation in which exposure to a drug induces changes that result in diminution of one or more of the drug's effects over time" (NOUGG, 2010, p. 126). In the case of opioids, steady-state dosing can lead to tolerance of unwanted opioid adverse effects (Ballantyne, 2014). However, development of tolerance to an opioid itself is characterized by the need for increasing or more frequent doses of the opioid to maintain the same degree of analgesic effect. Although tolerance is not as common as once thought, it is essential to assess for increased analgesic needs in patients receiving persistent opioid therapy (Ballantyne, 2014). The first sign of tolerance may be that the patient begins to experience regular end-of-dose failure. If manifestations of possible tolerance appear, appropriate evaluations should be made to rule out other causes of increased analgesic needs, such as disease progression or infection. Approaches to managing tolerance are (a) to increase the dosage of the analgesic, (b) to substitute another medication in the same class (e.g., changing from morphine to oxycodone), or (c) to add a medication from a different drug class that will augment pain relief without increasing adverse effects. It is important to note that there is no ceiling effect for opioid-agonist drugs and to recognize that drug tolerance is not synonymous with addiction.

Physical Dependence.

Like tolerance, **physical dependence** is an expected physiological response to ongoing exposure to pharmacological agents. "Physical dependence is a state of adaptation manifested by a drug class–specific withdrawal syndrome that can be produced by abrupt cessation, rapid dose reduction, decreasing blood level of the drug, and/or administration of an antagonist" (NOUGG, 2010, p. 124). Symptoms of opioid withdrawal are listed in Table 10-17.

TABLE 10-17
MANIFESTATIONS OF WITHDRAWAL FROM OPIOIDS

Type	Response
• Mood • Physical and behavioural	• Anxiety, agitation • Restlessness • Diaphoresis • Fever • Flulike symptoms (e.g., nausea, muscle aches) • Tremor • Tachycardia

When opioids are no longer needed to provide pain relief, a tapering schedule should be used in conjunction with careful monitoring. A typical tapering schedule begins with calculating the 24-hour dose used by the patient and dividing by 2. Of this decreased amount, 25% is given every 6 hours. After 2 days, the daily dose is reduced by an additional 25% every 2 days until the 24-hour oral dose is 30 mg (morphine equivalent) per day. After 2 days on this minimum dosage, the opioid is then discontinued. Despite this slow weaning schedule, the nurse should assess carefully for signs of opioid withdrawal. In addition to assessing and preventing opioid withdrawal, it is also important to recognize that other commonly prescribed medications for pain also can induce physical dependence and therefore must be slowly tapered. These include benzodiazepines and muscle relaxants.

Addiction.

Addiction is defined as

> *a primary, chronic, neurobiological disease with genetic, psychosocial, and environmental factors influencing its development and manifestations. It is characterized by behaviours that include one or more of the following: impaired control over drug use, compulsive use, continued use despite harm, and craving. (NOUGG, 2010, p. 124)*

Tolerance and physical dependence are not indicators of addiction. Rather, they are normal physiological responses to chronic exposure to certain drugs, including opioids.

Substance use disorders, including illicit drug use and misuse of prescription opioids, affect about 10% of the general population (Jovey, 2010). The available data are of limited quality and suggest that in patients being treated for persistent pain, the risk of concurrent substance use or addiction is generally the same or higher than that in patients without a substance use disorder (Jovey, 2010). For patients without a history of substance use disorder, the risk is thought to be significantly lower. For example, a 2010 Cochrane Review revealed that signs of addiction were present in 0.3% of patients without a documented history of substance use disorder who were being treated with opioids for persistent noncancer pain (Noble, Treadwell, Tregear, et al., 2010). People with a history of addiction can be managed successfully on opioids for their pain with careful monitoring; however, in this population, the risk for addiction may

be higher. Expectations of the health care team and the patient must be discussed openly and documented. Signs and symptoms of possible addiction must be monitored, and interventions promptly initiated.

In addition to fears about addiction, physical dependence, and tolerance, other barriers hinder effective pain management. These include concern about adverse effects, difficulties with remembering to take medications, desire to handle pain stoically, and not wanting to distract the health care provider from treating the disease. Table 10-18 lists examples of patient-related barriers to effective pain management and includes strategies to address the barriers.

TABLE 10-18

PATIENT & CAREGIVER TEACHING GUIDE
Reducing Patient-Related Barriers to Pain Management

Barrier	Nursing Considerations
Fear of addiction	• Provide accurate definition of *addiction.* • Explain that addiction is uncommon in patients taking opioids for pain relief.
Fear of tolerance	• Provide accurate definition of *tolerance.* • Teach that tolerance is a normal physiological response to long-term opioid therapy. If tolerance does develop, the medication may have to be changed (e.g., morphine in place of oxycodone). • Teach that there is no upper limit to pure opioid agonists (e.g., morphine). Dosages can be increased indefinitely, and the patient should not save medication for when the pain is worse. • Teach that tolerance to analgesic effects of opioids develops more slowly than do many adverse effects (e.g., sedation, respiratory depression). Tolerance does not ameliorate constipation; thus a regular bowel program should be started early.
Concern about adverse effects	• Teach methods to prevent and to treat common adverse effects. • Emphasize that adverse effects such as sedation and nausea decrease with time. • Explain that different medications have unique adverse effects and that other pain medications can be tried to reduce the specific adverse effect. • Teach nonpharmacological therapies to minimize the dosage of medication needed to control pain.
Fear of injections	• Explain that oral medicines are preferred. • Emphasize that even if the oral route becomes unusable, transdermal or in-dwelling parenteral routes can be used rather than injections.
Desire to be a good patient	• Explain that patients are partners in their care and that the partnership requires open communication on the parts of both patient and nurse. • Emphasize to patients that they have a responsibility to keep the nurse informed about their pain.
Desire to be stoic	• Explain that although stoicism is a valued behaviour in many cultures, failure to report pain can result in undertreatment and severe, unrelieved pain.
Forgetting to take analgesic	• Provide and teach use of pill containers. • Provide methods of record keeping for drug use. • Recruit family members as appropriate to assist with the analgesic regimen.
Fear of distracting the health care provider from treating the disease	• Explain that reporting pain is important for treating both the disease and its symptoms.
Concern that pain signifies disease progression	• Explain that increased pain or analgesic needs may reflect tolerance. • Emphasize that new pain may come from a non–life-threatening source (e.g., muscle spasm, urinary tract infection). • Institute pharmacological and nonpharmacological strategies to reduce anxiety. • Ensure that the patient and family members have current, accurate, comprehensive information about the disease and the prognosis. • Provide psychological support.
Sense of fatalism	• Explain that research has shown that pain can be managed in most patients. • Explain that with most therapies, a period of trial and error is necessary. • Emphasize that adverse effects can be managed.
Ineffectiveness of medication	• Teach that there are multiple options within each category of medication (e.g., opioids, NSAIDs) and that another medication from the same category may provide better relief. • Emphasize that finding the best treatment regimen often requires trial and error. • Incorporate nonpharmacological approaches in treatment plan.

NSAIDs, nonsteroidal anti-inflammatory drugs.

Institutionalizing Pain Education and Management

Besides patient and family barriers, other major barriers to effective pain management arise in connection with the health care provider: inadequate education, misconceptions about pain, and lack of organizational support (McGillion & Watt-Watson, 2015). Traditionally, medical and nursing school curricula have spent little time teaching future physicians and nurses about pain and effective pain management, although this is changing. This lack of emphasis was partially responsible for the insufficiency of health care providers' knowledge of and skills for treating pain adequately. Moreover, pain assessment and treatment were not priorities in clinical practice. Health care providers have misbeliefs about pain. Similar to patients, many clinicians confuse physical dependence, tolerance, and addiction and are more likely to assess pain by observing behaviours than by believing or eliciting a patient report (McGillion & Watt-Watson, 2015). Over the past few decades, some improvements have been made in overcoming these barriers. Some prelicensure, undergraduate health care programs are now devoting more time to addressing pain (Hunter, Watt-Watson, McGillion, et al., 2008; Watt-Watson & Murinson, 2013), and there is growing interest in interprofessional educational intervention trials for health care providers that target common pain-related misbeliefs.

The International Association for the Study of Pain has published a core curriculum on pain that was developed for the learning needs of a range of health care provider groups. Provincial organizations such as the RNAO (2013) have also developed evidence-informed practice guidelines on pain that are readily accessible (see the "Resources" section at the end of this chapter for the weblinks).

Health care institutions are also directing more, much-needed attention to their support of pain management. Researchers and health care providers have documented the central role of institutional commitment and practices in changing clinical practice; without institutional support, pain outcomes are unlikely to change. The pain management standards from the Canadian Pain Society's (2010) *Position Statement on Pain Relief* (see the "Resources" section at the end of this chapter) emphasize that patients have a right to the best pain relief possible and that measures to prevent or reduce acute pain are a priority. Many large tertiary and

quaternary university-affiliated care settings now have specialized teams to manage pain. One such example is the establishment of dedicated acute pain services (APS) that include advanced-practice nurses. These services provide expert management of postsurgical pain and complex pain conditions. Advanced-practice nurses, often nurse practitioners, work collaboratively with anaesthesiologists and allied health care providers to assess and manage pain and also to serve in leadership roles to promote best practice guidelines (Ladak, McPhee, Muscat, et al., 2013).

Ethical Issues in Pain Management

Fear of Hastening Death by Administering Analgesics

It is common for the health care provider, patient, and family members to be concerned that providing sufficient medication to relieve pain will precipitate the death of a terminally ill person (Voshall, Dunn, & Shelestak, 2013). The ethical justification for administering analgesics despite the possibility of hastening death follows the bioethical principle of the *rule of double effect*: that if an unwanted consequence (e.g., hastened death) occurs as a result of an action taken to achieve a moral good (e.g., pain relief), the action is justified according to ethical theory (Voshall, Dunn, & Shelestak, 2013). Unrelieved pain has negative psychological effects, such as feelings of hopelessness and depression, with high rates of suicide (Lynch, 2011).

Use of Placebos in Pain Assessment and Treatment

Placebos have been used inappropriately in the past to determine whether patients' pain was "real." Using medication placebos for pain, such as a saline injection instead of an opioid or an oral dosage of an inappropriate medication, is unethical.

Age-Related Considerations

Pain

Persistent pain is a common problem in older adults and is often associated with significant physical disability and psychosocial problems. The most common sources of pain among older adults are musculoskeletal conditions, such as osteoarthritis and low back pain, and previous fracture sites. Persistent pain often results in depression, sleep disturbance, decreased mobility, increased use of health care services, and physical and social role dysfunction. Despite its high prevalence, pain in older adults often is inadequately assessed and treated. However, there are several barriers to pain assessment in the older patient. In general, the barriers discussed earlier in the chapter are more prevalent among this population. For example, many older-adult patients believe that pain is a normal, inevitable part of aging. They may also believe that nothing can be done to relieve the pain. Older adults may not report pain for fear of being a "burden" or a "bad patient." They may have greater fears of taking opioids than patients in other age groups. Nurses must be vigilant in asking older people about their pain and its effects.

Another barrier to pain assessment in older adults is the relatively high prevalence of cognitive, sensory-perceptual, and motor problems that interfere with a person's ability to process information and to communicate (Gagliese & Melzack, 2003). Also, hearing and vision deficits may complicate assessment. Therefore, pain assessment tools may have to be adapted for older adults. For example, it may be necessary to use a large-print pain intensity scale. Although there is some concern that older adults have difficulty using pain scales, it has been documented that many older adults, even those with mild to moderate cognitive impairment, can use quantitative scales accurately and reliably (see Figure 10-7).

As for other patients with persistent pain, a thorough physical examination should be performed and the history thoroughly documented to identify causes of pain, possible therapies, and potential problems. Because depression and functional impairments are common among older adults with pain, the possibility of these also must be assessed.

Treatment of pain in older adults also is complicated by several factors. First, older adults metabolize drugs more slowly than do younger patients and thus are at greater risk for higher blood levels and adverse effects. For this reason, the adage "start low and go slow" is applied to analgesic

therapy in this age group. Second, the use of NSAIDs in older adults is associated with a high frequency of serious GI bleeding. For this reason, acetaminophen should be used whenever possible. Third, many older people take multiple medications for one or more chronic conditions. The addition of analgesics can result in dangerous drug interactions and more adverse effects. Fourth, cognitive impairment and ataxia can be exacerbated when analgesics such as opioids, antidepressants, and anticonvulsant drugs are used, a possibility that again necessitates health care providers to titrate medications slowly and monitor carefully for adverse effects.

Treatment regimens for older adults must incorporate nonpharmacological modalities. Exercise and patient teaching are particularly important nonpharmacological interventions for older adults with persistent pain. The roles of family and paid caregivers also should be included in the treatment plan.

Special Populations

Cognitively Impaired Individuals

Although patient self-report is a gold standard of pain assessment in most circumstances, severe cognitive impairment often prevents patients from communicating clearly about their pain. For these individuals, behavioural and physiological changes may be the only indicators that they are in pain. Therefore, the nurse must be astute at recognizing behavioural symptoms of pain.

Several scales have been developed to assess pain in cognitively impaired older patients (Gagliese & Melzack, 2014). Typically, these scales help assess pain according to common behavioural indicators such as the following:

- Vocalization: moaning, grunting, crying, sighing
- Facial expressions: grimacing, wincing, frowning, clenching teeth
- Breathing: noisy, laboured
- Body movements: restlessness, rocking, pacing
- Body tension: clenching fist, resisting movement
- Consolability: inability to be consoled or distracted

Because it is not possible to validate the meaning of the behaviours, nurses should rely on their own knowledge of the patient's usual behaviour. If the nurse does not know the patient's baseline behaviours, she or he should obtain this information from other caregivers, including family members. When pain behaviours are present, pain therapy should be instituted on an empirical basis, and patients should be carefully reassessed to evaluate treatment effectiveness.

Patients With Substance use Problems

Individuals with a past or current substance use disorder have the right to receive effective pain management. A comprehensive pain assessment is imperative, including a detailed history, physical examination, psychosocial assessment, and diagnostic workup to determine the cause of the pain. The use of screening tools to determine the possible risk for addiction has been described above. The goal of the pain assessment is to facilitate the establishment of a treatment plan that will relieve the individual's pain effectively, as well as prevent or minimize withdrawal symptoms.

Opioids may be used effectively and safely in patients with substance dependence when indicated for pain control. Opioid agonist and antagonist drugs (e.g., pentazocine [Talwin], butorphanol) should not be used in this population because they may precipitate withdrawal. The use of "potentiators" and psychoactive medications that do not have analgesic properties should also be avoided. In individuals who are tolerant to CNS depressants, larger doses of opioids or increased frequency of medication administration is necessary to achieve pain relief.

Effective pain management for people with addiction is challenging and requires expert leadership and consultation for assessment and facilitation of a planned, interprofessional team approach according to current Canadian guidelines (NOUGG, 2010). Team members must be aware of their own attitudes and misbeliefs about people with substance use problems, which have the possibility of resulting in undertreatment of pain.

Case Study

Pain

Source: Samuel Borges Photography/Shutterstock.com.

Patient Profile

Mrs. Cato is a 112-kg, 43-year-old Caribbean woman admitted for an incision and drainage of a right renal abscess. Her renal function is not impaired. She has a history of low back pain and takes oxycodone, 5 to 10 mg, every 6 hours as needed.

Subjective Data

- Lives alone
- Desires 0 pain during therapy but will accept 1 to 2 on a scale of 0 to 10
- Reports incision-area pain as a 2 or 3 between dressing changes and as a 10 during dressing changes
- States sharp, throbbing pain persists 1 to 2 hours after dressing change
- Reports pain between dressing changes controlled by two oxycodone tablets

Objective Data

- Requires twice-a-day dry-to-dry dressing changes for 1 week
- Morphine, 2 to 15 mg intravenously, for every dressing change
- Oxycodone, 5 to 10 mg, for breakthrough pain between dressing changes

Discussion Questions

1. Initially, what dosage of intravenous morphine should be given?
2. Describe the assessment data that support the dosage selected in Question 1.

3. How long should the nurse wait after the intravenous morphine dose to begin the dressing change?
4. If an initial dose of 6 mg intravenous morphine reduces the pain to a 6 during the dressing change, what nursing action is indicated for the next dressing change?
5. What nursing action is indicated if Mrs. Cato has pain 5 hours after her dressing change?
6. When Mrs. Cato is discharged, needing dressing changes for 3 days at home, how would the home care nurse organize her care? (The nurse knows that Mrs. Cato has obtained adequate pain relief with 8 mg of intravenous morphine.)

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. Pain is best described as
   a. A creation of a person's imagination
   b. An unpleasant, subjective experience
   c. A maladaptive response to a stimulus
   d. A neurological event resulting from activation of nociceptors
2. Which of the following inhibiting neurotransmitters is known for its involvement in pain modulation?
   a. Dopamine
   b. Acetylcholine
   c. Prostaglandin
   d. Norepinephrine
3. Which of the following words is most likely to be used to describe neuropathic pain? *(Select all that apply)*
   a. Dull
   b. Mild
   c. Aching
   d. Burning
   e. Sickening
   f. Electric
4. Which of the following is true of unrelieved pain?
   a. It is to be expected after major surgery.
   b. It is to be expected in a person with cancer.
   c. It is dangerous and can lead to many physical and psychological complications.
   d. It is an annoying sensation, but it is not as important as other physical care needs.
5. Which of the following is a critical step in the pain assessment process?
   a. Assessment of critical sensory components
   b. Teaching the client about pain therapies

c. Conducting a comprehensive pain assessment

d. Provision of appropriate treatment and evaluation of its effect

6. Which of the following is an example of distraction to provide pain relief?

a. TENS

b. Music

c. Exercise

d. Biofeedback

7. Which of the following are appropriate nonopioid analgesics for mild pain? *(Select all that apply)*

a. Oxycodone

b. Ibuprofen

c. Lorazepam

d. Acetaminophen

e. Acetaminophen with codeine

8. Which of the following is an important nursing responsibility related to pain?

a. Encourage the client to stay in bed.

b. Help the client appear not to be in pain.

c. Believe what the client says about the pain.

d. Assume responsibility for eliminating the client's pain.

9. A nurse is administering a prescribed dose of an intravenous opioid titrated for a person with severe pain related to a terminal illness. Which of the following actions is reflective of this practice?

a. Euthanasia

b. Assisted suicide

c. Enabling the client's addiction

d. Palliative pain management

10. A nurse believes that clients with the same type of tissue injury should have the same amount of pain. Which of the following statements best describes this belief?

a. It will contribute to appropriate pain management.

b. It is an accurate statement about pain mechanisms and an expected goal of pain therapy.

c. The nurse's belief will have no effect on the type of care provided to people in pain.

d. It is a common misconception about pain and a major contributor to ineffective pain management.

1. b; 2. d; 3. d, f; 4. c; 5. c; 6. b; 7. b, d; 8. c; 9. d; 10. d.

CHAPTER 11

Substance Use

Written by, Mariann M. Harding

Adapted by, Catherine Thibeault

LEARNING OBJECTIVES

1. Gain a broad understanding of the prevalence of substance use in Canada.
2. Situate substance use within the continuum of use perspective.
3. Discuss the core aspects of a caring and collaborative nursing relationship with people experiencing substance use–related conditions.
4. Describe the harm-reduction model.
5. Discuss screening and assessment of people experiencing substance use–related conditions.
6. Identify common substances of abuse, their effects, and associated health consequences.
7. Discuss nursing interventions for nicotine dependence, alcohol dependence, and opioid dependence.
8. Describe how to care for patients who experience intoxication, overdose, or withdrawal from stimulants, depressants, or hallucinogens.
9. Describe nursing management of the surgical patient with substance use.
10. Discuss the nursing management of pain in the patient who is substance dependent.
11. Describe the use of motivational interviewing as an approach to helping patients who use substances explore the possibility of behaviour change.
12. Discuss substance use conditions specific to the older adult.

KEY TERMS

Substance Use in Canada

Substance use and abuse affect a broad spectrum of Canadians, regardless of age, gender, socioeconomic class, educational level, cultural background, or geographic region. As such, it is important for nurses to routinely assess for substance use with every individual in all practice settings and to determine whether the pattern of use is problematic. Substance use is defined as the use or misuse of substance(s) despite the associated negative personal and social consequences. The American Psychiatric Association (APA, 2013) no longer recommends the use of the term *addiction* as a diagnostic label because it has an uncertain definition and negative connotation.

According to the Canadian Alcohol and Drug Use Monitoring Survey (CADUMS) (Health Canada, 2014), in 2012, 78.4% of Canadians aged 15 years and older reported past-year consumption of alcohol; 10.2% reported cannabis use; and 10.6% reported use of either cocaine, cannabis, speed, methamphetamines, Ecstasy, or hallucinogens (Table 11-1). Since 2013, the risk for abuse of fentanyl, a powerful opioid, has risen; in Canada, between 2009 and 2014, there have been at least 655 deaths where fentanyl was found to be the cause or a contributing cause, and it is thought that this figure is an underestimate (Canadian Centre on Substance Abuse, 2015). The results of the 2012 Canadian Tobacco Use Monitoring Survey (CTUMS) indicate that 16% (4.6 million) of Canadians aged 15 years and older are current smokers (Health Canada, 2012). This is a significant decrease from 1999, when 25% (6.1 million) of this population were reported to be current smokers (Health Canada, 2012).

TABLE 11-1

Highlights From the Canadian Alcohol and Drug Use Monitoring Survey (CADUMS) 2012

Alcohol
• 78.4% of Canadians reported drinking alcohol in the past year. • 82.7% of men and 74.4% of women reported alcohol use in the past year. • 18.6% of women drank more than 10 drinks per week, and the same percentage of men had 15 drinks per week. • Average age of first alcohol consumption was 15.9 years. • Youth aged 15 to 24 years had the highest rates of alcohol consumption.
Cannabis
• The prevalence of past-year use of cannabis reported by adults aged 25 years and older was 8.4%. • The rate of cannabis use among males (13.7%) was double that among women (7%).
Other Drug Use
• The most commonly reported illicit drugs after cannabis were Ecstasy (0.6%), hallucinogens (1.1%), and cocaine or crack (1.1%). • The rate of illicit drug use among males (3.1%) was almost triple that among females (1.1%). • The rate of drug use by youths 15–24 years of age was five times higher than that reported by adults 25 years and older. • The rates of psychoactive pharmaceutical use and abuse remain steady (24.1%) among adults. The prevalence was higher among females (26.7%) than males (21.3%).

Source: Health Canada. (2014). *Canadian Alcohol and Drug Use Monitoring Survey: Summary of results for 2012.* Retrieved from *http://www.hc-sc.gc.ca/hc-ps/drugs-drogues/stat/_2012/summary-sommaire-eng.php#s3*.

The significant personal and social costs of substance use to Canadians and their families manifest as poor physical and mental health, stress, relationship strain, and increased morbidity and mortality related to substance use. Not only do nurses play a key role in screening for, assessing, and promoting healthy choices regarding the use of substances; they also need to monitor for substance misuse.

Substance Use From a Continuum of Use Perspective

People who use substances have often been categorized, especially by health care providers, as those whose use is classified as *substance abuse* and those whose use is classified as *substance dependence.* It is more helpful to situate substance use along a continuum of use, capturing a spectrum ranging from nonuse to substance dependence. A continuum allows for a broader understanding of the range and severity of substance use behaviours across populations (Figure 11-1) (Herie & Skinner, 2010). Knowing the severity of substance use allows the health care team to work with the patient, tailoring treatment according to individual needs and preferences.

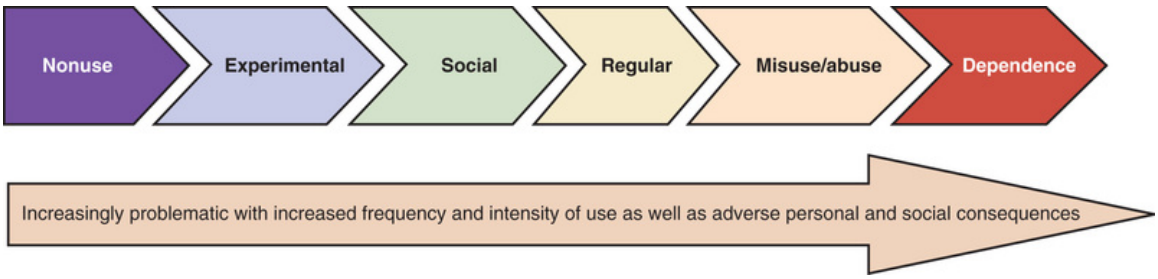

FIGURE 11-1 Continuum of use for substance use. Source: Herie, Marilyn, and Skinner, Wayne, *Substance Abuse in Canada* © 2010 Oxford University Press Canada. Reprinted by permission of the publisher.

This chapter focuses on the role of the medical-surgical nurse in identifying and working with patients in acute care settings who have a history of substance use. In this setting, nurses must recognize substance use, understand its effects on the patient's health, and help the patient manage withdrawal. The health care setting provides an opportunity for substance use screening and education. Vital aspects of the nursing role are determining if the patient is motivated to change substance use behaviour and making referrals to substance use treatment and rehabilitation programs. Failing to address a patient's substance use is a breach of professional responsibility.

Neurophysiology of Substances of Abuse

Substances of abuse are psychoactive in nature, meaning they affect key areas of the brain involved in pleasure and reinforcement. Caffeine is one example of a substance of abuse. Caffeine is a stimulant with reinforcing psychoactive qualities that result in mental alertness and enhanced mood. If taken regularly over a period of time, abrupt cessation of caffeine can lead to mild withdrawal symptoms. Substances with a higher index of abuse, such as cocaine or nicotine, engage the reward–pleasure system of the brain more intensely and more quickly. Substances with higher risk for dependency are those that possess fast onset and intense psychoactive characteristics (Koob, Kandel, Baler, et al., 2015; Reiss, Fiellin, Miller, et al., 2014).

Substances of abuse increase the availability of dopamine in the "pleasure area" of the mesolimbic system of the brain. This mechanism, the **brain reward system**, creates the sensation of pleasure in reaction to certain behaviours that are required for survival of the human species, such as eating and sex (Burchum & Rosenthal, 2016). **Psychological dependence**, the emotional and mental reliance on a substance because of the pleasurable and reinforcing effects of the substance, can result. Normally, neurons in the mesolimbic system release dopamine at a slow rate, producing normal affect or mood. Both endogenous and exogenous opiates have been found to increase the firing rate of dopaminergic neurons. Cocaine has been shown to decrease the reuptake of dopamine at the synapse, thereby decreasing its breakdown and increasing the amount of available dopamine. Nicotine, alcohol, marihuana, amphetamines, and caffeine also increase dopaminergic neuron activity at the synapse. The resulting increase in mesolimbic dopamine produces mood elevation and euphoria, factors that provide strong motivation to repeat the experience. Substances of abuse also increase the availability of other neurotransmitters, such as serotonin and γ-aminobutyric acid (GABA), but dopamine's effect on the reward system appears to be pivotal to the process of substance use and dependency (Taber, Black, Porrino, et al., 2012).

The *Diagnostic and Statistical Manual of Mental Disorders,* Fifth Edition (*DSM-5*), has replaced the terms *substance abuse* and *substance dependence* with **substance use disorder** (APA, 2013). Specific diagnostic criteria determine the level of severity of the disorder as mild, moderate, or severe. Substance use disorders result from the prolonged effects of psychoactive substances on the brain. Repeated long-term use of substances of abuse changes the neural circuitry involving the dopamine neurotransmitter system and reduces the responsiveness of dopamine receptors. This

decreased responsiveness leads to **tolerance**, the need for a larger dose of a substance to obtain the original effects, and also reduces the sense of pleasure from experiences that previously resulted in positive feelings. Without the substance, the individual experiences depression, anxiety, and irritability. To feel normal, the individual must take the substance.

A key aspect of substance use is the formation of the memory of the pleasurable experience of the substance that is long-lasting even in periods of nonuse. **Relief craving**, the intense desire for a substance, usually experienced after decreased use, is the result of the memory aspect related to the brain reward pathway. An important type of craving experienced by people who have experienced problematic substance use or dependency is **reward craving**, which occurs when in the presence of people, places, or things that they have previously associated with taking the substance. Cue-induced reward craving may occur after long periods of abstinence and is a common cause of **relapse**, or returning to substance use after a period of abstinence (Koob, Kandel, Baler, et al., 2015).

Attitudes Toward People Experiencing Substance-Related Problems

People with substance use–related conditions face significant stigma and prejudice largely perpetuated by pejorative images of substance use in media and society at large. Misunderstanding regarding the biopsychosocial aspects of substance use and associated health complications contributes to the generally accepted perspective that substance use and dependency are purely matters of personal choice. Substance use is, however, intimately linked to the effects of substances on the neurophysiology of the brain reward system. Substance use is a complex biopsychosocial condition that involves the whole person. The co-occurrence of mental illness and substance dependence (dual diagnosis) requires supportive interventions due to the increases in the severity of symptoms and poor outcomes for both disorders (Padwa, Larkins, Crevecoeur-MacPhail, et al., 2013).

Nurses must explore their own attitudes about people who use and abuse substances. It is critical to work with patients in a nonjudgemental and collaborative way. A positive nurse–patient dialogue about the impact of substance use can significantly improve health outcomes and increase the likelihood that the person will attempt to reduce harms associated with substance use.

The Harm-Reduction Perspective

Harm reduction focuses on reducing the harms associated with substance use across the continuum of use, from abstinence to high-risk use (Table 11-2). The harms targeted for reduction include the very real personal, social, and physical harms related to use of a substance from a public health perspective (Canadian Nurses Association, 2012). Laws against drinking and driving and nonsmoking bylaws are examples of harm-reduction strategies to protect people from the harms related to alcohol and smoking. Other examples include evidence-informed interventions such as needle-exchange programs and safer-sex education; these reduce the harms associated with high-risk substance use without demanding that the person stop such use.

TABLE 11-2

Key Elements of Harm Reduction

Harm Reduction
• Represents a value-neutral view of drug use and drug user with no moral, legal, or medical-reductionist limitations
• Accepts that at any given time some people are not ready to choose abstinence
• Promotes multiple services at one site as an alternative to traditional complex multisite service approaches
• Accepts that substance use occurs and works to minimize its harmful effects
• Promotes user participation in planning and creating programs and policies designed to serve them
• Recognizes that users are capable of making choices and taking responsibility in prevention of harm, treatment, and recovery
• Calls for nonjudgemental, noncoercive provision of services and resources for people who use drugs
• Does not attempt to minimize or ignore the many real and tragic harms and dangers associated with drug use
• Does not exclude abstinence as an option

Source: Adapted from Harm Reduction Coalition. (n.d.). *Principles of harm reduction*. Retrieved from *http://harmreduction.org/about-us/principles-of-harm-reduction/*; and Marlatt, G. A. (1996). Harm reduction: Come as you are. *Addictive Behaviours, 21*(6), 779–788. doi:10.1016/0306-4603(96)00042-1.

Foundational to harm reduction are respect for patient autonomy and a nonjudgemental approach. Harm reduction is collaborative and honours the patient's inherent dignity and ability to make informed decisions. There is considerable evidence to support harm reduction (Collins, Clifasefi, Logan, et al., 2012). Nurses must support patients' healthy choices and help them avoid risks associated with substance use (Carter & MacPherson, 2013).

Health Complications of Substance Use

Health complications and harms related to substances of abuse are related to three general factors: the substance, the route, and related high-risk behaviours. First, the inherent properties of the substance itself will have specific physiological harms associated with its use such as liver damage related to alcohol use and emphysema related to smoking. Second, the route by which the substance is taken will pose specific harms. For example, harms associated with oral consumption are different in nature from those associated with inhalation or intravenous use. Third, high-risk sexual behaviours, exposure to violence and trauma, and placing one's personal safety at risk may occur during substance use (Table 11-3).

TABLE 11-3

Common Health Problems Related to Substance Use

Substance	Health Problems*
Cocaine	Cardiac dysrhythmias, myocardial ischemia and infarction Seizures, stroke Psychosis
Amphetamines	Cardiac dysrhythmias, myocardial ischemia and infarction Liver, lung, kidney damage Mood disturbances, violent behaviour, psychoses
Sedative–hypnotics	Memory impairment Personality changes, depression
Opioids	Sexual dysfunction Gastric ulcers Glomerulonephritis
Inhalants	Cognitive and motor impairment Acute and chronic kidney injury
Cannabis	Bronchitis, chronic cough Depression, anxiety, schizophrenia Memory impairment
Behaviours	
Injecting drugs	Blood clots, phlebitis, skin infections Hepatitis B and C HIV/AIDS Other infections: endocarditis, tuberculosis, pneumonia, meningitis, tetanus, bone and joint infections, lung abscesses
Snorting drugs	Nasal sores, septal necrosis or perforation Chronic sinusitis
Risky sexual behaviour	HIV/AIDS Hepatitis B and C Sexually transmitted infections
Personal neglect	Malnutrition, impaired immunity Accidental injuries

*Throughout the text, the health problems related to substance use are discussed in the appropriate chapters where substance use–related behaviours are identified as risk factors for these problems.

HIV/AIDS, human immunodeficiency virus/acquired immune deficiency syndrome.

Nursing Management Substance Use

Assessment

The nurse engages with patients to understand if they use substances in ways that place them at risk. As a baseline, the nurse asks every patient about the use of all substances, including alcohol, prescribed medications, over-the-counter (OTC) drugs, caffeine, tobacco, and recreational drugs. He or she may use a simple one- or two-question screening test for substance use (Table 11-4) or the more in-depth Drug Abuse Screening Test (DAST-10), shown in Table 11-5. If there are any indications of substance use, the nurse determines when the patient last used the substance so that drug interactions or the onset of withdrawal can be anticipated. The nurse attempts to identify factors that influence the onset of withdrawal, including the substance used, dose taken, method of intake, and length of time the patient has been using the substance. Screening for alcohol abuse is discussed later in this chapter.

TABLE 11-4

Brief Screening Tool for Substance Use

1. Single-Question Tests
Use one of the following questions to screen for the presence of alcohol, drug, or tobacco use. • How often in the past year have you had five (men) or four (women) or more drinks in a day? • How many times in the past year have you used illegal drugs or prescription medications for nonmedical reasons? • In the past year, how often have you used tobacco products?
2. Two-Question Tests
Use the following two questions to screen for alcohol or drug use. • In the past year, have you ever drunk or used drugs more than you meant to? • Have you felt you wanted or needed to cut down on your drinking or drug use in the past year?

TABLE 11-5
Drug Abuse Screen Test (DAST-10)

In the last 12 months:		
1. Have you used drugs other than those required for medical reasons?	No	Yes
2. Do you abuse more than one drug at a time?	No	Yes
3. Are you always able to stop using drugs when you want to?	No	Yes
4. Have you had "blackouts" or "flashbacks" as a result of drug use?	No	Yes
5. Do you ever feel bad or guilty about your drug use?	No	Yes
6. Does your spouse (or parents) ever complain about your involvement with drugs?	No	Yes
7. Have you neglected your family because of your use of drugs?	No	Yes
8. Have you engaged in illicit activities in order to obtain drugs?	No	Yes
9. Have you ever experienced withdrawal symptoms or felt sick when you stopped taking drugs?	No	Yes
10. Have you had medical problems as a result of your drug use?	No	Yes

Source: Skinner, H. A. (1982). Drug Abuse Screening Test. *Addictive Behaviors*, *7*(4), 363–371. doi:10.1016/0306-4603(82)90005-3.

Health problems associated with substance use may be revealed through assessment of general appearance and nutritional status and through examination of the abdomen, skin, and cardiovascular, respiratory, and neurological systems. The presence of a mental health condition, such as anxiety, bipolar disorder, or depression, increases the risk for substance use disorder (Strobbe, 2014). Serum and urine drug screens can identify the types and amounts of substances present in the body. A complete blood count, serum electrolytes, blood urea nitrogen, creatinine, and liver function tests evaluate for electrolyte imbalances and cardiac, kidney, or liver dysfunction.

During the assessment, the nurse observes patient behaviours such as denial, avoidance, under-reporting or minimizing of substance use, or provision of inaccurate information. Possible behaviours and physical manifestations suggesting substance use are listed in Table 11-6. The list is not comprehensive.

TABLE 11-6

Manifestations Suggestive of Substance Use

- Vague physical complaints
- Insomnia, fatigue
- Headaches
- Seizure disorder
- Mood changes, anorexia, weight loss
- Overuse of mouthwash or toiletries
- Appearance of being older than stated age, unkempt appearance
- Leisure activities that involve alcohol, drugs, or both
- Sexual dysfunction, decreased libido, erectile dysfunction
- Trauma secondary to falls, auto accidents, fights, or burns
- Driving while intoxicated
- Failure of standard doses of sedatives to have a therapeutic effect
- Financial problems, including those related to spending for substances
- Defensive or evasive answers to questions about substance use and its importance in the person's life
- Problems in areas of life function (e.g., frequent job changes; marital conflict, separation, or divorce; work-related accidents, tardiness, absenteeism; legal problems; social isolation, estrangement from friends or family)

Nursing Diagnoses

Nursing diagnoses for patients with substance use problems include but are not limited to the following:

- *Acute confusion* related to substance misuse (*e.g.*, as evidenced by *alteration in cognitive functioning, agitation, misperception, and hallucinations)*
- *Risk for injury* as evidenced by *alteration in cognitive function* (impaired judgement)
- *Ineffective health maintenance* related to *ineffective coping strategies, impaired decision-making*

Planning

The nurse and the patient should establish goals related to (a) achieving the best possible physiological functioning, (b) acknowledging substance use, (c) understanding the biopsychosocial effects of substance use, and (d) participating in treatment or harm-reduction strategies.

Nursing Implementation

Urgent Care Situations.

Urgent care situations precipitated by substance use involve acute intoxication, overdose, or withdrawal. The patient may also present with trauma or injuries. Intoxication responses usually last less than 24 hours and are directly related to the ingestion of psychoactive substances. Overdose occurs with the ingestion of an excessive dose of one drug or with a combination of similarly acting drugs. Overdose leads to toxic reactions that may include respiratory and circulatory arrest and other life-threatening complications. Table 11-7 lists commonly abused substances, routes, and effects.

TABLE 11-7
Effects of Frequently Used Substances

Substance	Physiological and Psychological Effects	Effects of Overdose	Withdrawal Symptoms
Stimulants			
Nicotine	Increased arousal and alertness; performance enhancement; increased heart rate, cardiac output, and blood pressure; cutaneous vasoconstriction; fine tremor, decreased appetite; antidiuretic effect; increased gastric motility	Rare: Nausea, abdominal pain, diarrhea, vomiting, dizziness, weakness, confusion, decreased respirations, seizures, death from respiratory failure	Craving, restlessness, depression, hyperirritability, headache, insomnia, decreased blood pressure and heart rate, increased appetite
Cocaine Amphetamines: amphetamine, dextroamphetamine (Dexedrine), methamphetamine, crystal methamphetamine (crystal meth), methylenedioxy-methamphetamine (MDMA, Ecstasy), methylphenidate (Ritalin)	Euphoria, grandiosity, mood swings, hyperactivity, hyperalertness, restlessness, anorexia, insomnia, hypertension, tachycardia, marked vasoconstriction, tremor, dysrhythmias, seizures, dilated pupils, diaphoresis	Agitation; increased temperature, heart rate, respiratory rate, blood pressure; cardiac dysrhythmias, myocardial infarction, hallucinations, seizures, possible death	Severe craving, severely depressed mood, exhaustion, prolonged sleep, apathy, irritability, disorientation
Caffeine	Mood elevation, increased alertness, nervousness, jitteriness, irritability, insomnia; increased respirations, heart rate, and force of myocardial contraction; relaxation of smooth muscle, diuresis	Rare: Hyperstimulation, nervousness, confusion, psychomotor agitation, anxiety, dizziness, tinnitus, muscle twitching, elevated blood pressure, tachycardia, extrasystoles, increased respiratory rate	Headache, irritability, drowsiness, fatigue
Depressants			
Alcohol Sedative–hypnotics • Barbiturates: phenobarbital (Phenobarb), pentobarbital • Benzodiazepines: diazepam (Valium), chlordiazepoxide (Librax), alprazolam (Xanax) • Nonbarbiturates–nonbenzodiazepines: chloral hydrate	Initial relaxation, emotional lability, decreased inhibitions, drowsiness, lack of coordination, impaired judgement, slurred speech, hypotension, bradycardia, bradypnea	Shallow respirations; cold, clammy skin; weak, rapid pulse; hyporeflexia, coma, possible death	Anxiety, agitation, insomnia, diaphoresis, tremors, delirium, seizures, possible death
Opioids			

Substance	Physiological and Psychological Effects	Effects of Overdose	Withdrawal Symptoms
Heroin Morphine Opium Codeine Fentanyl (Duragesic) Meperidine (Demerol) Hydromorphone (Dilaudid) Pentazocine (Talwin) Oxycodone hydrochloride (Percocet) Methadone	Analgesia, euphoria, drowsiness, detachment from environment, relaxation, constricted pupils, constipation, nausea, decreased respiratory rate, slurred speech, impaired judgement, decreased sexual and aggressive drives	Slow, shallow respirations; clammy skin; constricted pupils; coma; possible death	Watery eyes, dilated pupils, runny nose, yawning, tremors, pain, chills, fever, diaphoresis, nausea, vomiting, diarrhea, abdominal cramps
Cannabis			
Marihuana Hashish	Relaxation, euphoria, lack of motivation, slowed time sensation, abrupt mood changes, impaired memory and attention, impaired judgement, reddened eyes, dry mouth, lack of coordination, decreased reflexes, tachycardia, increased appetite	Fatigue, paranoia, panic reactions, hallucinogen-like psychotic states	None except for rare insomnia, hyperactivity
Hallucinogens			
Lysergic acid diethylamide (LSD) Psilocybin (mushrooms) Dimethyltryptamine (DMT) Diethyltryptamine (DET) Methylenedioxy-amphetamine (MDA) Methylenedioxy-methamphetamine (MDMA, Ecstasy) Mescaline (peyote) Phencyclidine (PCP)	Perceptual distortions, hallucinations, delusions (PCP), depersonalization, heightened sensory perception, euphoria, mood swings, suspiciousness, panic, impaired judgement, increased body temperature, hypertension, flushed face, tremor, dilated pupils, constricted pupils (PCP), nystagmus (PCP), violence (PCP)	Prolonged effects and episodes, anxiety, panic, confusion, blurred vision, increases in blood pressure and temperature, seizures, coma, death (PCP), skeletal muscle contraction, dehydration, paranoia, psychosis	None
Inhalants			
Aerosol propellants Fluorinated hydrocarbons Nitrous oxide (in deodorants, hairspray, pesticide, canned whipped cream, spray paint, cookware coating products) Solvents (gasoline, kerosene, nail polish remover, typewriter correction fluid, cleaning solutions, lighter fluid, paint, paint thinner, glue) Anaesthetic agents (nitrous oxide, chloroform) Nitrites (amyl nitrite, butyl nitrite)	Euphoria, decreased inhibitions, giddiness, slurred speech, illusions, drowsiness, clouded sensorium, tinnitus, nystagmus, dysrhythmias, cough, nausea, vomiting, diarrhea; irritation to eyes, nose, mouth	Anxiety, respiratory depression, cardiac dysrhythmias, loss of consciousness, sudden death, suicide	None

Overdose.

An overdose is an emergency situation, and management is based on the type of substance involved. If multiple substances have been ingested, a complex and potentially confusing clinical picture can result. The first priority of care in the case of overdose is always the patient's ABCs (airway, breathing, and circulation). Continuous monitoring of neurological status, including level of consciousness and respiratory and cardiovascular function, is critical until the patient is stable. Vital signs and intake and output should be monitored. Emergency management of overdose and toxicity of central nervous system (CNS) stimulants and CNS depressants is presented later in the chapter in Tables 11-13 and 11-20.

Pharmacological agents are administered as ordered to counteract toxic effects of drugs. Naloxone or flumazenil may be administered when a depressant effect is present but the ingested drug is unknown. Naloxone rapidly reverses the effects of opioids, and flumazenil reverses the effects of benzodiazepine overdose. The effects of these antagonists necessitate frequent monitoring because these drugs have a short half-life and may need to be readministered after the initial reversal of toxic effects. Specific antagonists are not available for other drugs of abuse, but a variety of other medications may be used to control symptoms.

The patient who has overdosed on sedative–hypnotics other than benzodiazepines must be treated aggressively and may require dialysis to decrease the drug level and to prevent irreversible CNS-depressant effects and death. Gastric lavage and administration of activated charcoal may be instituted if the drug was taken orally within 4 to 6 hours. CNS stimulants are not used in the treatment of depressant-drug overdose.

As soon as the patient is stable, a thorough history and physical examination must be attempted. When the patient is unwilling or unable to give a history, a collateral history should be obtained from the patient's significant others. Recent substance use, including type, amount, and time, and the presence of any chronic illnesses, are important in planning ongoing care. A patient who intentionally overdosed should not return home until seen by a psychiatric professional.

Withdrawal.

The nurse must be alert to the possibility of withdrawal in any patient who has a history of substance use. **Withdrawal** is defined as a constellation of physiological and psychological responses that occur upon abrupt cessation or reduced intake of a substance on which an individual is dependent. In general, withdrawal signs and symptoms are opposite in

nature from the direct effects of the drug (Table 11-8). Because abused substances are psychoactive, changes are consistently noted in the neurological system. These changes often manifest as acute anxiety and protracted depression. Withdrawal from CNS depressants, including alcohol, benzodiazepines, and barbiturates, can be dangerous and may be life-threatening. When caring for patients who are withdrawing from any substance, nurses should monitor physiological function, ensure safety and comfort, prevent the progression of symptoms, provide reassurance and orientation, and determine if the patient is motivated to engage in long-term treatment.

TABLE 11-8

Onset, Peak, Duration, and Withdrawal Onset of Abused Substances

Substance and Route	Onset	Peak	Duration	Onset of Withdrawal Symptoms
Inhaled				
Nicotine	Immediate	5 min.	5–15 min.	3–4 hr.
Marihuana	5–20 min.	30–60 min.	3–7 hr.	—
Cocaine	Immediate	5–30 min.	60 min.	9 hr.
Inhalants	Immediate	10–15 min.	20–45 min.	—
Intravenous				
Cocaine	Immediate	10–20 min.	20–30 min.	2 hr.
Opioids	Immediate	60–90 min.	2–4 hr.	8–10 hr.
Amphetamines	Immediate	10–20 min.	20–30 min.	2 hr.
Oral				
Alcohol	15–20 min.	60–90 min.	12–14 hr.	6–12 hr.
Amphetamines	10–30 min.	60–90 min.	2–4 hr.	8–10 hr.
Sedative–hypnotics	15–30 min.	2–4 hr.	4–12 hr.	12–16 hr.
Caffeine	10–20 min.	30 min	3–7 hr.	12–24 hr.
Opioids	30 min.	2 hr.	4–8 hr.	8–10 hr.
Intranasal				
Cocaine	3–5 min.	5–30 min.	2–4 hr.	4 hr.
Amphetamines	3–5 min.	5–20 min.	45 min.	2 hr.
Buccal				
Nicotine	10–15 min.	20–30 min.	30–60 min.	1–2 hr.

Perioperative Care.

An individual who abuses substances is more likely to have accidents and injuries that necessitate surgery. Optimally, health problems such as malnutrition, dehydration, and infection should be treated before surgery is performed. All trauma victims must be carefully assessed for signs and symptoms of substance overdose and withdrawal that could lead to adverse drug interactions with analgesics or anaesthetics. For example, if an accident victim has injuries that cause CNS depression, alcohol use may be missed.

Special precautions must be taken for the patient who is intoxicated or alcohol dependent and requires surgery. The patient dependent on substances is at high risk for postoperative complications and death. Acute withdrawal and delirium tremens (DTs) may be triggered by the cessation of alcohol consumption. The patient who is alcohol dependent but is not currently drinking usually requires an increased level of anaesthesia because of cross-tolerance. The intoxicated individual needs a decreased level of anaesthesia because of the synergistic effect of the alcohol. Vital signs, including body temperature, must be closely monitored to identify signs of withdrawal, possible infections, and respiratory or cardiac problems (Marley, Calabrese, & Thompson, 2014).

A patient's pattern of use may be unknown at the time of elective surgery. Preoperative assessment must include a thorough health history and assessment of substance use, including questions related to alcohol, nicotine, and caffeine use (both nicotine and caffeine are discussed later in this chapter). Respiratory changes in smokers make introduction of endotracheal and suction tubes more difficult and increase the risk for postoperative respiratory problems. During the patient's surgical recovery period, the nurse should be alert for signs and symptoms of drug interactions with pain medications or anaesthesia or for signs of withdrawal. Postoperative headaches, for example, may be caused by caffeine withdrawal in heavy users. Special nursing considerations for the substance-abusing patient undergoing surgery are presented in Table 11-9.

TABLE 11-9

Considerations for Patients With Problematic Substance Use Who Are Undergoing Surgery

- Standard amounts of anaesthetic and analgesic drugs may not be sufficient if patient is cross-tolerant.
- Anaesthetic agents may have a prolonged sedative effect if the patient has liver dysfunction. This situation necessitates an extended observation period.
- Patients have an increased susceptibility to cardiac and respiratory depression.
- Patients have an increased risk for bleeding, postoperative complications, and infection.
- Withdrawal symptoms from substances may be delayed for up to 5 days because of effects of anaesthetics and pain medications.
- Dosage of pain medications must be reduced gradually.

Acute Pain Management Considerations.

Health care providers may demonstrate reluctance to treat acute pain with opioid medications in people who use substances. However, it must be noted that the effective treatment of acute pain is a key priority for all

people, including those who use substances. It is appropriate, therefore, to use opioid analgesia to help all people manage acute pain.

If the patient acknowledges opioid use, it is important to determine the types and the amounts of drug used. It is best to avoid exposing the patient to the drug of abuse, and effective equianalgesic doses of other opioids may be determined if daily drug doses are known. Severe pain should be treated with opioids. The use of one opioid is preferred, but nonopioid and adjuvant analgesics and nonpharmacological pain relief measures may also be used as appropriate. Withdrawal symptoms can exacerbate pain and lead to medication-seeking behaviour. To maintain opioid blood levels and prevent withdrawal symptoms, health care providers should provide analgesics around the clock. Supplemental doses should be used to treat breakthrough pain. For patients who abuse opioids to achieve adequate pain control, the nurse should advocate for these patients to receive much higher doses than those used in drug-naive patients.

Stimulants and Stimulant Withdrawal

Substances in this category of agents stimulate the CNS and generally cause increased alertness, increased heart rate, and a sense of euphoria.

Withdrawal from cocaine and amphetamines does not usually cause obvious physical symptoms, but physical and behavioural manifestations do occur. Craving for the drug is intense during the first hours to days of drug cessation and may continue for weeks. The nurse may identify withdrawal symptoms in a patient dependent on cocaine or amphetamines who is hospitalized for management of other health problems. Nursing management of withdrawal symptoms is supportive and includes measures to decrease agitation and restlessness in the early phase and to allow the patient to sleep and eat as needed in later phases. Mild symptoms of stimulant withdrawal can also be experienced by the patient dependent on caffeine when meals and fluids are withheld before diagnostic testing or during a surgical experience. A nicotine replacement system should be provided for tobacco users to control symptoms of withdrawal when they are hospitalized.

Nicotine

Characteristics

Nurses are likely to encounter patients with tobacco use disorder (TUD). Persons with TUD are dependent on the drug nicotine due to using tobacco products. Nicotine has a rapid onset of action, making it one of the most rapidly addicting substances of abuse. A number of products contain nicotine, including smoked tobacco (cigarettes, cigars, pipes), smokeless tobacco (chew, snuff, dip), and some electronic cigarettes. Smoking tobacco is the most popular form of tobacco use in Canada (Reid, Hammond, Rynard, et al., 2015); in 2013, 19% of the population over the age of 12 smoked daily or occasionally (Statistics Canada, 2013). Considering the magnitude and severity of the risks associated with nicotine dependence, it is crucial that nurses screen for and offer interventions for nicotine dependence.

Physiological Effects of Use

When nicotine is absorbed, it produces a wide range of effects in the peripheral nervous system and CNS. Responses include increased blood

pressure, heart rate, cardiac output, coronary blood flow, and cutaneous vasoconstriction. During smoking, nicotine is absorbed quickly into the bloodstream and travels to the brain in a matter of seconds. In the brain, the action of nicotine on nicotinic receptors causes general CNS stimulation with increased alertness and arousal. The effects last about 1 to 2 hours before withdrawal symptoms occur, leaving the person feeling tired, irritable, and anxious. The need to have the "high" again makes the person crave more nicotine, leading to addiction. After withdrawal from nicotine, cue-induced relief craving may cause smoking relapse. The effects of nicotine are listed in Table 11-7.

Smoking tobacco is the most harmful method of nicotine use and injures nearly every organ in the body (Figure 11-2). Although those who use smokeless tobacco are at lower risk for lung disease, it is not without complications. Holding tobacco in the mouth is associated with periodontal disease and cancer of the mouth, cheek, tongue, throat, and esophagus (Centers for Disease Control and Prevention, 2015).

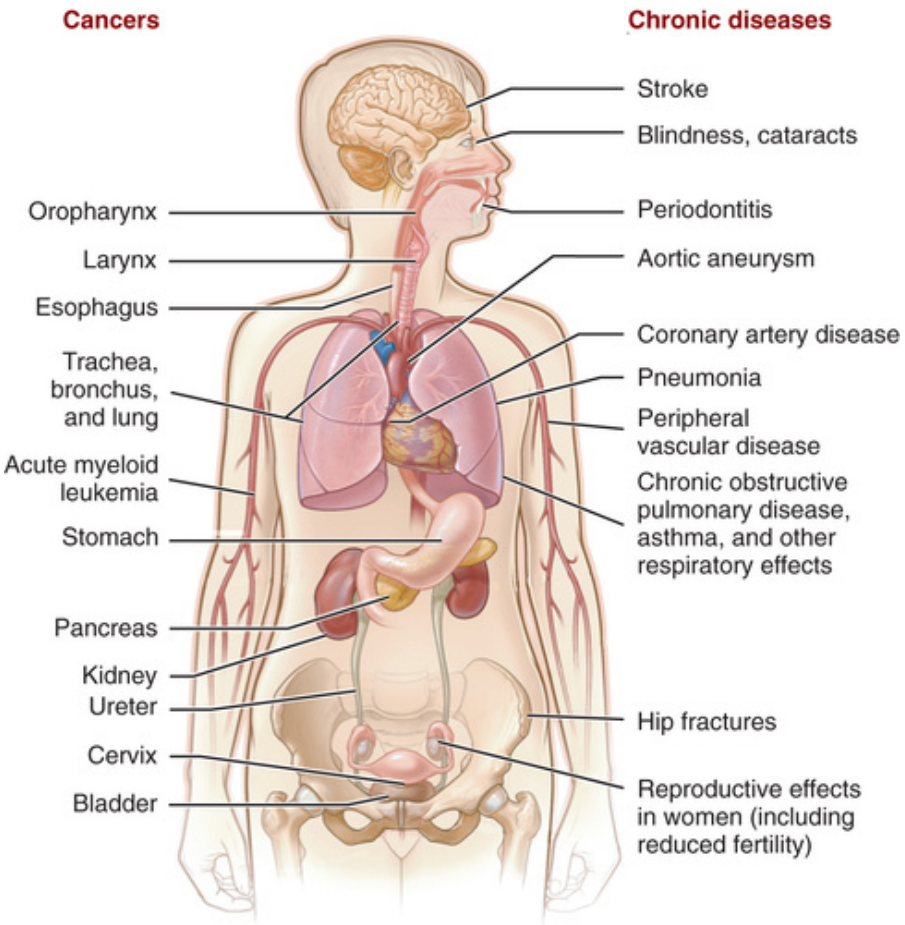

FIGURE 11-2 Health effects of smoking. Source: Samet, J. M. (2013). Tobacco smoking. *Thoracic Surgery Clinics, 23*(2), 103.

Electronic cigarettes resemble and feel like traditional cigarettes. These battery-operated devices turn nicotine and other chemicals, including propylene glycol, glycerin, and flavourings, into an aerosol or vapour. These devices do not contain tobacco. Emerging information indicates e-cigarettes are not harmless. E-cigarettes containing nicotine have the potential to increase the risk for cardiovascular and respiratory problems (Hajek, Etter, Benowitz, et al., 2014), and the liquid nicotine solutions used in refillable e-cigarettes may cause poisoning or skin irritation. Although e-cigarettes are thought to be harmful to health, they are likely to be substantially less harmful than tobacco cigarettes. However, the long-term health effects of vaping have not been examined and are therefore unknown at this time.

Health Complications

The complications of nicotine abuse are related to dose and method of ingestion. Cigarette smoking is the single most preventable cause of death. Cigarette smoking also causes chronic lung disease, cardiovascular disease, stroke, and cataracts. Smoking during pregnancy can cause stillbirth, low birth weight, sudden infant death syndrome (SIDS), and other serious pregnancy complications (Cui, Shooshtari, Forget, et al., 2014). In addition, many of these substances, such as carbon monoxide, tar, arsenic, and lead, are poisonous and toxic to the human body. Together with the increased myocardial oxygen consumption that nicotine causes, carbon monoxide significantly decreases the oxygen available to the myocardium. The result is an even greater increase in heart rate and myocardial oxygen consumption that may lead to myocardial ischemia.

The chronic respiratory irritation caused by cigarette smoke is the most important risk factor in the development of lung cancer and chronic obstructive pulmonary disease (COPD). Chronic irritation from smoking also is a factor in the increased incidence of cancer of the mouth, larynx, and esophagus in those who smoke tobacco in any form. Smokeless tobacco users also experience the systemic effects of nicotine on the cardiovascular system, increasing the risk for cardiovascular disease.

Women are at greater risk than men for smoking-related diseases. Women who smoke have almost double the risk of myocardial infarction than men and may also have nearly double the risk of lung cancer as men. Smoking in women is associated with greater menstrual bleeding and duration of dysmenorrhea as well as greater variability in menstrual cycle length. In addition, there is strong evidence that breast and cervical cancer risks are increased among women who smoke (American College of Obstetricians and Gynecologists, 2010).

Collaborative Care: Nursing Interventions for Tobacco Use Disorder

A combination of medications, behavioural approaches, and support is believed to be most effective in addressing nicotine dependence and long-term tobacco cessation.

Tobacco Use Cessation.

With each patient encounter, the nurse should ask about tobacco use, assess the person's level of motivation to change, and advise the person about the importance of quitting. The Registered Nurses' Association of Ontario (RNAO; 2007) algorithm “Ask, advise, assist, arrange” is an

effective approach for working collaboratively with people with nicotine dependence. This approach identifies minimal and intensive clinical interventions that can be used at each patient encounter, depending on the time available (see the Resources at the end of this chapter). These interventions are designed to identify tobacco users, encourage them to quit, determine their willingness to quit, assist them in quitting, and arrange for follow-up to prevent relapse. Simply screening for and assessing for smoking has significant impact as an intervention to help people quit smoking. Smoking cessation is the single most effective intervention to increase quality of life and decrease the morbidity and mortality directly caused by smoking. The Tobacco Free RNAO website contains many resources that nurses can use to help patients quit smoking (see the Resources at the end of this chapter).

Nicotine Replacement Therapy and Pharmacotherapeutic Interventions for Nicotine Dependence.

A variety of smoking cessation products are available to help support users in quitting, including prescription medicines as well as OTC products such as nicotine patches, inhalers, and gum. Nicotine replacement therapy (NRT) products are one type of smoking cessation solution. These products reduce the craving and withdrawal symptoms associated with cessation by supplying the body with smaller amounts of nicotine (Table 11-10). Because most health care facilities are tobacco-free environments, admitted patients who are addicted to nicotine may experience withdrawal symptoms since they are unable to smoke. Offering NRT to those who desire it will assist in controlling withdrawal symptoms during hospitalization and promote continued cessation after discharge.

TABLE 11-10

Caring for the Patient With Tobacco Use Disorder

The Five *A*s for Users Who Desire to Quit	The Five *R*s for Users Unwilling to Quit
1. **Ask:** Identify all tobacco users at every contact. a. "Have you used any form of tobacco in the past 6 months?" b. "Do you smoke (even a puff now and again) or use tobacco products of any kind?" c. "Have you ever considered stopping?" 2. **Advise:** Strongly urge all tobacco users to quit. a. "As your nurse, the most important advice I can give you is to quit smoking." 3. **Assess:** Determine willingness to make a quit attempt. 4. **Assist:** Develop a plan with the patient to help the patient quit (e.g., counselling, medication). 5. **Arrange:** Schedule follow-up or refer patient to smoking cessation program.	1. **Relevance:** Ask the patient to indicate why quitting is personally relevant (e.g., health). 2. **Risks:** Ask the patient to identify his or her potential risks consequences of tobacco use. 3. **Rewards:** Ask the patient to identify potential benefits of stopping tobacco use. 4. **Roadblocks:** Ask patient to identify barriers or impediments to quitting. 5. **Repetition:** Repeat process every clinic visit.

Washington, DC: U.S. Public Health Service; and Registered Nurses Association of Ontario. (2007). *Best practice guideline: Integrating smoking cessation into nursing practice.* Toronto: Author. Retrieved from *http://rnao.ca/bpg/guidelines/integrating-smoking-cessation-daily-nursing-practice*.

Non-nicotine products also play a role in helping users quit. Varenicline (Champix) is a drug used to aid smoking cessation. Varenicline is unique in that it has both agonist and antagonist actions. Its agonist activity at one subtype of nicotinic receptor provides some nicotine effects to ease withdrawal symptoms. If the person does resume smoking, its antagonist action blocks the effects of nicotine at another subtype of nicotinic receptor, making smoking less enjoyable. Bupropion (Zyban), an antidepressant drug, reduces the urge to smoke, reduces some symptoms of withdrawal, and helps prevent weight gain associated with smoking cessation. Product manufacturers advise that these products should be used with counselling and that physicians and patients should consider using NRT before non-nicotine products (Government of Canada, 2013a).

Along with using a smoking cessation product, users who wish to quit are more likely to succeed if they participate in a tobacco cessation program. Nurses should be aware of community resources that assist users who are motivated to quit. Many programs teach users to avoid high-risk situations for smoking relapse and help them develop coping skills, such as cigarette refusal skills, assertiveness, alternative activities, and peer support systems.

The advice and motivation provided by health care providers can be a powerful force in smoking cessation. *Best Practice Guidelines on Smoking*

Cessation, available on RNAO's website, is an excellent resource for the nurse helping patients to quit smoking: see Appendix D, "The Benefits of Quitting Smoking"; Appendix H, "Ask, Advise, Assist, Arrange Protocol"; and Appendix L, "Quit Smoking: First-Line Medications Compared." A link to this document appears in the Resources at the end of this chapter. Table 11-11 lists inpatient tobacco cessation interventions.

TABLE 11-11

Inpatient Tobacco Cessation Interventions

Take the following steps for every hospitalized patient:
1. Ask each patient on admission if he or she uses tobacco, and document tobacco use status.
2. For current tobacco users, list tobacco use status on the admission problem list and as a discharge diagnosis.
3. Use counselling and medication to help all tobacco users maintain abstinence and to treat withdrawal symptoms.
4. Provide advice and assistance on how to quit during hospitalization and remain abstinent after discharge.
5. Arrange for follow-up regarding smoking status. Supportive contact should be provided for at least a month after discharge.

Cocaine and Other Stimulants

Characteristics

In 2013, 0.9% of Canadians reported using cocaine or crack within the past year (Government of Canada, 2013b). The most common method of cocaine use is intranasal (snorting), but it may be smoked as "crack" cocaine (Figure 11-3) or in "freebase" form, injected intravenously, taken orally, or absorbed through mucous membranes. It must be manipulated either by placing it in a pipe to smoke it or by melting it down with a heat source and then adding liquid for the purpose of intravenous use.

FIGURE 11-3 **A,** Powder cocaine, which can be easily snorted or injected. **B,** Crack cocaine, a chalklike derivative of cocaine whereby cocaine is mixed with other substances such as baking soda. Source: A, Tatiana Popova/Shutterstock.com; B, Kevin L Chesson/Shutterstock.com.

The different types of amphetamines and related drugs such as methylphenidate are stimulant drugs that speed up the CNS. Stimulants may be prescribed for treatment of narcolepsy or attention deficit disorders and for weight control. However, methamphetamine and smokable methamphetamine crystals ("crystal meth," "ice") are in great demand on the street. These drugs act like the hormone adrenalin, which is a natural stimulant. Other drugs with similar effects include cocaine, Ecstasy, ephedrine, and caffeine. In 2013, 1% of Canadians aged 15 years and older reported using a stimulant (including those prescribed for attention deficit disorder) in the past 12 months. Sixteen percent of people who used stimulants reported abusing them. The rate of abuse for youth aged 15 to 19 was 32% (20 000), and for young adults aged 20 to 24, 40% (14 000) (Government of Canada, 2013b).

Effects of Use

All stimulants work in part by increasing the amount of dopamine in the brain, producing euphoria and increasing energy and alertness. This action on the brain reward system magnifies pleasure and leads to rapid dependence. Cocaine and other stimulants also affect the peripheral nervous system and the cardiovascular system. Amphetamines are similar to cocaine and produce euphoria, hyperactivity, and increased heart rate and blood pressure. Initial use results in increased alertness, improved performance, relief of fatigue, and anorexia. As with cocaine use, amphetamines used over time may lead to irritability, anxiety, paranoia,

and hostile and violent behaviours. Additional physical and psychological effects are presented in Table 11-12.

TABLE 11-12

Effects of Cocaine and Amphetamine Use

	Early Effects	Long-Term Effects
Central nervous system	Excitation, euphoria, restlessness, talkativeness	Depression, hallucinations, tremors, visual disturbances, seizures, headache, insomnia, stroke
Cardiovascular system	Tachycardia, hypertension, angina, dysrhythmias, palpitations	Dysrhythmias, hypotension, heart failure, myocardial infarction, cardiomyopathy
Respiratory system	Increased respiratory rate, dyspnea, chest pain, epistaxis	Chronic cough, inflamed throat, congestion of lungs, brown or black sputum production, pneumonia, respiratory distress and/or arrest, pulmonary edema, rhinorrhea, rhinitis, erosion and perforation of the nasal septum
Reproductive system	Heightened sexual desire, delayed orgasm and ejaculation; women may have difficulty achieving orgasm	Difficulty maintaining erection and ejaculating; loss of interest in sexual activity; women may develop aberrant sexual behaviour
Gastro-intestinal system	Decreased appetite	Dehydration, weight loss, nausea; intestinal ischemia may cause gangrenous bowel
Psychological	Behaviour changes or mood swings	Depression or suicidal thoughts

Smoking and intravenous (IV) methods result in the fastest absorption and the highest "rush." Effects of cocaine use are short, which is the main reason people who use cocaine are compelled to seek out and purchase more and more cocaine throughout the day to sustain the euphoric effects and why a great deal of money can be spent on cocaine over a short period of use. During periods of use, the person may not be sleeping, eating, or performing self-care. Amphetamines have a longer half-life than cocaine and, because they are usually taken orally, have a longer effect. Patients with stimulant toxicity present with *sympathetic overdrive* (increased stimulation of the sympathetic nervous system). The patient experiences restlessness, hypervigilance, agitated delirium, impaired judgement, and paranoia with psychotic symptoms. Table 11-12 describes the effects of cocaine and amphetamine use.

Withdrawal

Cocaine withdrawal is usually accompanied by intense dysphoria, fatigue, and irritability. In the first 9 hours to 14 days, withdrawal is characterized by intense craving and cocaine-seeking behaviour. There is marked agitation, feelings of depression, exhaustion, and a need to sleep.

Eventually mood is stabilized, but a desire to return to the drug, especially prompted by cue-induced craving, remains for a long period of time.

Abrupt cessation of stimulants can lead to a "crash." The patient may be depressed and experience fatigue, prolonged sleep, vivid dreams, irritability, increased appetite, and disorientation. Supportive care includes maintaining a quiet environment and allowing the patient to sleep and eat as desired. If a patient has severe depression, the nurse should initiate suicide precautions and refer for further treatment.

Complications

Routes of administration have important health complications. IV administration may result in collapse and scarring of the veins at the injection site, cellulitis, wound abscess, endocarditis, hepatitis B virus (HBV) and hepatitis C virus (HCV) infection, and human immunodeficiency virus (HIV) infection. With intranasal use, the nasal septum and mucosa may be damaged, and frequent sniffing and rhinitis are common signs of chronic intranasal use. Pulmonary damage from smoking crack may be apparent as evidenced by black or dark brown sputum and a form of pneumonia known as "crack lung." Bilateral loss of eyebrow and eyelash hair may occur during "freebasing." Dental caries and loose or broken teeth are also frequently seen as a consequence of using cocaine by any route.

A *stimulant psychosis* may occur with the chronic use of any stimulant. A cocaine psychosis usually progresses from paranoid delusions to visual hallucinations of "snow lights" (coloured lights perceived when cocaine is administered) and tactile hallucinations of bugs crawling under the skin. Skin excoriations from scratching; needle marks; and elevated blood pressure, heart rate, and temperature are findings that help differentiate a stimulant psychosis from schizophrenia.

Collaborative Care

Emergency management of cocaine intoxication will depend on the findings at the time of treating the patient and may be complicated by the possibility that the patient has combined cocaine use with that of heroin, alcohol, or phencyclidine hydrochloride (PCP). Symptoms of cocaine and stimulant toxicity and emergency management are presented in Table 11-13.

TABLE 11-13

EMERGENCY MANAGEMENT
Cocaine and Amphetamine Toxicity

Etiology	Assessment Findings	Interventions
Intranasal, inhalation, parenteral, oral, vaginal, rectal, or sublingual administration of cocaine; oral or parenteral administration of amphetamines	**Cardiovascular** • Palpitations • Tachycardia • Hypertension • Dysrhythmias • Myocardial ischemia or infarction **Central Nervous System** • Feeling of impending doom • Euphoria • Agitation • Combativeness • Seizures • Hallucinations • Confusion • Paranoia • Fever **Other** • Track marks • Consumption of bags of cocaine	**Initial** • Ensure patent airway • Anticipate need for intubation if respiratory distress evident • Establish IV access and initiate fluid replacement as appropriate • Obtain a 12-lead ECG • Treat ventricular dysrhythmias as appropriate with lidocaine, bretylium, or procainamide • Administer IV haloperidol for psychosis • Administer IV diazepam (Valium) or lorazepam (Ativan) for seizures • Naloxone IV should be given if CNS depression is present and concurrent opiate use is suspected • Anticipate the need for propranolol (Inderal) or labetalol for hypertension and tachycardia **Ongoing** • Monitor vital signs, level of consciousness, cardiac rhythm • Use restraints only if needed to protect the patient and staff

CNS, central nervous system; *ECG,* electrocardiogram; *IV,* intravenous.

Caffeine

Characteristics

Caffeine is the most widely used psychoactive substance in the world and, in most people, can be safely used to promote alertness and alleviate fatigue. Although weaker than other stimulant drugs, caffeine shares their characteristics of intoxication, tolerance, and withdrawal symptoms with regular and consistent patterns. The consumption of energy drinks high in caffeine content among children and youth is a growing health concern. In addition to being a component of many beverages, caffeine is found in numerous prescription and OTC analgesics, stimulants, appetite suppressants, and cold and flu preparations.

Effects of Use

Caffeine is a relatively weak CNS stimulant. It is a diuretic and a myocardial stimulant. It relaxes smooth muscles, promotes vasodilation, constricts cerebral arteries, increases gastric acid secretion, and enhances contraction of skeletal muscles. Oral doses of 200 mg (two cups of coffee) can elevate mood, produce insomnia, increase irritability, cause anxiety, and offset fatigue. Heavy intake of 500 mg or more per day is known to cause intoxication manifested by nervousness, insomnia, gastric hyperacidity, muscle twitching, confusion, tachycardia or cardiac dysrhythmias, and psychomotor agitation. The effects of caffeine are presented in Table 11-7.

Physical and psychological dependence on caffeine have been found with chronic use of more than 500 mg/day. However, dependence may occur in some individuals at lower doses, especially in children and youth who have smaller body mass. The most commonly reported withdrawal symptoms are headache, irritability, drowsiness, and fatigue that occur within 12 to 24 hours following abstinence (see Table 11-7). Caffeine withdrawal may be responsible for some cases of headache that occur after general anaesthesia.

Complications

Habitual caffeine users are reported to have slightly higher blood pressure, heart rates, and basal metabolic rates (see Table 11-7). Because symptoms of chronic use develop gradually, most people with caffeine dependence do not link sleep disruption, anxiety, and other symptoms with caffeine intake. Women with high consumption of caffeine are at particular risk for loss of bone mineral density, a risk for the development of osteoporosis later in life. In toxic doses, caffeine influences behaviour patterns and may precipitate panic states.

Collaborative Care

Management of the patient with symptoms of caffeine dependence includes assisting the patient to gradually reduce or stop the intake of caffeine. A list of caffeinated products itemizing their caffeine content may be helpful to the patient who quits coffee only to unknowingly substitute other foods and beverages containing caffeine. Substituting decaffeinated beverages may also help. Toxic reactions to caffeine and lethal doses of

caffeine are managed symptomatically, with attention to maintaining respirations and controlling hypertension, dysrhythmias, and seizures.

Depressants

Substances classified as depressants have common physiological effects and include alcohol, sedatives, hypnotics, and opioids. Depressants are also widely recognized for their abuse potential, which leads to rapid development of tolerance, dependence, and medical emergencies involving overdose and withdrawal.

Alcohol

Characteristics

Alcohol is the most widely consumed substance of abuse in North America. In Canada, 76% of the population aged 15 and older drink alcohol (Government of Canada, 2013b). The use of alcohol, whether by occasional drinkers or by those who are alcohol dependent, is linked to negative consequences, including automobile accidents, arrests, violence, poor job performance, trauma, and associated injuries requiring emergency intervention.

Alcohol dependence is currently viewed as a chronic, progressive, potentially fatal condition if left untreated. Numerous factors appear to be interrelated in the development of alcohol dependence and may include genetic and biological factors, psychosocial factors, and cultural–environmental background. Alcohol dependence generally occurs over a period of years and may be preceded by heavy social drinking.

Health teaching about the risks associated with consuming more than the recommended low-risk drinking guidelines (Table 11-14) is essential. Although there is evidence of the health benefits of consuming wine, it must be noted that the health benefits are associated with low consumption of one standard drink (142 mL [5 oz.] glass of 12% alcohol wine), and, in fact, consumption of more than this amount is associated with adverse health risks such as increased risk for hypertension and cardiovascular disease.

TABLE 11-14
Canada's Low-Risk Drinking Guidelines

Drinking is a personal choice. If you choose to drink, these guidelines can help you decide when, where, why, and how much.
Guideline 1
Reduce your long-term health risks by drinking no more than: • 10 drinks per week for women, with no more than two drinks per day most days • 15 drinks per week for men, with no more than three drinks per day most days Plan nondrinking days every week to avoid developing a habit.
Guideline 2
Reduce your risk for injury and harm by drinking no more than three drinks (for women) and four drinks (for men) on any single occasion. Plan to drink in a safe environment. Stay within the weekly limits outlined in Guideline 1.
Guideline 3
Do not drink when you are: • Driving a vehicle or using machinery and tools • Taking medicine or other drugs that interact with alcohol • Doing any kind of dangerous physical activity • Living with mental or physical health problems • Living with alcohol dependence • Pregnant or planning to be pregnant • Responsible for the safety of others • Making important decisions
Guideline 4
If you are pregnant or planning to become pregnant, or if you are about to breastfeed, the safest choice is to drink no alcohol at all.
Guideline 5
If you are a child or youth, you should delay drinking until your late teens. Talk with your parents about drinking. Alcohol can harm the way your brain and body develop. If you are drinking, plan ahead, follow local alcohol laws, and stay within the limits outlined in Guideline 1.
Defining "a Drink"
For these guidelines, "a drink" means: • 341 mL (12 oz.) bottle of 5% alcohol beer, cider, or cooler • 142 mL (5 oz.) glass of 12% alcohol wine • 43 mL (1.5 oz.) serving of 40% distilled alcohol (e.g., rye, rum, gin) Low-risk drinking helps to promote a culture of moderation. Low-risk drinking supports healthy lifestyles.
Tips
Set limits for yourself and abide by them. Drink slowly. Have no more than two drinks in any three hours. For every drink of alcohol, have one nonalcoholic drink. Eat before and while you are drinking. Always consider your age, body weight, and health problems that might suggest lower limits. Although drinking may provide health benefits for certain groups of people, do not start to drink, or increase your drinking, for health benefits.

Source: Butt, P., Beirness, D., Gliksman, L., et al. (2011). *Alcohol and health in Canada: A summary of evidence and guidelines for low-risk drinking.* Ottawa, ON: Canadian Centre on Substance Abuse.

Effects of Use

Alcohol affects almost all cells of the body and has complex effects on the neurons in the CNS, leading to slowed respirations and heart rate; it also

affects memory, judgement, and coordination (Mukherjee, 2013). Absorption is slower in the presence of water or food, especially proteins and fats. Faster absorption occurs when alcohol is mixed with carbonated liquids. Canada's low-risk drinking guidelines (see Table 11-14) recommend that women limit consumption to 10 standard drinks per week, with no more than two drinks per day most days and that men limit consumption to no more than 15 standard drinks per week, with no more than three drinks per day most days.

The effects of alcohol are related to the blood alcohol concentration (BAC) in the body and individual susceptibility. Alcohol is measurable in the blood within 15 to 20 minutes of ingestion, peaks in 60 to 90 minutes, and is excreted in 12 to 24 hours. BAC is affected by the amount consumed, the drinking rate, body size and composition, drink concentration, and hormones (Table 11-15). As such, children and youth who have lower body mass are more susceptible to the effects of alcohol. People who have developed high tolerance to the effects of alcohol have greater risk for complicated withdrawal from alcohol that can lead to seizures and death.

TABLE 11-15

Blood Alcohol Concentration and Related Effects

BAC* (mmol/L)	Psychophysiological Effect
4.3	Light and moderate drinkers begin to feel some effects. Approximate BAC is reached after one drink.†
8.7	Most people begin to feel relaxed.
13.0	Judgement is mildly impaired. People are less able to make rational decisions about their capabilities (e.g., driving skills).
17.4	Definite impairment of muscle coordination and driving skills occurs. Person is legally intoxicated according to Canada's *Criminal Code*.‡
21.7	Clear deterioration of reaction time and control is observed. Person is legally intoxicated in most provinces and territories. Some provinces permit slightly higher levels than those permitted by the federal government.
26.0	Vomiting occurs unless this level is reached slowly.
32.6	Balance and movement are impaired. Equivalent of one-half pint of whisky is circulating in the bloodstream.
65.1	Many people lose consciousness.
86.8	Most people lose consciousness, and some die. For 50% of adult humans, 86.8 mmol/L is the accepted lethal dose.§
97.7	Breathing stops; person eventually dies.

*BAC is generally recorded in millimoles per litre (mmol/L) of blood. BAC is dependent on how much alcohol is consumed, how fast it is consumed, and the person's weight.

†One drink is 341 mL beer, 142 mL wine, or 43 mL distilled spirits, all of which provide the same amount of alcohol.

‡Canada Safety Council. (2009). *Canada's blood alcohol laws among the strictest in the Western world.* Retrieved from *http://canadasafetycouncil.org/news/canada-s-blood-alcohol-laws-among-strictest-western-world*; provincial and territorial blood alcohol limits for drivers vary.

BAC, blood alcohol concentration.

Alcohol Intoxication

Intoxication, as evidenced by increasing BAC, results in behavioural and physical changes (see Table 11-15). Behavioural effects may include relaxation, sedation, disinhibition, aggression, impaired judgement, irritability, euphoria, depression, and emotional lability. Physical signs include slurred speech, lack of motor coordination, nystagmus, and flushing resulting from dilation of peripheral blood vessels. Disturbances in memory and blackouts may occur in dependent drinkers. People are at higher risk for self-injurious behaviours while intoxicated, as a result of impaired judgement and impulsivity. People are also at risk for significant

mood dysregulation and depression, and risk for suicide is an important consideration. Fatalities caused by drinking and driving, head injuries, physical trauma, and violence are closely linked to alcohol intoxication.

Acute Alcohol Intoxication.

It is important to obtain as accurate a history as possible, using collateral information as necessary, and assess for injuries, trauma, diseases, and hypoglycemia. Patients with alcohol intoxication may also be hypoglycemic from a lack of food intake. Vital signs and level of consciousness should be monitored. Generally, the heart rate is normal in uncomplicated intoxication but elevated in withdrawal.

The nurse should remain with the patient as much as possible, orienting to reality as necessary. Agitation and anxiety are common, and the patient should be assessed for increasing belligerence and a potential for violence. The patient is also at high risk for injury because of lack of coordination and impaired judgement, and protective measures should be used. It is critical to continue assessment and interventions until the BAC has decreased to at least 21.7 mmol/L and until any associated disorders or injuries have been ruled out.

Alcohol Withdrawal

If there is any indication of alcohol or other CNS-depressant use when a patient is hospitalized, the nurse should always question when the patient last used the substance. This information will help the nurse anticipate drug interactions or the time of possible onset of withdrawal symptoms. After excessive drinking, individuals may experience hangovers manifested by malaise, nausea, headache, thirst, and a general feeling of fatigue.

A patient with alcohol dependence who is hospitalized for other health conditions often develops alcohol withdrawal when the ingestion of alcohol is abruptly stopped. The signs and symptoms of alcohol withdrawal generally begin 6 to 12 hours after the patient's last drink and may last for 3 to 5 days. Characteristic symptoms include tremulousness, anxiety, increased heart rate, increased blood pressure, sweating, nausea, vomiting, hyper-reflexia, agitation, and insomnia. The most common severe manifestations are hallucinations and seizures. Seizures are most likely to occur 24 to 48 hours after the last drink in untreated alcohol withdrawal (Table 11-16). Alcohol-withdrawal delirium is a serious and potentially lethal complication that usually has its onset 48 to 72 hours

after the last drink. Delirium components include disorientation, visual or auditory hallucinations, and agitation. Death may be caused by hyperthermia, peripheral vascular collapse, or cardiac failure.

TABLE 11-16

Stages of Alcohol Withdrawal

Time of Appearance After Alcohol Last Used	Symptoms
6–12 hours	Minor withdrawal symptoms: insomnia, tremors, anxiety, gastro-intestinal upset, headache, diaphoresis, palpitations, anorexia, nausea, tachycardia, hypertension
12–14 hours	Visual, auditory, or tactile hallucinations
24–48 hours	Withdrawal seizures: generalized tonic–clonic seizures
48–72 hours	Alcohol-withdrawal delirium (delirium tremens): hallucinations (predominantly visual), disorientation, agitation, diaphoresis

Source: Sachdeva, A., Choudhary, M., & Chandra, M. (2015). Alcohol withdrawal syndrome: Benzodiazepines and beyond. *Journal of Clinical and Diagnostic Research*, *9*(9), VE01–VE07. doi:10.7980/JCDR/2015/13407.6538.

Key nursing intervention and management of alcohol withdrawal is based on early and accurate assessment. Nurses should assess for tachycardia, dehydration, fever, diaphoresis, dysrhythmias, and liver impairment, in addition to cognition and level of consciousness. The Clinical Institute Withdrawal Assessment for Alcohol Scale, Revised (Table 11-17) is a standardized assessment tool that can be used to assess and monitor for withdrawal symptoms caused by alcohol withdrawal. Treatment of intermediate withdrawal usually involves the administration of a benzodiazepine (chlordiazepoxide, diazepam, lorazepam, and oxazepam are most commonly used) to prevent withdrawal-related seizure (Sachdeva, Choudhary, & Chandra, 2015). If the person has compromised liver function or is an older adult, a short-acting benzodiazepine may be preferred (Hammond, Niciu, Drew, et al., 2015). A recent report suggests that non-benzodiazepine anticonvulsant drugs may be beneficial (Hammond, Niciu, Drew, et al., 2015).

TABLE 11-17

Clinical Institute Withdrawal Assessment for Alcohol (CIWA)

Patient Name:_____ (Last Name, First Name)
Time:_____ Total Score (max score = 67)_____ Temp: _____BP:_____/_____ Apex rate:_____
Resps:_____ Initials:____
_____ (print name and credentials) (signature)

Nausea & Vomiting
Ask: "Do you feel sick to your stomach? Have you vomited?" *Observation:*

0 No nausea/vomiting
1
2
3
4 Intermittent nausea with dry heaves
5
6
7 Constant nausea, frequent dry heaves and vomiting

Tremor
Arms extended and fingers spread apart.
Observation:

0 No tremor
1 Not visible, but can be felt fingertip to fingertip
2
3
4 Moderate, with patient's arms extended
5
6
7 Severe, even with arms not extended

Paroxysmal Sweats
Observation:

0 No sweat visible
1 Barely perceptible sweating, palms moist
2
3
4 Beads of sweat obvious on forehead
5
6
7 Drenching sweats

Anxiety
Ask: "Do you feel nervous?" *Observation:*

0 No anxiety, at ease
1 Mildly anxious
2
3
4 Moderately anxious, or guarded, so anxiety is inferred

Tactile Disturbances
Ask: "Have you any itching, pins and needles sensations, any burning, any numbness, or do you feel bugs crawling on or under your skin?" *Observation:*

0 None
1 Very mild itching, pins and needles, burning or numbness
2 Mild itching, pins and needles, burning or numbness
3 Moderate itching, pins and needles, burning or numbness
4 Moderately severe hallucinations
5 Severe hallucinations
6 Extremely severe hallucinations
7 Continuous hallucinations

Auditory Disturbances
Ask: "Are you more aware of sounds around you? Are they harsh? Do they frighten you? Are you hearing anything that is disturbing to you? Are you hearing things you know are not there?" *Observation:*

0 Not present
1 Very mild harshness or ability to frighten
2 Mild harshness or ability to frighten
3 Moderate harshness or ability to frighten
4 Moderately severe hallucinations
5 Severe hallucinations
6 Extremely severe hallucinations
7 Continuous hallucinations

Visual Disturbances
Ask: "Does the light appear to be too bright? Is its colour different? Does it hurt your eyes? Are you seeing anything that is disturbing to you? Are you seeing things you know are not there?" *Observation:*

0 Not present
1 Very mild sensitivity
2 Mild sensitivity
3 Moderate sensitivity
4 Moderately severe hallucinations
5 Severe hallucinations
6 Extremely severe hallucinations
7 Continuous hallucinations

Headache, Fullness in Head
Ask: "Does your head feel different? Does it feel like there is a band around your head?" Do not rate for dizziness or lightheadedness. Otherwise, rate severity.

0 Not present
1 Very mild
2 Mild
3 Moderate
4 Moderately severe
5 Severe
6 Very severe
7 Extremely severe

Orientation & Clouding of Sensorium
Ask: "What day is this? Where are you? Who am I?" *Observation:*

0 Oriented and can do serial additions
1 Cannot do serial additions or is uncertain about date

5 6 7 Acute panic as seen in severe delirium or acute schizophrenic reactions Agitation *Observation:* 0 Normal activity 1 Somewhat more than normal activity 2 3 4 Moderately fidgety and restless 5 6 7 Paces back and forth during most of interview, or constantly thrashes about	2 Disoriented for date by no more than 2 calendar days 3 Disoriented for date by more than 2 calendar days 4 Disoriented for place and/or person

Source: Brands, B., Kahan, M., Selby, P., et al. (Eds.). (2000). *Management of alcohol, tobacco and other drug problems: A physician's manual* (p. 77). Toronto: Centre for Addiction and Mental Health.

A quiet, calm environment is important to prevent exacerbation of symptoms. The use of restraints and IV lines should be avoided whenever possible. Supportive care is needed to ensure adequate rest and nutrition. Nursing care for the patient in alcohol withdrawal is presented in Nursing Care Plan 11-1.

Nursing Care Plan 11-1

Alcohol Withdrawal

NURSING DIAGNOSIS	**Risk for injury** as evidenced by *alteration in psychomotor functioning* (sensorimotor deficits)
Expected Patient Outcomes	**Nursing Interventions and *Rationales***
• Reports no falls or injuries • Experiences decrease in tremors and psychomotor activity • Reports no seizures • Verbalizes risk for injury associated with alcohol use before discharge	• Assess for risk factors such as impaired mobility (e.g., unsteady gait), sensory deficits, tremors, impaired judgement, confusion, seizure activity *to plan appropriate preventive measures.* • Assess for signs of injury such as lacerations, bruises, or burns *to treat appropriately.* • Monitor vital signs frequently, especially heart rate, *because prompt recognition of extreme autonomic nervous system response is necessary for early intervention to prevent progression of symptoms.* • Administer benzodiazepines as ordered *to control hyperactivity*, thiamine *to reduce neurological complications (e.g., Wernicke's encephalopathy),* and antiseizure medications as ordered *to prevent seizures.* • Use seizure precautions *to prevent injury.*
NURSING DIAGNOSIS	**Acute confusion** related to *substance misuse* as evidenced by *alteration in cognitive functioning, misperception, agitation, hallucinations* related to *sensory overload* as evidenced by *impaired interpretation of environmental stimuli, disorientation, and hallucinations*
Expected Patient Outcomes	**Nursing Interventions and *Rationales***
• Reports no hallucinations • Remains oriented to person, place, and time	• Assess patient's orientation and cognition *to determine appropriate interventions.* • Provide quiet and nonstimulating environment *to reduce external stimuli and calm overactive CNS.* • Orient to nurse and environment with each contact; use calm, approach; provide consistent staff; explain procedures and what is expected *to assist in orientation and decrease anxiety.* • Administer benzodiazepines as ordered *to reduce CNS stimulation.* • Administer antipsychotic medication (e.g., haloperidol [Haldol]) if ordered *to decrease severity of hallucinations*. (Be aware that Haldol lowers the seizure threshold.)
NURSING DIAGNOSIS	**Ineffective breathing pattern** related to *hyperventilation and respiratory muscle fatigue*
Expected Patient Outcomes	**Nursing Interventions and *Rationales***
• Maintains effective breathing • Reports no indications of hypoxia	• Monitor respiratory rate, depth, and pattern *so appropriate interventions may be taken.* • Position patient on side and in semi-Fowler's position *to reduce possibility of aspiration and to enhance lung expansion by lowering diaphragm.* • Monitor effects of medications given for withdrawal *to detect respiratory depression.* • Encourage coughing and deep breathing *to prevent complications of hypoventilation.* • Administer supplemental oxygen *to treat hypoxia.*

CNS, central nervous system.

Complications

Physical complications of chronic alcohol abuse are outlined in Table 11-18 and are frequently the reasons that alcohol-dependent individuals seek health care. Complications may also arise from the interaction of alcohol with commonly prescribed or OTC drugs. Drugs that interact with alcohol in an additive manner include antihypertensives, antihistamines, antianginals, and salicylates (Aspirin). Alcohol taken with Aspirin may cause or exacerbate gastro-intestinal (GI) bleeding. Alcohol taken with acetaminophen (Tylenol) may increase the risk for liver damage. **Potentiation,** a drug interaction causing a response greater than the sum of the individual responses to each drug, occurs when an additional CNS

depressant is taken with alcohol, increasing the effect. Heavy drinkers may be tolerant (require an increased dose for effect) to other depressant drugs such as benzodiazepines or opioids, even if they have never used these drugs. This is called **cross-tolerance**.

TABLE 11-18

Effects of Chronic Alcohol Abuse

Body System	System Effects
Central nervous system	Alcoholic dementia; Wernicke's encephalopathy (confusion, nystagmus, paralysis of ocular muscles, ataxia); Korsakoff syndrome (confabulation, amnesic disorder); impairment of cognitive function, psychomotor skills, abstract thinking, and memory; depression, attention deficit, labile moods, seizures, sleep disturbances
Peripheral nervous system	Peripheral neuropathy including pain, paresthesias, weakness
Immune system	Increased risk for tuberculosis and viral infections, especially pneumonia; increased risk for cancer of oral cavity, pharynx, esophagus, liver, colon, rectum, and possibly breast
Hematological system	Bone marrow depression, anemia, leukopenia, thrombocytopenia, blood clotting abnormalities
Musculo-skeletal system	Painful or tender swelling of large muscle groups; painless progressive muscle weakness and wasting; osteoporosis
Cardiovascular system	Elevated pulse and blood pressure; decreased exercise tolerance; cardiomyopathy (irreversible); increased risk for hemorrhagic stroke, coronary artery disease, hypertension, sudden cardiac death
Hepatic system	Steatosis (reversible)—nausea, vomiting, hepatomegaly; alcoholic hepatitis (reversible)—anorexia, nausea, vomiting, fever, chills, abdominal pain, cirrhosis; cancer
Gastro-intestinal system	Gastritis, peptic ulcer, esophagitis, esophageal varices, enteritis, colitis, Mallory–Weiss tear, pancreatitis
Digestive system	Decreased appetite, indigestion, malabsorption, vitamin deficiencies
Urinary system	Diuretic effect from inhibition of antidiuretic hormone
Endocrine and reproductive system	Altered gonadal function, testicular atrophy, decreased beard growth, decreased libido, diminished sperm count, gynecomastia, glucose intolerance, early menopause, fetal alcohol spectrum disorder
Integumentary system	Palmar erythema, spider angiomas, rosacea, rhinophyma

Complications Associated With Chronic Alcoholism.

One complication of chronic alcohol abuse is **Wernicke's encephalopathy**, an inflammatory, hemorrhagic, degenerative condition of the brain. Wernicke's encephalopathy is caused by a thiamine deficiency resulting from poor diet and alcohol-induced suppression of thiamine absorption. Because Wernicke's encephalopathy is potentially reversible, IV thiamine is often administered to intoxicated patients. Untreated or progressive Wernicke's encephalopathy may lead to **Korsakoff syndrome**, an

irreversible form of amnesia characterized by loss of short-term memory and an inability to learn (Xiong & Kenedi, 2016).

Collaborative Care

Cessation of drinking is the short-term goal that is accomplished through **withdrawal management**. Withdrawal management consists of interventions and processes aimed at addressing the physiological and psychological symptoms that occur in response to stopping a substance on which physiological and psychological dependence has developed. Management of alcohol withdrawal frequently includes the use of medications to decrease symptoms, increase the level of comfort, and decrease the risk of seizures and DTs. Table 11-19 presents the clinical manifestations of alcohol withdrawal and suggested drug treatment.

TABLE 11-19

Clinical Manifestations of Alcohol Withdrawal and Suggested Drug Treatment

Clinical Manifestations	Drug Treatment

• Gross tremors
• Seizures
• Hallucinations
• Minor withdrawal syndrome
  • Tremulousness, anxiety
  • Increased heart rate
  • Increased blood pressure
  • Sweating
  • Nausea
  • Hyper-reflexia
  • Insomnia
• Major withdrawal
  • DTs
  • Altered level of consciousness
  • Visual–auditory hallucinations
  • Increased hyperactivity without seizures
	• Benzodiazepines (e.g., chlordiazepoxide [Librax])
	• Thiamine (to prevent Wernicke's encephalopathy)
	• Multivitamins (folic acid, B vitamins)
	• Phenytoin (Dilantin) for seizures or past history of seizures
	• Magnesium sulphate (if serum magnesium is low)
	• Temazepam (Restoril) for sedation
	• Haloperidol (Haldol) for hallucinations

DTs, delirium tremens

NOTE: For DTs, provide intravenous fluids (do not overhydrate), cooling blanket, well-lit quiet room, consistent staff, and frequent checks of vital signs; check for hypoglycemia; assess any other health problems.

Patients should be referred to inpatient or intensive outpatient programs for continued support and treatment if they so desire. Treatment includes behavioural therapy and may also include drugs that block the desired effects of alcohol or agents that prevent drinking by causing aversive consequences when alcohol is consumed, such as naltrexone.

Sedative–Hypnotics

Characteristics

Commonly abused sedative–hypnotic agents include barbiturates, benzodiazepines, and barbiturate-like drugs. Benzodiazepine-class medications are effective and important in the treatment of panic attacks and severe anxiety. However, in practice, benzodiazepine medications are widely prescribed for generalized anxiety and, at times, for sleep disturbance for long periods of time, which can contribute to the development of tolerance and risk for misuse. A person who becomes tolerant to the effects may increase the dose and frequency of use without medical advice or indication. A second and more common pattern that has the potential for misuse or dependency involves illegal sources and often begins with intermittent use by teenagers or young adults at parties.

Effects of Use

Sedative–hypnotic drugs act primarily on the CNS, causing sedation at low doses and sleep at high doses. Excessive amounts produce an initial euphoria and an intoxication that includes impaired judgement, slurred speech, and loss of inhibitions and motor coordination. Although benzodiazepines are believed to have a wide margin of safety, they are not without adverse reactions, including rebound anxiety and insomnia with short-acting drugs and confusion and memory loss with long-acting drugs. These drugs are usually taken orally, but barbiturates may be injected intravenously. The effects of sedative–hypnotics are presented in Table 11-7.

Tolerance to the sedative effects develops rapidly, necessitating higher doses to achieve euphoria. Withdrawal from sedative–hypnotics can be very serious. The patient may develop anxiety, tremors, weakness, nausea with or without vomiting, muscle cramps, and increased reflexes. After 24 hours, the patient begins craving the drug and may experience delirium, seizures, and respiratory and cardiac arrest.

Complications

An overdose of a sedative–hypnotic may cause death as a result of respiratory depression. Symptoms of overdose are listed in Table 11-20. Complications associated with IV use of the drugs (e.g., blood-borne infections) can also occur.

TABLE 11-20

EMERGENCY MANAGEMENT
Overdose of Depressant Drugs

Etiology	Assessment Findings	Interventions
Ingestion, inhalation, or injection of CNS depressants—accidental or intentional	• Aggressive behaviour • Agitation • Confusion • Lethargy • Stupor • Hallucinations • Depression • Slurred speech • Pinpoint pupils • Nystagmus • Seizures • Needle tracks • Cold, clammy skin • Rapid, weak pulse • Slow or rapid shallow respirations • Decreased O_2 saturation • Hypotension • Dysrhythmia • ECG changes • Cardiac or respiratory arrest	**Initial** • Ensure patent airway • Anticipate intubation if respiratory distress evident • Establish IV access • Obtain temperature • Obtain 12-lead ECG • Obtain information about substance (name, route, when taken, amount) • Obtain specific drug levels or comprehensive toxicology screen • Obtain a health history including drug use and allergies • Administer antidotes as appropriate • Perform gastric lavage if necessary • Administer activated charcoal and cathartics as appropriate **Ongoing** • Monitor vital signs, temperature, level of consciousness, O_2 saturation, cardiac rhythm

CNS, central nervous system; *ECG,* electrocardiogram; *IV,* intravenous, O_2, oxygen.

Withdrawal From Sedative–Hypnotics.

Withdrawal from sedative–hypnotics can be highly variable, and the severity and the onset of symptoms depend on many factors, including the drug, the pattern of use, the dose and duration of use, and the presence of concurrent alcohol use. Symptoms may begin 12 hours after cessation of a short-acting drug and more than 100 hours after cessation of a long-acting drug. Withdrawal from high doses is potentially life-threatening and necessitates close monitoring in an inpatient setting. Management is symptomatic and includes a gradual reduction in drug dosage; abrupt cessation of the drug is not recommended. Long-acting agents such as diazepam (Valium), chlordiazepoxide (Librax), clonazepam, or phenobarbital may be substituted for the drug and tapered after

stabilization. Mild to moderate symptoms can persist for 2 to 3 weeks after a 3- to 5-day period of acute symptoms.

Collaborative Care

Overdoses of benzodiazepines may be treated with flumazenil, a specific benzodiazepine antagonist. There are no known antagonists to counteract the effects of other sedative–hypnotic medications. Emergency life support measures must be taken in cases of overdose. Medically supervised tapering off over an extended period of time is recommended for withdrawal management of people with benzodiazepine dependency.

Opioids

Characteristics

Opiates are substances that are directly derived from the opium poppy, such as morphine and codeine. **Opioids** is an umbrella term that includes both opiates and the many semisynthetic and synthetic narcotic agents used as analgesics. Commonly abused opioids are identified in Table 11-7. Opioid antagonists include naloxone.

Heroin, oxycodone, and fentanyl are commonly used street drugs. Although the rates of opioid dependency are lower than those for other illegal drugs, their use is associated with high levels of crime, violence, HIV infection, and death from overdose. Heroin is emerging as a drug of choice because it is often cheaper than prescription opioids (Canadian Public Health Association, 2014).

The vast majority of people who are prescribed opioid medications for the treatment of acute and chronic pain do not develop problematic or aberrant use patterns. However, certain risk factors, including the presence of mental health disorder or physical ill-health, as well as some sociodemographic factors, will increase the risk of nonmedical use (Katz, El-Gabalawy, Keyes, et al., 2013). Individuals who have experienced trauma are at greater risk for developing a substance use disorder (Macy & Goodbourn, 2012).

Effects of Use

By acting on opiate receptors and neurotransmitter systems in the CNS, opioids cause CNS depression and a major effect on the brain reward system. As drugs of abuse, they are taken orally, sniffed, smoked, or taken

intravenously. The primary effects include analgesia, drowsiness, slurred speech, detachment from the environment, hunger, decreased respiratory rate, GI peristalsis, and decreased pupil size. Tolerance to the analgesic effects of opioids develops slowly, whereas tolerance to the euphoric psychological effects develops much more quickly; therefore, people who are misusing opioids for a sense of euphoria will require increasingly high amounts to achieve the same effect. Physiological tolerance to opioids is lost very quickly. After a few days of abstinence, lower tolerance may lead to fatal overdoses should people resume taking the same amount they had been accustomed to taking.

Opioid Overdose

Signs of overdose of opioids include pinpoint pupils, clammy skin, depressed respiration, and decreased level of consciousness that can lead to coma and death if the overdose is not treated. Unintentional overdose frequently occurs with recreational use of the drugs because of the unpredictability in potency and purity. Opioid overdose is a medical emergency and should be treated in an acute medical setting. Treatment includes administering a naloxone infusion and maintaining airways. Giving naloxone 0.4 mg to 2.0 mg intravenously puts the person into withdrawal temporarily, and, as such, repeat doses may be required. Signs of overdose are presented in Table 11-7.

Opioid Withdrawal

Withdrawal from opioids occurs with decreased amounts or cessation of the drug after a period of moderate to heavy use. Symptoms may include craving, abdominal cramps, diarrhea, nausea, and vomiting. They are extremely uncomfortable and similar to a bout of stomach flu (Table 11-21). Opioid withdrawal usually peaks 2 to 3 days after the last use and resolves by days 5 to 7. Interventions to support withdrawal include comfort measures and medications for relief of symptoms.

TABLE 11-21

Symptoms of Opioid Withdrawal Versus Opioid Intoxication

Opioid Overdose	Opioid Withdrawal
Early Signs	• Dysphoric mood • Nausea or vomiting • Abdominal cramps • Myalgia (muscle pain) • Lacrimation (teary eyes) • Rhinorrhea (runny nose) • Mydriasis, piloerection • Sweating • Diarrhea • Yawning • Fever • Insomnia • Anxiety • Agitation • Fatigue • Tachycardia
• Nodding off/drowsiness • Slurred speech • Emotional lability • Myosis	
Late Signs	
• Respiratory depression • Prolonged QT interval • Ventricular arrhythmias • Coma

Complications

A key consideration in people with regular chronic use of opioids is opioid-induced constipation, which can lead to bowel obstruction. An important point of health teaching for patients is to advise them to avoid bulk-forming laxatives, which in fact will make the constipation worse. Osmotic agents that will aid in the relief of opioid-induced constipation are recommended. As mentioned above, a lower tolerance can result in the risk of death caused by unintentional overdose. Health problems associated with opioid use are presented in Table 11-3.

Collaborative Care

Opioid dependency is a chronic and relapsing condition, and thus a long-term treatment approach is taken. Best outcomes are achieved with psychosocial interventions plus pharmacotherapy (Vancouver Coastal Health and Providence Health Care Opioid Use Disorder Treatment Committee, 2015).

Withdrawal Management.

Withdrawal management alone is not recommended (Vancouver Coastal Health and Providence Health Care Opioid Use Disorder Treatment Committee, 2015). However, pharmacological treatment using methadone or buprenorphine in combination with psychosocial intervention has been found to be very effective (Amato, Davoli, Minozzi, et al., 2013).

Methadone.

Methadone is a potent long-acting agonist opioid that, at the right dose, allows the person who takes it to feel comfortable and free of withdrawal symptoms for 24 hours. Methadone is dispensed as a liquid mixed with juice that is taken daily. Until a period of stability is achieved, as evidenced by improved psychosocial functioning and abstinence from substance use, the person is dosed daily at a pharmacy or specialized clinic. With stability, the patient may be provided take-home doses of methadone, as long as he or she can be responsible for ensuring safe storage and handling.

In the surgical setting, it is important to review the routine and medication history of the person who is taking methadone to ensure that no doses have been missed; it is also essential to confirm when the person last took a dose to avoid double-dosing and overdosage. Upon discharge, the health care team must coordinate care to ensure that the patient can resume dosing in the community to avoid any missed doses. Since methadone can be sedating, people on methadone maintenance therapy should be advised to avoid using other sedating substances such as alcohol and benzodiazepines.

Buprenorphine.

Buprenorphine has properties of being both a partial opioid agonist and an antagonist and is less sedating than methadone. It is available as a sublingual oral tablet for substitution therapy. It is taken once daily and, like methadone, allows the person to be free of withdrawal symptoms for 24 hours at the right dose. Buprenorphine has a better safety profile than methadone, in that the risk of overdose is much lower, because buprenorphine binds to more receptors. Therefore, if additional opioids are used, they have fewer receptors to bind to, thereby reducing the risk for overdosage (Handford, Kahan, Srivastava, et al., 2011).

Maintenance.

The choice of agonist treatment for long-term maintenance depends on the patient's history, the presence of other illnesses, patient preference, and

response to treatment. It is critical, however, that the patient receive psychosocial support. While there is no strong evidence supporting any one particular psychotherapy approach, monitoring and supporting the patient's mental health is an essential aspect of care (Vancouver Coastal and Providence Health Care Opioid Use Disorder Treatment Committee, 2015).

Hallucinogens

Hallucinogens are a variety of psychoactive substances that produce a change in level of consciousness, alter mood, and induce hallucinations. Table 11-7 identifies common hallucinogens and their effects.

Characteristics

According to the Government of Canada (2013b), about 11% of all Canadians aged 15 and older had used cannabis at least once in the past year, and about 28% of those who had used cannabis in the past 3 months reported that they used it every day or almost every day. *Cannabinoids* are chemicals found in the cannabis plant, and the chemical most responsible for the psychoactive effects is tetrahydrocannabinol (THC). At low to moderate doses, THC produces effects similar to alcohol and other CNS depressants. These include euphoria, decreased inhibition, and impaired coordination. Long-term use is associated with a wide range of effects, particularly on cardiopulmonary and mental health. Adolescents who use cannabis regularly are at higher risk for psychotic symptoms, particularly when there is coexisting or family history of psychosis (George & Vaccarino, 2015). Cannabinoids may be natural or synthetic.

The Canadian government has legalized the use of marihuana for specific medical reasons. Physicians may prescribe pharmaceutical cannabinoids, nabilone (an oral tablet containing a synthetic THC), or herbal marihuana. Illegal synthetic THC derivatives (e.g., K2, Spice), which contain varying amounts of different ingredients, have unpredictable effects and are more toxic. In some instances, death has occurred with a single use.

Effects of Use

Marihuana produces three principal effects: euphoria, sedation, and hallucinations. The most commonly affected organs are the brain and the cardiovascular and respiratory systems. Signs of intoxication are presented in Table 11-7. Problems of chronic use include impaired short-term memory, decreased motor coordination, tremors, and increased heart and respiratory rates. A condition known as *amotivational syndrome,* characterized by apathy, dullness, and disinterest, may also occur. Patients with *acute marihuana toxicity* can present with acute psychotic episodes,

especially if the patient used a synthetic derivative. Cannabis can induce tachycardia and hypertension, triggering dysrhythmias and myocardial infarction.

Withdrawal can occur in a hospitalized patient who is a heavy cannabis user. The patient may experience irritability, anxiety, anorexia, chills, disturbed sleep, fever, and tremors (Hesse & Thylstrup, 2013). No specific drug therapy is effective in treating withdrawal. Supportive care includes measures such as administration of analgesics and hydration to ensure patient comfort. Panic and flashbacks are managed by providing a quiet environment and reassuring the patient, and benzodiazepines may provide symptom relief.

Collaborative Care

In acute marihuana intoxication, the nurse should perform a physical examination, a toxicology screen, and a thorough history. The main interventions are to provide a quiet environment and to support and reassure the patient by explaining what is happening. The patient should understand that the level of intoxication may fluctuate over several days as metabolites are released.

Inhalants

Inhalation is the major route of ingestion for a number of common household and industrial volatile substances. Forms of use include sniffing, huffing, bagging, and spraying. Because inhalants are readily accessible, are inexpensive, and produce a rapid high, their use among preadolescents and adolescents is high.

There are four main classes of inhalants: volatile solvents, aerosols, anaesthetic agents, and nitrites. Inhalants are rapidly absorbed and reach the CNS quickly. Most are depressants, and their effects are similar to those of alcohol, including slurred speech, lack of coordination, euphoria, and dizziness. The effects are relatively brief, lasting only 60 to 90 minutes. Long-term use can result in neurological problems, including damage to parts of the brain that control cognition, movement, vision, and hearing. Common agents and their effects are presented in Table 11-3.

The patient with inhalant toxicity may experience dizziness, euphoria, disinhibition, nystagmus, slurred speech, and lethargy. The effects usually resolve within minutes to a few hours. Managing inhalant toxicity usually consists of providing supportive care. However, in some cases, users need

emergency treatment for dysrhythmias, heart failure, or CNS hyperactivity (e.g., seizures).

Nursing Management Addictive Behaviours

Nursing Assessment and Screening

Early recognition and identification of a patient with substance use disorder is crucial to successful treatment outcomes for any health problem. A health history should include questioning about the use of all substances, including prescribed medications, OTC drugs, herbal and homeopathic products, caffeine, tobacco, alcohol, and recreational drugs, noting pattern, amount, frequency of use, reasons for use, and reasons for nonuse. Screening tools for drug abuse were presented in Tables 11-3 and 11-4. The nurse must be alert to signs and symptoms of the many health problems associated with substance use that may be apparent during the physical examination. Assessment of the patient's general appearance and nutritional status and examination of the abdomen, the skin, and the cardiovascular, respiratory, and neurological systems often reflect problems associated with substance use.

Although various screening tools are available, one that nurses easily use to identify alcohol dependence is the Alcohol Use Disorders Identification Test (AUDIT) (Table 11-22). A person with a score of eight points or less is considered not to have problematic use, whereas nine points or above suggests problematic use and warrants further assessment. Another instrument frequently used is the CAGE (cut down, annoy, guilt, eye-opener drinks) questionnaire (Table 11-23).

TABLE 11-22

Alcohol Use Disorders Identification Test (AUDIT)

Please answer each question by checking one of the circles in the second column.		
		Score
1. How often do you have a drink containing alcohol?	• Never • Monthly or less • 2–4 times/mo. • 2–4 times/wk. • 4+ times/wk.	(0) (1) (2) (3) (4)
2. How many drinks containing alcohol do you have on a typical day when you are drinking?	• 1 or 2 • 3 or 4 • 5 or 6 • 7 to 9 • 10 or more	(0) (1) (2) (3) (4)
3. How often do you have six or more drinks on one occasion?	• Never • Less than monthly • Monthly • Weekly • Daily or almost daily	(0) (1) (2) (3) (4)
4. How often during the last year have you found that you were not able to stop drinking once you had started?	• Never • Less than monthly • Monthly • Weekly • Daily or almost daily	(0) (1) (2) (3) (4)
5. How often in the last year have you failed to do what was normally expected of you because you were drinking?	• Never • Less than monthly • Monthly • Weekly • Daily or almost daily	(0) (1) (2) (3) (4)
6. How often during the last year have you needed a first drink in the morning to get yourself going after a heavy drinking session?	• Never • Less than monthly • Monthly • Weekly • Daily or almost daily	(0) (1) (2) (3) (4)
7. How often during the last year have you had a feeling of guilt or remorse about drinking?	• Never • Less than monthly • Monthly • Weekly • Daily or almost daily	(0) (1) (2) (3) (4)
8. How often during the last year have you been unable to remember what happened the night before because you had been drinking?	• Never • Less than monthly • Monthly • Weekly • Daily or almost daily	(0) (1) (2) (3) (4)

Please answer each question by checking one of the circles in the second column.		
		Score
9. Have you or someone else been injured as a result of your drinking?	• No • Yes, but not in the last year • Yes, during the last year	(0) (2) (4)
10. Has a relative, friend, doctor, or other health worker been concerned about your drinking or suggested that you cut down?	• No • Yes, but not in the last year • Yes, during the last year	(0) (2) (4)

Scoring for AUDIT: Questions 1 through 8 are scored 0, 1, 2, 3, or 4. Questions 9 and 10 are scored 0, 2, or 4 only. The minimum score (nondrinkers) is 0, and the maximum possible score is 40. A score of 9 or more indicates hazardous or harmful alcohol consumption.

Source: Reprinted from *The Alcohol Use Disorders Identification Test,* 2nd edition, WHO, p. 17, Copyright 2001.

TABLE 11-23

CAGE Questionnaire Adapted to Include Drugs (CAGE AID)

Have you felt you ought to cut down on your drinking *(or drug use)*?
_____Yes _____No
Have people annoyed you by criticizing your drinking *(or drug use)*?
_____Yes _____No
Have you felt bad or guilty about your drinking *(or drug use)*?
_____Yes _____No
Have you ever had a drink (or used drugs) first thing in the morning to steady your nerves or get rid of a hangover *(or to get the day started)*?
_____Yes _____No

Note: In the general population, two or more positive answers indicates a need for a more in-depth assessment.

Source: Fleming, M. F., & Barry, K. L. (1992). *Addictive disorders.* St. Louis: Mosby; and Ewing, J. A. (1984). Detecting alcoholism: The CAGE questionnaire. *Journal of the American Medical Association, 252,* 1905–1907. doi:10.1001/jama.1984.03350140051025.

Nursing Diagnoses

Nursing diagnoses for the patient in alcohol withdrawal may include but are not limited to those presented in Nursing Care Plan 11-1. In addition, other nursing diagnoses for an individual with substance use may include but are not limited to the following:

- *Ineffective coping* related to *inadequate confidence in ability to deal with situation*
- *Risk for infection* as evidenced by *invasive procedure* (IV drug use)
- *Imbalanced nutrition: less than body requirements* related to *insufficient dietary intake*
- *Ineffective health maintenance* related to *impaired decision-making* (substance misuse)
- *Dysfunctional family processes* related to *substance misuse*

Planning

Nurses need to effectively assess for, manage, and evaluate patients experiencing intoxication, overdose, and withdrawal symptoms because these clinical situations will arise in all settings, from the emergency department to a surgical environment. But most important, positive, nonjudgemental, supportive, and therapeutic dialogue is fundamental.

Nursing Implementation

Health Promotion.

Prevention of substance use problems and addictive behaviours includes primary, secondary, and tertiary prevention. Primary prevention targets primarily adolescents and young adults by offering education about short- and long-term effects, negative outcomes and effects of continued use of addictive substances. Secondary prevention focuses on early detection of substance use, interventions through peer or employee assistance programs, and continuing education about substance-free alternatives and stress-management techniques. Tertiary prevention addresses dependence and includes motivating individuals to enter addiction treatment and referring to treatment and relapse-prevention programs.

Motivational Interviewing: Engaging in a Supportive Dialogue With People With Problematic Substance Use.

The nurse is in a unique position to motivate and facilitate behaviour change while caring for patients in primary and acute care settings. When a patient seeks care for health problems related to substance use or when hospitalization interferes with the normal use of substances, the patient's awareness of problems associated with addictive behaviours is increased. Intervention by nurses at this time can be a crucial factor in promoting behaviour change.

Motivational interviewing is "a directive, patient-centred counselling style for eliciting behaviour change by helping patients to explore and resolve ambivalence" (Rollnick & Miller, 1995, p. 326). Motivational interviewing uses nonconfrontational interpersonal techniques to motivate patients to change behaviour by eliciting talk about substance use. Patients are able to hear themselves speak and gain awareness of how they perceive their substance use. The role of the nurse is to listen and reflect back to the person, bring to light positive change talk, and recognize that ambivalence is normal and expected when anyone is confronted with having to make a change. The key aspects of successful motivational interviewing are presented in Table 11-24.

TABLE 11-24
Key Aspects of Successful Motivational Interviewing

- Express empathy.
- Provide positive reinforcement and encouragement for gains made by the patient.
- Listen rather than tell.
- Gently persuade, with the understanding that change is up to the patient.
- Identify discrepancy between patient's goals or values and current behaviour.
- Help the patient recognize the discrepancies between where he or she is and where he or she hopes to be.
- Avoid argument and direct confrontation, which can cause defensiveness and a power struggle.
- Adjust to, rather than oppose, patient resistance.
- Focus on the patient's strengths to support the hope and optimism needed to make changes.

The stages of change identified in the **transtheoretical model of change** include precontemplation, contemplation, preparation, action, maintenance, and termination (Prochaska & Velicer, 1997), as described in Chapter 4. The stages are not viewed as linear but, rather, as a cycle through which patients move back and forth. During the process of change, relapse and small **lapses** (very short periods of substance use, followed by quick return to maintaining nonuse) are part of the journey and a normal aspect of behaviour change. Patients who do not change behaviours or who return to substance use after a period of cessation are often labelled "noncompliant" and "unmotivated." However, this development may reflect a normal relapse or may indicate that the

interventions used do not consider the patient's stage of change. It is important for the nurse to identify the patient's current stage of readiness for change and the stage to which the patient is moving.

In the precontemplation stage, patients are not concerned about their substance use and are not considering changing their behaviour. During this stage, it is most important for the nurse to help the patient increase awareness of risks and problems related to the current behaviour. A patient in the contemplation stage of change often experiences ambivalence. The patient sees that the behaviour is a problem and that change is necessary yet feels that change is too difficult or that the pleasures of continuing the behaviour are worth the risks. During this stage of change, the nurse should help the patient thoughtfully consider the positive and negative aspects of the substance use. It is useful to summarize the patient's concerns and affirm the patient's ambivalence. As the patient moves from contemplation to preparation, a commitment to change can be strengthened by helping the patient develop self-efficacy. Self-efficacy in this case is the patient's optimism that substance use behaviours can be changed. The nurse should support even the smallest effort to change. The resolution of acute health problems or discharge from the hospital often occurs before the patient moves to the preparation and action stages of change. If the patient demonstrates a readiness to change, as evidenced by entering the contemplation stage or beyond, the nurse must support the continuation of the change process by making appropriate referrals to community resources.

Ethical Dilemmas

Duty to Report

Situation

A patient who has been treated for severe alcohol-withdrawal complications discloses to the nurse that he is a long-distance truck driver and has been working for the past 10 years. As part of the substance use assessment, the nurse learns that he seems to have developed high tolerance to alcohol, with daily consumption and only short periods of abstinence since his divorce last year. He had no previous substance use history or problematic substance use before last year.

Important Points for Consideration

- Nurses have an ethical obligation to prevent harm to patients and the public.
- Nurses are responsible for communicating concerns regarding harms to the patient as well as communicating them to the patient's team of health care providers.
- Nurses must know the legal reporting obligations regarding driver licensing for their province or territory.

Clinical Decision-Making Questions

1. How should the nurse handle this situation?
2. What are the provisions of the province or territory's legal reporting obligations regarding impaired driving?

Age-Related Considerations

Nurses and other health care providers are much less likely to recognize substance misuse and substance use in older adults than in younger adults. Older adults do not fit the image that people in today's society have of those who abuse substances. In addition, patterns of substance use in older adults are considerably different from those in younger and middle-aged adults. Because alcohol and substance use among older adults is often mistaken for other conditions associated with the aging process (e.g., neuropathy, anemia, mental status changes), the problem often goes undiagnosed and untreated.

The prescription drugs used by older adults are primarily psychoactive in nature, including sedative–hypnotic, anxiolytic, and opioid agents. Simultaneous use of OTC drugs, prescription drugs, and alcohol occurs in many older adults. This presents a pattern of drug misuse and abuse that is not commonly seen in younger populations.

The effects of alcohol and other psychoactive substances increase with aging. Age-related decreases in circulation, metabolism, and excretion slow the body's detoxification of drugs, potentiate tolerance, and accelerate physical dependence (physiological adaptation to ongoing exposure such that use and cessation cause an expected physiological response). Physiological changes that accompany aging may lead to intoxication at levels of intake that may not have been a problem earlier in life.

The adverse effects of interaction of alcohol and other drugs also increase with aging. When taken with alcohol, sedative–hypnotic drugs, minor tranquilizers, and CNS depressants have additive and synergistic effects. Misuse and abuse of psychoactive agents, either alone or in combination, by older adults may cause confusion, disorientation, delirium, memory loss, and neuro-muscular impairment. The effects of alcohol and drug use can also be mistaken for medical or psychiatric conditions common among older adults, such as insomnia, depression, poor nutrition, heart failure, and frequent falls. Withdrawal symptoms also occur in the older adult when alcohol, opioids, or sedative–hypnotics are abruptly stopped, and these symptoms may be more severe than in younger individuals. Because of the possibility of alcohol use in older adults, the nurse should always consider that behaviour changes in the older patient may be caused by alcohol use or withdrawal.

Identification of substance misuse, abuse, and dependence in the older patient presents a challenge. Evidence of addictive disorders is not always obvious in the older adult since, as mentioned above, manifestations may be similar to those caused by common health problems of old age. As with all patients, it is important for the nurse to discuss all drug and alcohol use with older patients, including use of OTC, herbal, and homeopathic medications. The nurse should also assess the patient's knowledge of the medications that he or she takes. It is important, too, to screen for warning signs such as unexplained falls, neglect of personal hygiene, and complaints of mood, sleep, or memory problems.

Patient education for the older adult includes teaching about the desired effects, possible adverse effects, and appropriate use of prescribed and OTC medications. The nurse should recommend that the patient use only one pharmacy because many pharmacies maintain a medication profile on each individual that may prevent problems with drug interactions. Patients should be advised not to drink alcohol when using prescribed and OTC medications.

Developmental, physical, and psychosocial changes that occur with aging contribute to late-onset abuse of alcohol and other drugs. The older adult may have difficulty coping with losses that occur with increasing age, such as retirement, death of family and friends, relocation, social isolation, and poor health.

The nurse should monitor people who are experiencing losses and identify those who are having difficulty coping. Home visits by a nurse provide a good opportunity for assessment of the problems and also provision of valuable support. A nurse who suspects an alcohol or substance use disorder in an older patient should refer the patient for treatment. It is a mistaken belief that older people have little to gain from alcohol and drug dependence treatment. As with younger patients, the rewards of treatment can lead to greater quality and quantity of life for older adults.

Case Study

Substance Use

Source: Pavel Kriuchkov/Shutterstock.com.

Patient Profile

Mrs. Carla Muller, a 78-year-old woman, is admitted to the emergency department after falling and injuring her right shoulder and arm. She has been widowed for 4 years and lives alone. Recently, her best friend died. Her only family is a daughter who lives out of town. When the nurse contacts the daughter by phone, the daughter tells the nurse that her mother appears to have been more disoriented and confused over the past year when they have talked on the phone.

Subjective Data

- Is complaining of severe pain in her right shoulder and upper arm.
- Admits she had some wine in the late afternoon to stimulate her appetite.
- Has experienced several falls in the past 2 months.
- Reports that she fell after taking her sleeping pill, prescribed by her physician because she does not sleep well.
- Speaks with hesitation and slurs.
- Says she smokes about half a pack of cigarettes a day.

Objective Data

Physical Examination

- Oriented to person and place, but not time.
- Blood pressure 162/94, pulse 92, respirations 24.
- Bruising and edema of right upper arm.
- Tremors of hands.

Diagnostic Tests

- Radiographic examination reveals comminuted fracture of the proximal humerus necessitating surgical repair.
- Blood alcohol concentration (BAC) 26 mmol/L.
- Complete blood count: hemoglobin 106 g/L; hematocrit 0.38 (38%).

Discussion Questions

1. What other information is needed to assess Mrs. Muller's condition?
2. How should questions regarding these areas be addressed?
3. What factors may contribute to Mrs. Muller's use of psychoactive substances?
4. ***Priority decision:*** What priority nursing interventions are appropriate during Mrs. Muller's preoperative period?
5. What possible complications and other health problems may become apparent during Mrs. Muller's postoperative recovery?
6. What nursing interventions are appropriate following Mrs. Muller's surgery?
7. ***Priority decision:*** Based on the assessment data presented, what are the priority nursing diagnoses for Mrs. Muller? Are there any collaborative problems?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. Which of these statements is true?
   a. Only a small percentage of Canadians are affected by substance use issues.
   b. Tobacco use is the leading cause of preventable morbidity and mortality.
   c. The highest incidence of substance use is among youth.
   d. Substance use is more prevalent in urban areas.
2. What term best describes a pattern of compulsive, continued use of a substance despite significant personal harms and withdrawal syndromes?
   a. Abuse
   b. Substance use disorder
   c. Tolerance
   d. Addictive behaviour
3. When engaging a client experiencing substance use or dependency, which of the following is the nursing intervention based on?
   a. A comprehensive and thorough screening and assessment of substance use
   b. A holistic biopsychosocial approach to care
   c. A nonjudgemental, collaborative therapeutic relationship that honours client autonomy and choice
   d. Assessment of safety concerns and stabilization of acute illness
4. When using a harm-reduction approach with clients experiencing substance use problems, what is the key aim of the nurse?
   a. To provide harm-reduction supplies and health teaching
   b. Not to coerce or force the individual to quit his or her substance use
   c. To ensure that clients have access to health care services
   d. To reduce the harms associated with substance use
5. When screening and assessing for substance use, which of the following are some key aspects to cover?

a. Use of substances, pattern of use, route, frequency of use, and date and time of last use

b. Medical history and psychiatric history

c. Social supports

d. Legal history

6. What is a long-term effect of addictive substances on the brain?

a. Increased availability of dopamine

b. Destruction of the mesolimbic system

c. Loss of pleasure from experiences that previously resulted in enjoyment

d. Potentiation of effects of similar drugs taken when the individual is drug free

7. Which of the following is the most appropriate nursing intervention for a client who is seen at the clinic for increasing shortness of breath but who is not interested in quitting smoking?

a. Accept the client's decision and do not intervene until the client expresses a desire to quit.

b. Realize that some smokers will never quit and that trying to assist them only increases the client's and the nurse's frustration.

c. Increase the client's motivation to quit by explaining that continued smoking will only increase the breathing problems.

d. Ask the client at every clinic visit to identify the relevance, the risks, the benefits of quitting, and the barriers to quitting.

8. While caring for a client who is experiencing alcohol withdrawal, what actions should the nurse take? *(Select all that apply)*

a. Monitor neurological status on a routine basis.

b. Provide a quiet, nonstimulating, dimly lit environment.

c. Pad the side rails and place suction equipment at the bedside.

d. Orient the client to environment and person with each contact.

e. Administer antiseizure drugs and sedatives to relieve symptoms during withdrawal.

9. A client who is dependent on IV barbiturates is scheduled for surgery following an automobile accident. What is important for the nurse to recognize in this case?

a. The client may need less pain medication during the postoperative period.
b. The client should be provided with tapering doses of barbiturates following surgery.
c. The client may have an immediate onset of withdrawal symptoms when given anaesthetic and analgesic agents.
d. The client has a low risk for physical withdrawal symptoms but is likely to experience craving and drug-seeking behaviour during the postoperative period.

10. Which of the following is important in pain management of clients dependent on opioids or other CNS depressants?
a. Realize the goal is to treat acute pain.
b. Avoid treating the pain.
c. Understand that opioid analgesia may worsen an addictive disease.
d. Addiction treatment remains a priority while the client is in pain.

11. In which of the following behaviours should the nurse engage during motivational interviewing with a client? *(Select all that apply)*
a. Insist that the client maintain abstinence while undergoing therapy.
b. Relate motivational techniques to the client's stage of behaviour change.
c. Use any method of communication that will make the client change behaviour.
d. Identify discrepancy between the client's goals or values and current behaviour.
e. Ask a prescribed set of questions to increase the client's awareness of addiction behaviours.

12. To which factors are substance use problems in older adults most commonly related?
a. Use of drugs and alcohol as a social activity
b. Misuse of prescribed and OTC drugs and alcohol
c. Continued use of illegal drugs initiated during middle age
d. A pattern of binge drinking for weeks or months with periods of sobriety

1. b; 2. b; 3. c; 4. d; 5. a; 6. c; 7. d; 8. a, c, d, e; 9. b; 10. a; 11. b, d; 12. b.

CHAPTER 12

Complementary and Alternative Therapies

Written by, Virginia (Jennie) Shaw

Adapted by, Jane Tyerman

LEARNING OBJECTIVES

1. Describe commonly used complementary and alternative therapies.
2. List indications for the use of traditional Chinese medicine (TCM).
3. Describe the general types of herbal therapy and indications for their use.
4. List concepts to be included in patient teaching with regard to herbal supplements.
5. Describe the practice of holistic nursing through the use of complementary and alternative therapies.
6. Describe the process of assessing patients' use of complementary and alternative therapies.
7. Describe the roles of the nurse in integrating complementary and alternative therapies into nursing practice.

KEY TERMS

acupuncture, p. 197
alternative therapies, p. 194
complementary therapies, p. 194
healing touch, p. 201
herbal therapy, p. 197

holistic nursing, p. 203

massage therapy, p. 198

neurofeedback, p. 196, Table 12-4

prayer, p. 202

therapeutic touch, p. 201

traditional Chinese medicine (TCM), p. 196

The general health of Canadians is steadily improving, as evidenced by lower mortality rates and increased life expectancy. Biomedical and technological advances have contributed to these improvements. However, conventional therapy has been less helpful in alleviating symptoms of chronic illnesses, and chronic health challenges are at an epidemic high. Furthermore, conventional (Western, mainstream) approaches to health care tend to be depersonalized and often fail to account for all aspects of an individual—that is, not only body but also mind and spirit. Canada's Indigenous peoples have healing traditions that attempt to balance the four parts of the person: the physical, mental, emotional, and spiritual.

Increasing access to global perspectives has resulted in greater exposure to healing philosophies from many cultures, offering both consumers and health care providers many new ideas about health and healing (Fontaine, 2014).

Various terms have been used to describe health-related approaches that are considered outside the mainstream of the system of health care dominant in Canada and other Western cultures: *alternative, complementary, integrative, nontraditional, unconventional, holistic, natural,* and *unorthodox*. Currently, the term most frequently used to refer to such modalities and practices is *complementary and alternative therapies.* According to Health Canada (2012), **complementary therapies** are therapies that accompany traditional Western health practices, whereas **alternative therapies** are used instead of traditional health practices. Most of these practices were developed outside of conventional biomedical approaches and are generally available without medical authorization. Furthermore, many of these modalities are similar to autonomous nursing interventions such as touch, massage, stress management, and activities to facilitate wellness and enrich health.

Complementary and alternative therapies are harmonious with many of the values of nursing (Canadian Nurses Association [CNA], 2017; College & Association of Registered Nurses of Alberta, 2011; College of Nurses of Ontario, 2014a). These values include a view of humans as holistic beings,

an emphasis on healing, recognition that the professional–patient relationship should be a partnership, and a focus on health promotion and illness prevention. Nursing's interest in complementary and alternative perspectives is reflected in the formation of specialty nursing groups. For example, the Canadian Holistic Nurses Association (CHNA; n.d.) was established to recognize holistic nursing as a specialty and to ensure holistic practices are considered within a health maintenance and promotion framework. Despite this, nurses may face challenges in providing alternative therapies, such as a lack of knowledge for adequate patient education and the fact that these techniques are often not supported within a biomedical health care system.

To provide direction, the College of Nurses of Ontario (CNO; 2014b) has published practice guidelines for complementary and alternative therapies, which identify the responsibilities of the nurse: (a) to ensure the appropriateness of the chosen therapy, (b) to have adequate knowledge, skill, and judgement to provide the therapy safely and effectively, and (c) to understand the potential outcomes of the therapy. Additionally, nurses need to be aware that patients often under-report or do not report their use of alternative and complementary modalities to their health care provider because of fear of being judged or of not having their health care needs met. It is important that the nurse be nonjudgemental and amenable to the patient's needs.

Health care providers have raised important questions about the effectiveness and safety of complementary and alternative approaches in view of their increased use by consumers. In response to these questions, the Canadian Interdisciplinary Network for Complementary and Alternative Medicine Research (INCAM) was established to foster excellence in complementary and alternative medicine (CAM) research. Its objectives are to build a sustainable network that facilitates and supports research, promote knowledge transfer among researchers, and thus avoid the duplication of research efforts (see the Resources at the end of this chapter). It is difficult to classify the enormous array of complementary and alternative health practices. For analytical purposes, the National Center for Complementary and Integrative Health (NCCIH, 2015) classified these therapies into specific groups: natural products, mind and body practices, and other CAM approaches. Table 12-1 offers descriptions of major categories. Tables 12-2, 12-3, and 12-4 describe select therapies within each category. The list of therapies continually changes as practices proven safe and effective become accepted as “mainstream” health care practices.

TABLE 12-1

NCCIH CATEGORIES OF COMPLEMENTARY AND ALTERNATIVE THERAPIES

Category	Description
Mind and body practices	Therapies focused on the effects of mind–body practices on the brain, mind, body, and behaviours. Science of psychoneuroimmunology demonstrates the strength of this mind–body connection (see Table 12-2).
Natural products	Substances found in nature that are used for their effect on health and wellness (see Table 12-3).
Other CAM practices	Therapies not included in the other categories of CAM therapies (see Table 12-4).

CAM, complementary and alternative medicine.

Source: National Center for Complementary and Integrative Health (NCCIH). (2015). *Complementary, alternative, or integrative health: What's in a name?* Retrieved from *https://nccih.nih.gov/health/integrative-health*.

TABLE 12-2

MIND AND BODY PRACTICES

Examples	Description
Relaxation breathing	Slow, diaphragmatic breathing and exercises, used to elicit the relaxation response. See Chapter 8 for further information.
Meditation	State of being with increased concentration and awareness. Focuses one's attention and increases self-awareness. Two branches exist: (a) inclusive/mindfulness and (b) exclusive/concentrative. Mindfulness meditation focuses on "living in the moment" without judgement. Concentrative meditation involves "moving inward," often initiated by concentrating on the breath, a mantra, or an object. Outcomes may include relaxation, spiritual growth, and personal healing.
Biofeedback	Method of learned control of physiological responses of the body (Fontaine, 2011). Information about one or more physiological functions is received, interventions are used, and a feedback loop allows for voluntary control of certain functions.
Yoga	Activity that includes mental and physical exercises, ethical principles, and guidelines for healthy living. Part of the Ayurvedic medical system. Canadians use yoga mostly for its physical benefits and for stress reduction.
Guided imagery	Use of the mind to generate images that have a calming effect on the body. Involves use of vision, sound, smell, and taste, as well as movement, position, and the sense of touch. Outcomes may include reduction of anxiety, relaxation, enhanced immunity, and changes in hormonal responses.
Hypnotherapy	Attainment of a state of attentive, focused concentration with suspension of some peripheral awareness. May be effective in promoting healing, decreasing pain, managing chronic illness, and preparing for surgery and other procedures (Fontaine, 2011).
Music therapy	Listening to music and creating music. Type of music used is individually determined. Outcomes may include relaxation, decreased anxiety, and decreased pain.
Art therapy	Creative expression through a variety of artistic mediums. May be used to facilitate expression of emotions, memories, and conscious and unconscious concerns. Outcomes may include decreased stress, as well as facilitation of healing from past distress or trauma.
Chiropractic therapy	Therapy that restores and maintains health by proper aligning the spine through a variety of adjustment and manipulation techniques. Correct spinal alignment facilitates self-healing and improves health and well-being.
Pressure point therapy	Application of finger and hand pressure to specific areas of the body (acupressure points defined by charts of energy meridians) to improve energy flow, relieve pain, and stimulate the body's innate healing abilities.
Massage therapy	Manipulation of soft tissues to improve health and promote healing. Outcomes include relaxation, reduced tension, improved immune function, increased flexibility, and pain relief.
Hand-mediated biofield energies	Therapeutic touch involves the use of the practitioner's hands to assess and balance the patient's energy field. Healing intent is incorporated. This technique is based on the belief that healing is facilitated when the human energy field is in balance.
Reiki	A Japanese therapy that involves use of the hands to affect the human energy field, with the intent to heal.

TABLE 12-3

NATURAL PRODUCTS

Examples	Description
Herbal therapy	Use of unrefined plant-based products to treat, prevent, or cure disease. Effects are slow and less dramatic than effects of pharmaceutical drugs.
Nutraceuticals	Vitamin and mineral supplements. The best source of vitamins and minerals is a well-balanced diet. Nonetheless, many Canadians take supplements regularly.
Nutritional therapy	Special diets for health promotion. Such diets must be studied for potential benefit.
Aromatherapy	Use of plants' essential oils for their beneficial effect. Canadians seek out this therapy primarily for stress reduction and use these oils via inhalation or topical application. In some other cultures, essential oils are used more comprehensively in health care.
Probiotic therapy	Use of live microorganisms that are similar to those found in the human digestive tract and that aid digestion.

TABLE 12-4

OTHER COMPLEMENTARY AND ALTERNATIVE MEDICINE PRACTICES

Examples	Description
Manipulation of energy fields: bio-electromagnetics	Magnet therapy based on the principle that every animal, plant, and mineral has an electromagnetic field that allows other objects to interact with it as part of one unified energy system (Fontaine, 2011); magnets are frequently used to reduce pain, relieve swelling and inflammation, and promote healing of soft tissue and bone.
Neurofeedback (neurotherapy and EEG biofeedback)	A noninvasive drug-free technique whereby electrodes are placed on the scalp to monitory brain activity. Inappropriate waveforms are decreased and appropriate waveforms are increased through positive computer-generated visual or auditory reinforcement (Cortese, Ferrin, Brandeis, et al., 2016). This treatment is used for such conditions as epilepsy, stroke, depression, fibromyalgia, PTSD, and ADHD.
Homeopathy	Therapy based on the adage "like cures like." Remedies are specially prepared from the same substance that causes the symptom or problem. Extremely small amounts of the substance are used for the remedy. The remedies are generally safe and free from interactions with other medications. Remedies are believed to work through an energy transfer.
Naturopathy	Therapy based on promotion of health rather than on symptom management. Focus is on enhancing the body's natural healing response through a variety of individualized interventions such as nutrition, herbology, homeopathy, physical therapies, and counselling. Naturopathic physicians are graduates of accredited naturopathic medical schools, and licensing varies by province or territory.
Whole Medical Systems	
Ayurvedic medicine	A practice based on the balance of mind, body, and spirit and developed in India. Disease is viewed as an imbalance between a person's life force (*prana*) and basic metabolic condition (*dosha*). Interventions include breathing exercises, nutrition, detoxification, herbs, meditation, and yoga.
Traditional Chinese medicine (TCM)	One of the world's oldest, most holistic medical systems. Based on restoring and maintaining the balance of vital energy (*qi*). Interventions include acupressure, acupuncture, Chinese herbology, cupping, moxibustion, nutrition, meditation, tai chi, and qigong.
Spiritual Therapies	
Indigenous health care	Practices based on a domain wherein all things have a "spirit." Community is valued and plays a role in the healing process. Gratitude to and harmony with nature are central themes. Medicine men and women use herbs and natural medicines, spiritual rituals, and ceremonies. It is imperative that nurses recognize the importance of incorporating Indigenous healing traditions in the care of Indigenous patients (Beaulieu, 2012; Phillips, 2010).
Prayer	Communication with a deity or the sacred. Found in all cultures. A frequently used therapy. Nurses may incorporate prayer into their practice.

ADHD, attention-deficit/hyperactivity disorder; *EEG,* electroencephalogram; *PTSD,* post-traumatic stress disorder.

Alternative Medical Systems

Alternative medical systems are complete methods of health-related theory and practice that were developed outside of the Western biomedical model, often in other cultures. For some countries, these are their traditional systems. Traditional Chinese medicine is one of the subcategories that NCCIH has identified.

Traditional Chinese Medicine

Traditional Chinese medicine (TCM) is one of the world's oldest and most comprehensive medical systems. It has evolved over several thousand years of cultural and philosophical developments, as well as extensive clinical observation and testing. Several major concepts constitute Chinese medicine. The principle of *yin and yang* is a core tenet of Chinese art, philosophy, and science, as well as TCM. Various states are associated with yin energies (feminine energy—cold, heavy, moist, negative) and yang energies (masculine energy—hot, dry, light, positive). Yin and yang are viewed as dynamic, interacting, and interdependent energies, neither of which can exist without the other, each containing some part of the other within it (Figure 12-1). These energies are a part of everything in nature and must be maintained in a harmonious state of balance to achieve optimal health. Imbalance is associated with illness. TCM modalities are used to restore balance between yin and yang energies.

FIGURE 12-1 Symbol of yin and yang. The circle representing the whole is divided into yin (black) and yang (white). The small circles of opposite colour within those regions illustrate that within the yin, there is yang, and within the yang, there is yin. The dynamic curve dividing them indicates that yin and yang are continuously shifting in balance. Thus yin and yang create each other, control each other, and transform into each other.

Strengths of TCM include its individualized system of diagnosis and treatment, as well as its focus on prevention. Assessment tools include a comprehensive health history, tongue examination, and pulse examination. TCM includes an array of modalities, the most common of which are acupuncture and Chinese herbal medicine. These modalities are used together to replenish and smooth the flow of qi (pronounced “chee”) throughout the body. When yin and yang are in balance, qi, or the fundamental life force, flows evenly through the body, leading to good health. Qi is a form of energy found in all life; when it is disrupted, illness and pain can occur. Other TCM interventions include acupressure, moxibustion, cupping, Chinese massage, meditative physical exercise (e.g., tai chi and qigong), and nutrition counselling. Tai chi and qigong are slow-movement exercises that focus on breathing.

Acupuncture.

Acupuncture is the primary treatment modality used by TCM practitioners. In 1983, the Chinese Medicine and Acupuncture Association of Canada was federally incorporated in order to unite practitioners of TCM and acupuncture in Canada. In **acupuncture**, fine needles are inserted into the circulation of qi underneath the skin's surface. The insertion points depend on the diagnosis and the nature of the complaint. With proper point selection and manipulation, acupuncture corrects disruptions in the flow of qi.

Clinical studies have indicated that acupuncture is effective in reducing pain, fighting inflammation, accelerating wound healing, and promoting nerve regeneration (Crane, Ogborn, Cupido, et al., 2012; Fontaine, 2014; Swanson, Keithley, Johnson, et al., 2015; Vickers, Cronin, Maschino, et al., 2012). Table 12-5 has a more complete listing of the uses of acupuncture. Acupuncture is considered a safe therapy when the practitioner has been appropriately trained and uses disposable needles. Patients should review the credentials of their practitioners.

TABLE 12-5

CONDITIONS FOR WHICH ACUPUNCTURE MAY BE BENEFICIAL

Pain Management • Low back pain • Headache pain • Osteoarthritis • Cervical neck pain • Musculo-skeletal and myofascial pain • Fibromyalgia **Surgical Analgesia** • Procedural analgesia • Postoperative pain • Postoperative nausea and vomiting **Chemotherapy-Induced Nausea**	**Gynecological and Obstetric Conditions** • Induction of labour • Infertility • Menopausal symptoms • Dysmenorrhea
Neurological Disorders • Acute stroke • Stroke rehabilitation	**Asthma** **Gastro-Intestinal Conditions** • Irritable bowel syndrome • Chronic constipation
	Substance Abuse • Smoking cessation • Opioid dependence

Acupressure.

Acupressure is a natural, hands-on healing therapy based on the same principles as acupuncture. Finger pressure is applied along the body's energy meridians. Acupressure works by accessing and releasing blocked or congested energy in the body. Acupressure can be used for many conditions, including postoperative nausea, chemotherapy-induced nausea, and headaches. Jin Shin Do and reflexology are other forms of pressure-point therapies that stimulate certain areas within the body to help balance the body's energies (Fontaine, 2014).

Mind–Body Medicines

Mind–body interventions include a variety of techniques designed to facilitate the mind's capacity to affect bodily function. These include behavioural, psychological, social, and spiritual approaches to health. Specific examples of therapies and approaches are included in Table 12-2. Within this category, the methods NCCIH considers “mainstream” include behavioural approaches such as psychotherapy, certain uses of hypnosis, biofeedback, patient education, and support groups. Nurses frequently use many of these bio-behavioural approaches.

Natural Products

Biologically based therapies include herbal therapies (phytotherapy), special diet therapies, and ortho-molecular medicine (see Table 12-3).

Herbal Therapies

Herbal therapy is the use of individual herbs or combinations of herbs for therapeutic benefit. An herb is a plant or plant part (bark, roots, leaves, seeds, flowers, or fruit) that produces and contains chemical substances that act on the body. It is estimated that approximately 25 000 plant species are used medicinally throughout the world, and approximately 30% of modern prescription drugs are derived from plants. Botanical medicine is the oldest known form of medicine; archaeological evidence suggests that Neanderthals used plant-based remedies 60 000 years ago. Today, about 80% of the world's population relies extensively on plant-derived remedies (Fontaine, 2011).

Since the early 1980s, interest in herbal therapies has increased in countries whose health care practices are dominated by the biomedical model. Interest in herbal products is related to several factors, including the high cost of and the potential for severe adverse effects associated with pharmaceutical drugs. Herbal remedies are considered “natural” and therefore may be viewed as safer and more appealing. Since they are directly available to consumers, individuals can assume more autonomy with regard to their health care.

More than 73% of Canadians now consume natural health products in the form of traditional herbal products, vitamins and mineral supplements, and homeopathic preparations. To ensure that these products are safe, Health Canada established the Office of Natural Health Products in 2008. In January 2004, the Natural Health Products Regulations were implemented to ensure the safety of over-the-counter (OTC) products. In contrast, in the United States, herbal products used for medicinal value are classified as dietary supplements. As such, they lie outside the jurisdiction of many of the safety and regulatory rules covering foods and drugs.

Clinical Applications of Herbal Therapy.

Medicinal plants work in much the same way as drugs; both are absorbed and trigger biological effects that can be therapeutic. Many have more than one physiological effect and thus can be used for more than one condition. A number of herbs have been determined to be safe and effective for a variety of conditions. Boxes with descriptions of herbs related to specific diseases are found throughout this book (see the accompanying "Complementary & Alternative Therapies" box).

Complementary & Alternative Therapies

Information related to the following complementary and alternative therapies can be found throughout this text.

- Acupuncture
- Bilberry
- Biofeedback
- Echinacea
- Garlic
- Ginger
- Ginkgo biloba
- Ginseng
- Glucosamine
- Goldenseal
- Guided imagery
- Herbs and supplements that affect blood clotting
- Herbs and supplements that affect blood glucose levels
- Herbs and supplements used for menopause
- Herbs for surgical patients
- Herbs that affect healing
- Lipid-lowering agents
- Milk thistle
- Music therapy
- Saw palmetto
- Valerian
- Zinc

Although most herbal therapies can safely be used without professional assistance, adverse effects and interactions with prescription drugs can and do occur. Adverse effects resulting from the use of herbal remedies may be under-reported, which thus promotes the impression that herbal remedies are completely safe to use. Because consumers tend not to discuss their use of herbal therapies with their primary health care provider, herb–drug interactions may also be under-reported. For safety, patients who are scheduled for surgery should be advised to stop taking herbal remedies 2 to 3 weeks before surgery. Patients who are being treated with conventional drug therapy should be advised to discontinue herbal remedies that produce similar pharmacological effects because the combination may lead to an excessive reaction or to unknown interaction effects. General patient teaching guidelines related to herbal therapy use are presented in Table 12-6.

TABLE 12-6

PATIENT & CAREGIVER TEACHING GUIDE
Herbal Therapies

When teaching patients and caregivers about herbal therapies the nurse should:

- Ask the patient about use of herbal therapies. Document a complete history of herbal use, including amounts, brand names, and frequency of use. Ask the patient about allergies.
- Investigate whether herbs are used instead of or in addition to traditional medical treatments. Find out whether herbal therapies are used to prevent disease or to treat an existing problem.
- Instruct the patient to inform health care providers of any intention to take herbal treatments before doing so.
- Make the patient aware of the risks and benefits associated with herbal use, including reactions when herbs are taken in combination with other drugs.
- Advise the patient using herbal therapies to be aware of any adverse effects while taking herbal treatments and to immediately report them to the health care provider.
- Make the patient aware that moisture, sunlight, and heat may alter the components of herbal products.
- Inform the patient of the need to be aware of the reputation of the manufacturers of herbal products and the safety of the product before buying herbal treatments.
- Encourage the patient to read labels of herbal therapies carefully. Advise the patient not to take more of an herb than is directed.
- Inform the patient that most herbal therapies should be discontinued at least 2 to 3 weeks before surgery.
- Inform the patient that the employees of health food stores may not have any educational background in the actions, interactions, and efficacies of the herbal therapies sold in the store they are working in. It is the responsibility of the patient to ensure that the information received comes from someone who has the appropriate background and education to be providing that information.

Patients who take herbal therapies should be advised to adhere to the suggested dosage. If taken in high doses, herbal preparations can be toxic. The potency of a particular herbal remedy can vary widely because of factors such as where and how it was grown, how it was harvested, and how it was processed. Herbal medicines should be purchased only from reputable manufacturers. Health Canada (2015) advises Canadians to use only herbal products that have been approved for sale under the Natural Health Products Regulations. If the product has been assessed, it will have a drug identification number (DIN) or natural products number (NPN) on its label. This certifies that the product has passed a review of formulation, labelling, and instructions for use. Because of the potential for adverse effects, pregnant women, nursing mothers, and older adults with liver or cardiovascular disease should use caution in consuming herbal products. Commonly used herbs are listed in Table 12-7, and some are pictured in Figure 12-2. Commonly used dietary supplements are found in Table 12-8.

TABLE 12-7
COMMONLY USED HERBS*

Name	Uses Informed by Scientific Evidence	Comments
Aloe	Treat constipation	• Should be used no longer than 7 days for constipation • May cause electrolyte imbalances • May lower blood glucose level
Black cohosh	Decrease menopausal symptoms	• Generally safe when used for up to 6 months by healthy, nonpregnant women • May lower blood pressure
Echinacea	Treat upper respiratory tract infections	• Should be used with caution by patients with conditions affecting the immune system • May lead to liver inflammation • Only short-term use is recommended
Evening primrose	Treat eczema, skin irritation	• Contraindicated in individuals with seizure disorders
Feverfew	Prevent migraine headaches	• May increase risk of bleeding • Stopping long-term use may lead to withdrawal symptoms
Garlic	May decrease cholesterol and low-density lipoproteins (studies have been inconsistent)	• May increase risk of bleeding • May lower blood glucose level
Ginger	Ease nausea and vomiting during pregnancy	• May increase risk of bleeding • Should not exceed 1 g/day during pregnancy • Supervision by health care provider is recommended for pregnant women considering use of ginger
Ginkgo biloba	Treat symptoms of claudication	• Generally well tolerated in recommended dosages for up to 6 months • May increase risk of stroke • May increase risk of bleeding • May affect blood glucose levels
Ginseng (*Panax* species, including Asian and American ginseng)	May improve mental performance May enhance immune system May lower blood glucose level in type 2 diabetes mellitus	• May increase or decrease blood pressure • May increase risk of bleeding • May lower blood glucose levels • May reduce effectiveness of warfarin • Should be avoided by patients with hormone-sensitive conditions, such as breast cancer
Hawthorn	Treat mild to moderate heart failure	• May add to the effects of cardiac glycosides, antihypertensives, and cholesterol-lowering drugs
Kava	Treat anxiety	• Should be used only under the supervision of a health care provider • Should be avoided by patients with liver problems and by patients taking medications that affect the liver • May increase drowsiness • Should be used with caution with herbs or supplements that are metabolized by the kidneys
Milk thistle	Treat hepatitis caused by viruses or alcohol; treat cirrhosis	• May lower blood glucose levels • May interfere with the liver's cytochrome P450 enzyme system

Name	Uses Informed by Scientific Evidence	Comments
St. John's wort	Treat mild to moderate depression for a short term (studies on benefits of use are contradictory)	• Well tolerated in recommended dosages for 1–3 months • May lead to serious interactions with herbs, supplements, OTC drugs, or prescription drugs • Interferes with metabolism of drugs that use cytochrome P450 enzyme system • May lead to increased adverse effects when taken with other antidepressants • Advise patients to consult a health care provider before self-medicating with St. John's wort
Zinc	Treat upper respiratory tract infections	• Relatively safe • Should not be taken with dairy products or caffeine, which will reduce its absorption

*Advise patients who are pregnant or lactating to consult a health care provider before they use any herbs. Scientific evidence for the use of most herbs during pregnancy or lactation is limited.

OTC, over-the-counter.

TABLE 12-8
COMMONLY USED DIETARY SUPPLEMENTS*

Name	Uses Informed by Scientific Evidence	Comments
Chondroitin sulfate	Treat osteoarthritis	• Should be used with caution in patients who have bleeding disorders or are taking anticoagulants • Avoid in patients who are at risk for or diagnosed with prostate cancer
Coenzyme Q_{10}	Treat hypertension	• May decrease blood glucose levels
Fish oil/omega-3 fatty acids	Treat hypertension or hypertriglyceridemia Prevent cardiovascular disease	• May increase risk of bleeding • May increase blood glucose levels in patients with diabetes • May increase low-density lipoprotein (LDL) level
Glucosamine	Treat osteoarthritis	• May decrease effectiveness of insulin or other drugs used to control blood glucose levels • May increase risk of bleeding
Melatonin	Treat jet lag Decrease sleep latency (time to fall asleep)	• May increase risk of bleeding • Should be used with caution in patients who have bleeding disorders or are taking anticoagulants • May decrease blood pressure • Should be used with caution in patients with diabetes or hypoglycemia • Should be used with caution by patients with seizure disorder
Probiotics (live bacteria or yeast)	Re-establish gut flora, especially after prolonged antibiotic therapy	• Should be used with caution in patients with compromised immune system or gastro-intestinal disorders

*Advise patients who are pregnant or lactating to consult a health care provider before they use any supplements. Scientific evidence for use during pregnancy or lactation is limited.

Manipulative and Body-Based Practices

Manipulative and body-based practices include interventions and approaches to health care that are based on manipulation or movement of the body. Examples include chiropractic therapy, pressure-point therapies, massage, and hand-mediated biofield therapies. Massage therapy is one of the body-based practices nurses commonly use.

Massage Therapy

Massage therapy includes a range of techniques that the practitioner uses to manipulate the soft tissues and joints of the body. Involving touch and movement, massage is typically delivered with the hands, although elbows, forearms, or feet may be used. Massage techniques are used in body work, sports training, physiotherapy, nursing, chiropractic therapy, osteopathy, and naturopathy. Benefits of massage include effects on the musculo-skeletal, circulatory, lymphatic, and nervous systems. Massage also positively affects mental and emotional states. Massage therapy continues to grow in popularity; most people who use massage therapy do so as a means of reducing stress.

Clinical Applications of Massage Therapy.

Until the 1970s, nurses were taught to perform "P.M. care," which consisted of a back rub and other measures to promote relaxation and sleep. After that time, P.M. care and back rubs became the exception rather than the rule. Yet today, with the increased focus on providing holistic care, nurses are again recognizing the benefits of massage. Massage promotes health and wellness and has been shown to improve quality of life (Hymel & Rich, 2014; Toth, Marcantonio, Davis, et al., 2013). The role of the nurse in massage differs from that of the registered massage therapist. Whereas massage therapists can provide more comprehensive massage therapies, nurses can use specific massage techniques as part of nursing care when indicated by findings in patient assessment. For example, a back massage can be used to help promote sleep. For a bedridden patient, gentle massage can stimulate circulation. When a nurse determines that massage may be indicated in meeting a patient goal, the nurse must first assess the patient's preference regarding touch and massage. The nurse should consider cultural and social beliefs and discuss

potential benefits with the patient. The indicated plan of care (e.g., hand massage, back massage) can then be implemented, and reassessment can be performed after the massage.

Massage Techniques.

Nursing use of massage typically begins with *effleurage,* or gliding strokes, to promote relaxation. Stroking is done from distal to proximal, along the long axis of the muscle (Figure 12-3, A). After relaxing the muscles with *effleurage, pétrissage,* or a kneading stroke, may be used to gently lift and knead the muscle (see Figure 12-3, B). Gently scented lotions or diluted essential oils may be included in the massage. Forms of massage are often used for pregnant women. Essential oils should not be used for massage on a pregnant patient because they can be harmful to the fetus (Fontaine, 2014).

FIGURE 12-3 Massage. **A,** Using *effleurage* to relax the back. **B,** Using *pétrissage* to relax arm muscles. Source: Lori Karhu, RMT, RN, San Antonio, TX.

A simple hand massage (Figure 12-4) can be used for a calming and relaxing effect, especially for patients who are anxious or agitated. When a patient is frustrated or agitated, a hand massage can act as a distraction and return the person to a calm state.

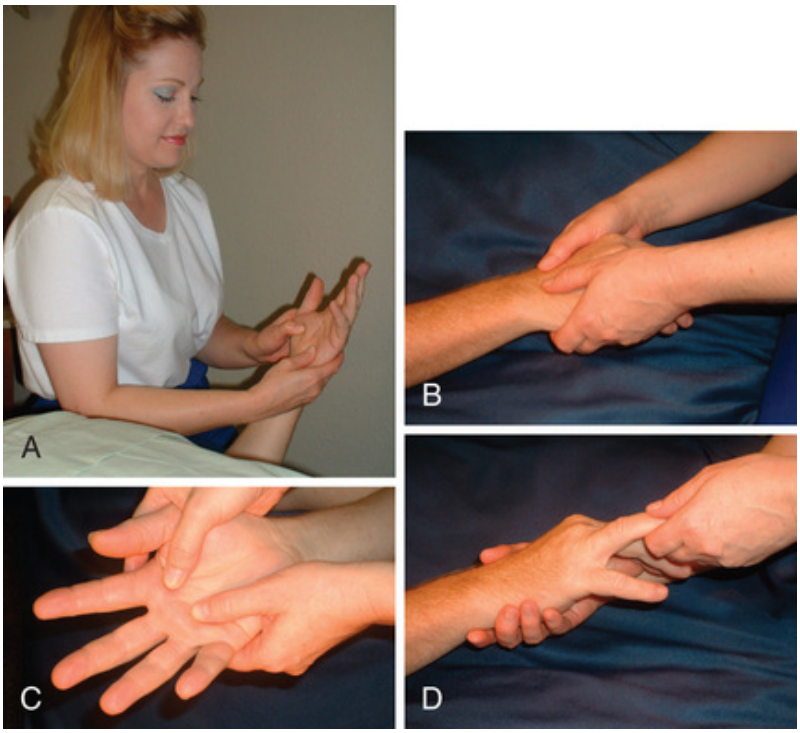

FIGURE 12-4 **A,** Hand massage. **B,** Technique of hand massage: Bend the wrist backward and forward to relax the wrist, then massage the wrist and top of the hand, using circular movements. **C,** Massage the palm of the hand with the cushions of the thumbs, using circular movements. **D,** Massage each finger from the base to the tip. Source: Lori Karhu, RMT, RN, San Antonio, TX.

Family members can be taught to perform massage on their loved one, providing a way for family members to participate in patient care. This can be therapeutic for both the patient and the family, even when the loved one is mentally ill or unresponsive. Massage is beneficial during all aspects of the life continuum. During the end-of-life process, hospice nurses may incorporate massage into their nursing care, inasmuch as the massaging touch can lessen pain and restlessness. Massage is contraindicated in patients who have had recent injuries, trauma, or, surgery and in patients with open wounds, deep venous thrombosis, inflammation or infections, bleeding, edema, or decreased sensation.

Hand-Mediated Biofield Energies

Energy therapies are those that involve the manipulation of energy fields. They focus on energy fields originating within the body (biofields, or human energy fields) (Gerard, 2012) or those from other sources (electromagnetic fields). Examples of biofield therapies include therapeutic

touch, healing touch, and Reiki. Biofield healing therapies (see Table 12-2) are based on the theory that energy systems in the body need to be balanced and repatterned to enhance healing. Some forms of energy therapy manipulate biofields by applying pressure or manipulating the body by placing the hands in, or through, these fields.

Therapeutic Touch.

Therapeutic touch is a method of detecting, balancing, and repatterning the human energy field. It is a contemporary interpretation of several ancient healing practices. It involves the conscious use of the hands to direct or modulate human energy fields. Therapeutic touch was developed in the 1970s by a nurse, Dolores Krieger, and a traditional healer, Doris Kunz. According to Krieger (1997), therapeutic touch is based on the assumptions that a human being is an open energy system, a balanced flow of energy underlies good health, and illness is a reflection of an imbalance in an individual's energy field.

Clinical Applications of Therapeutic Touch.

During the actual treatment, nurses use their hands to assess the patient's energy field. Hands are positioned 5 to 15 cm from the body. The energy field is assessed for bilateral similarities or differences in the flow of energy. The next step is clearing and balancing the energy field. Nurses then work with the energy field of the patient, involving the intentionality (the conscious effort to bring about healing or to be healed) of the patient and the intentionality of the nurse. The session ends with a smoothing of the energy. Therapeutic touch is not a diagnostic tool but is used as a form of treatment in conjunction with a biomedical treatment plan.

Research has been conducted on the effectiveness of therapeutic touch for a wide range of conditions, including wound healing; sleep promotion; enhancement of immune function; and the reduction of anxiety, agitation, postoperative pain, tension headache, and stress. The research findings have been inconclusive, which indicates the need for further research. Specialized instruction is needed to perform therapeutic touch. Some individuals are able to “feel” the energy field more readily than others. However, with patience, determination, and a desire to help others, anyone (including family members) can learn to use therapeutic touch.

Healing Touch.

Healing touch is a nurse-based program founded in the 1980s by a nurse, Janet Mentgen. It is a biofield therapy that encompasses a group of noninvasive techniques that use the hands to clear, energize, and balance the human and environmental energy fields. The nurse gently places his or her hands on or near the patient's clothed body. In accordance with established guidelines, the nurse assesses the patient's energy field, realigns energy flow, eliminates energy blockages, reactivates the mind–body–spirit connection, and then evaluates the process (Healing Beyond Borders, 2015; Healing Touch Canada, 2016). It is an organized system designed to assist the patient to self-heal.

Clinical Applications of Healing Touch.

Research on energy therapies is in the early stages. However, research does indicate that healing touch may be effective in reducing blood pressure, improving mood, reducing stress and anxiety, and reducing pain (Thomas, Stephenson, Swanson, et al., 2013). Education for healing touch is a multilevel program leading to certification. Information on classes, resources, and practice is available at the Healing Beyond Borders website (see the Resources at the end of this chapter).

Other Complementary and Alternative Medicine Practices

Spiritual Therapies

Prayer.

Prayer (described in Table 12-4) is one of the mind–body interventions used most commonly by all cultures, and yet it is difficult to define. Viewed globally, prayer can be described as connecting with the sacred. An ancient healing practice, prayer has been acknowledged in health care literature. Terms such as *distant healing*, *mental healing,* and *spiritual healing* are used as researchers attempt to study the outcomes of prayer. The term *theosomatic medicine* has been developed to describe the study of health as related to an apparent connection between a deity and the human body. In exploring this connection, religious involvement has been found to be generally associated with lower levels of illness and higher levels of wellness. Prayer has been linked to the prevention of illness and to healing from disease (Fontaine, 2011).

Forms of Prayer.

Forms of prayer include meditative prayer, ritualistic prayer, colloquial prayer, and intercessory (or petitionary) prayer. Meditative prayer involves openness to the divine and does not require words or thoughts. Ritualistic prayer involves repeated words and phrases and is commonly associated with formal liturgy. Colloquial prayer involves spontaneous thought and conversation with the divine. Intercessory prayer involves making a request for specific needs to be met (Fontaine, 2011).

Clinical Applications of Prayer.

Nurses are committed to spiritual care as part of their holistic practice. Spiritual assessments can guide nurses in identifying patients' needs. Different formats or tools for assessment may be used.

Nurses need cross-cultural knowledge about prayer practices, awareness of patients' spiritual needs, and engagement in rigorous research that examines the effects of prayer. Nursing literature indicates that prayer is an intervention valued by many patients (Fontaine, 2011). Patients may request intercessory prayer: that is, for someone to pray with them or for them. Self-reflection is important in this situation. Knowing their own beliefs and values, nurses can decide to meet the patient's

request directly. However, many nurses feel uncomfortable praying with their patients. Barriers to praying with patients include lack of time, personal discomfort, lack of experience, and lack of private space (Fontaine, 2011). If, for whatever reason, the nurse feels uncomfortable or is unable to address the patient's request directly, the nurse may consult with a spiritual director or religious leader. In most hospitals, chaplains of various faiths and denominations are available to meet with patients. Because many patients find prayer comforting, especially during times of illness, nurses must ensure that spiritual needs are met.

Nurses also report using prayer in more personal ways (Fontaine, 2011; Helming, 2011). Many nurses who are hesitant to pray with their patients say that they do pray for their patients. Some also describe using prayer before their shift or as they start their day, seeking inner guidance for effective nursing care. Nurses may use prayer for emotional support, motivation, spiritual awareness, or enhanced professional performance.

Age-Related Considerations

Complementary and Alternative Therapies

Older adults with non–life-threatening, chronic conditions are most likely to use complementary and alternative therapies. For older adults, safety concerns involve herb–drug interactions or toxicity from polypharmacy and age-related changes in pharmacokinetics (Touhy, Jett, Boscart et al., 2012). Decreased renal and liver function may slow metabolism and excretion of herbs and dietary supplements. Because older patients are a more vulnerable population, the nurse must discuss the risks and benefits of using herbal products and also encourage patients to inform their health care provider of any herbal product or dietary supplement that they are taking.

Nursing Management Complementary and Alternative Therapies

The role of the nurse with regard to complementary and alternative therapies is evolving. Roles of the nurse may include (a) assessing patients' use of complementary and alternative therapies and their risk for complications or adverse interactions with conventional therapies; (b) serving as a resource about complementary or alternative therapies, including teaching patients about these options, providing information about evidence concerning effectiveness, and making referrals to qualified practitioners; (c) serving as a provider of therapies for which the nurse obtains training and certification, such as therapeutic touch or acupuncture; and (d) conducting research about complementary and alternative approaches. The nurse must be able to perform these roles nonjudgementally. If patients believe they are being judged because of their use of complementary or alternative therapies, they will stop communicating and will withhold this information from their health care providers.

A resource for nurses and patients in Canada with regard to complementary and alternative therapies and practitioners is the Natural Health Practitioners of Canada (NHPC). "The NHPC is committed to promoting and improving the health of Canadians through information about holistic treatments" (NHPC, 2016).

Assessment

Collection of data on patients' use of complementary and alternative therapies is part of a thorough nursing assessment. It is especially important because most patients do not voluntarily tell their health care provider about their use of these therapies. However, they usually share this information with a nurse when asked. Nurses must ask general open-ended questions, while remaining nonjudgemental and respectful of the patient's response.

Examples of assessment questions to ask include the following:

1. What are you doing to maintain or improve your health and well-being?

2. How involved are you in planning and carrying out your health-related care?
3. What is your view of the ideal relationship between yourself and your primary health care provider?
4. Do you have any conditions that have not responded to conventional medicine? If so, have you tried any other approaches?
5. Are you using any vitamin, mineral, dietary, or herbal supplements or energy-based therapies?
6. Are you interested in obtaining information about alternative or complementary approaches?

Along with assessing use, the nurse needs to document the effectiveness of interventions that the patient uses.

Serving as a Resource and Promoting Safety

According to the Canadian Nurses Association's Code of Ethics, nurses must respect and promote people's autonomy and help them both express their health needs and obtain desired information in order to make informed decisions (CNA, 2017). A wide variety of therapies fall within the category of complementary and alternative therapies, and some of these therapies may be ineffective or even harmful. However, patients self-select these therapies, generally without consulting a health care provider. Safety concerns encompass the reliability of information, the safety and effectiveness of therapies, and the regulation of practitioners. Patients most commonly get their information about such therapies from health food stores, word of mouth, books, magazines, and the Internet. Patients need to be encouraged to seek professional assistance with these decisions. If a patient questions the nurse on how to find a registered practitioner of natural health practices in Canada, the nurse can refer the patient to the NHPC's website (see the Resources at the end of this chapter). This organization maintains a directory of registered natural health practitioners in Canada. Serving as a patient advocate, the nurse provides information on both conventional therapies and complementary and alternative therapies. Patients should be advised that complementary therapies do not replace conventional therapies but can often be used in combination with conventional therapies. By providing information for the patient, the nurse fosters informed decision making.

To serve as a resource for patients, nurses must first develop their own knowledge base. Even if specific information about complementary and

alternative therapies is not provided in basic nursing programs, nurses are educated to be critical thinkers and problem solvers. Thus nurses are prepared to seek ongoing education regarding complementary and alternative therapies and to continue to read and critique research on these therapies.

As ethical practitioners, nurses need to be aware of their biases and judgements with regard to complementary and alternative therapies. Biased and judgemental attitudes do not allow the nurse to provide the best care possible for the patient.

Providing Holistic Self-Care and Holistic Nursing Practice

Some individuals choose to become nurses because they want to care for others—to be a caregiver for their patients. This is a compelling reason to choose nursing. Yet many nurses fail to recognize that "caring for others" can occur only when their values and practices include "care for self" (Fontaine, 2011). Self-care (caring for one's own general level of health and well-being) is essential on both a personal and professional level. On a personal level, self-care involves commitment to maintaining one's own level of wellness. Keeping one's mind, body, and spirit healthy is required so that one has the strength to care for others. On a professional level, self-care is important because nurses are role models. They are role models for family, friends, patients, other health care providers, and the community. By demonstrating self-care practices, nurses motivate other people to achieve greater health and wellness.

Learning about complementary and alternative therapies can be one pathway to self-care. Initially, nurses are eager to learn about complementary and alternative therapies so that they can provide better patient care and be holistic in their approach. However, nurses often find that these therapies can also be used personally to enhance their own level of health and wellness. Because many different therapies are included as part of complementary and alternative therapies, each individual nurse should be able to find ways to promote personal well-being. Examples of therapies commonly used by nurses for personal well-being include relaxation breathing, meditation, prayer, yoga, massage, and music.

Professional nursing, from the outset, included care of the whole person, which is the concept of mind–body–spirit. However, the Western biomedical model, with its focus on the physical body, transformed nursing practice into a more "medical" model. The relatively recent

increase in the use of complementary and alternative therapies provides an opportunity for nursing to return to its origin and a focus on holistic nursing practice. **Holistic nursing** incorporates mind–body–spirit principles into the development of a caring–healing relationship with patients. Core concepts of holistic nursing include the following: (a) the nurse accepts patients as they are, without judgement and with compassion; (b) the nurse's care is based on holism and integrates mind–body–spirit principles; (c) the nurse serves as a facilitator, recognizing the patient's capacity for self-healing; (d) the nurse incorporates self-care and self-responsibility, recognizing the greater interconnectedness of all individuals; and (e) the nurse's practice is guided by holistic education and research (Dossey & Keegan, 2013).

Nursing interventions include therapeutic listening and empathy. The nurse also promotes a therapeutic environment and honours cultural diversity. The holistic nurse may also choose to integrate complementary and alternative therapies as part of nursing practice, recognizing the value of both conventional and complementary and alternative therapies.

Serving as a Provider

Nursing has a long history of providing therapies that have been considered complementary and alternative. These include massage, relaxation therapy, music therapy, and therapeutic touch, as well as other strategies to promote comfort, reduce stress, improve coping, and promote symptom relief. The practice of nursing is defined in legislation throughout Canada and commonly includes promoting, maintaining, and restoring health and assessing and providing care through supportive, preventive, therapeutic, rehabilitative, and palliative means. Nurses also support a holistic approach that supports and values patient choice while promoting health and well-being (CNA, 2015; CNO, 2014b; College & Association of Registered Nurses of Alberta, 2011). The requirements for use of a specific complementary or alternative therapy are not different from those for other nursing interventions. The nurse should have specific training in the use of the therapy and should be aware of the evidence base that addresses the conditions for which the therapy is indicated, the effectiveness of the therapy, and the potential for adverse outcomes or synergistic effects. Nurses are responsible for ensuring that the patient has given consent for a given therapy. The patient must be aware of the proposed benefit and any potential risks involved. The nurse must

document the effectiveness of the interventions. A mechanism must be in place to evaluate the care outcomes.

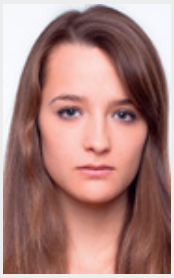
Participating in Research

Nurses are responsible for critiquing and applying relevant research findings to their practice, as well as participating in the identification of researchable problems. Applying research evidence on complementary and alternative therapies into practice is one strategy for developing evidence-informed approaches. Participating on teams whose focus is to develop evidence-informed protocols that address appropriate use of complementary and alternative therapies is another effective approach. Practising with a questioning mind can facilitate identification of research questions that can be investigated with research-trained health care providers. Types of research considerations that can be addressed through questions include describing the extent of patients' use of specific therapies, exploring patients' experiences of using various complementary and alternative therapies, and documenting the effectiveness of therapies commonly used by nurses.

Patient interest and participation in complementary and alternative therapies are increasing. Therefore, nurses must be knowledgeable about the multiple therapies available and must develop effective strategies to document the use of these therapies. It is also important for nurses to keep abreast of the current research in this area to provide accurate information to both patients and other health care providers. Nurses are well positioned to become the link between conventional therapy and complementary and alternative therapies.

Case Study

Abdominal Distress



Source: sematadesign/Shutterstock.com

Patient Profile

Jane Craigo, a 21-year-old university student, was seen in the student health centre for increasing episodes of abdominal fullness and discomfort with alternating diarrhea and constipation.

Subjective Data

- Reports that irritable bowel syndrome was diagnosed several years ago
- Was told to eat more fibre, drink at least eight glasses of water per day, consume foods such as peas, prunes, and oatmeal
- States that she has tried to change her diet but due to her limited budget cannot afford fresh fruits and vegetables
- Consumes mainly fast foods, due to her busy schedule
- Drinks six to eight colas per day because she does not like water
- Has not been able to effectively reduce her abdominal distress
- Is taking a heavy course load this semester
- Has to work 20 hours each week for her work–study contract

Discussion Questions

1. Assess what Ms. Craigo is currently doing to help alleviate the symptoms.
2. Explain the psychological stressors that may be contributing to Ms. Craigo's abdominal discomfort.
3. Describe how her current diet may be affecting her, both physiologically and psychologically.
4. What complementary or alternative therapy (or therapies) would be appropriate for Ms. Craigo?

5. How could the nurse recommend complementary therapies to Ms. Craigo's physician? What arguments could support their use?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. Which of the following statements best describes complementary and alternative therapies?
   a. They are used as a primary form of treatment.
   b. They contradict the values of nursing.
   c. They are based on extensive scientific research.
   d. They were developed outside the Western biomedical model.
2. Which of the following clients is most likely to benefit from treatment by a traditional Chinese medicine practitioner?
   a. A client with pneumonia
   b. A client with mental illness
   c. A client with chronic back pain
   d. A postoperative client with low blood pressure
3. Which of the following herbal treatments can cause life-threatening adverse effects when combined with antidepressants?
   a. Ginkgo biloba
   b. St. John's wort
   c. Kava
   d. Valerian
4. Which herbs can increase a client's risk of bleeding? *(Select all that apply)*
   a. Aloe
   b. Kava
   c. Garlic
   d. Ginger
   e. Feverfew
5. Which of the following statements describes holistic nursing? *(Select all that apply)*
   a. Holistic nursing focuses on physical health.
   b. Holistic nursing is practised only by experienced nurses.
   c. Holistic nursing promotes self-care and self-responsibility.

d. Holistic nursing is based on the biomedical model of health care.

e. Holistic nursing incorporates mind–body–spirit principles.

6. In assessing a client's use of complementary and alternative therapies, which of the following actions is a priority to include?

a. Assess the client's compliance with all treatment modalities.

b. Determine the client's knowledge of the therapies that he or she is using.

c. Use the term *alternative therapies* when assessing the client's use of these therapies.

d. Reinforce the benefits of traditional Western medicine.

7. Which of the following best describes the role of the nurse involved with complementary and alternative therapies?

a. Caring for clients rather than caring for self

b. Prescribing the appropriate herbal therapies for a client

c. Serving as a resource to guide clients in the safe use of therapies

d. Advocating for use of complementary and alternative therapies instead of conventional health care

1. d; 2. c; 3. b; 4. c, d, e; 5. c, e; 6. b; 7. c.

CHAPTER 13

Palliative Care at the End of Life

Written by, Linda A.L. Upchurch

Adapted by, Andrea Mowry

LEARNING OBJECTIVES

1. Describe nursing management of common physical manifestations at the end of life.
2. Describe nursing management of common psychosocial manifestations at the end of life.
3. Explain the process of grief and bereavement.
4. Discuss some of the variables that affect end-of-life care.
5. Discuss key ethical and legal issues related to hospice palliative care.
6. Explore the special needs of family caregivers of a dying patient.
7. Discuss the special needs of the nurse who cares for dying patients and their families.

Hospice Palliative Care

The term **hospice** originates from the Latin word *hospes,* a term that referred to either a travelling guest or a traveller's host (Lutz, 2011). In the 1960s, the pioneering work of Dame Cicely Saunders, a nurse, social worker, and physician, revived the hospice tradition; the first modern hospice, St. Christopher's Hospice, established in 1967 in England, provides end-of-life (EOL) services for patients with advanced malignant disease (Canadian Hospice Palliative Care Association [CHPCA], 2016).

The term **palliative** (relief of suffering to improve quality of life) also originates from a Latin word, *palliaire,* which means "to cloak." In 1974, Dr. Balfour Mount, a Canadian physician at the Royal Victoria Hospital in Montreal, first coined the term *palliative care* to refer to treatment with the goal of symptom relief (Lutz, 2011). The World Health Organization (WHO) formally described palliative care as "an approach that improves the quality of life of patients and their families facing the problems associated with a life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial and spiritual" (WHO, 2015). Specific goals of palliative care are listed in Table 13-1.

TABLE 13-1

GOALS OF PALLIATIVE CARE

- Provide relief from symptoms, including pain.
- Regard dying as a normal process.
- Affirm life and neither hasten nor postpone death.
- Support holistic patient care and enhance quality of life.
- Offer support to patients to live as actively as possible until death.
- Offer support to the family during the patient's illness and in their own bereavement.

Source: Reprinted from *Cancer,* WHO, WHO Definition of Palliative Care, Copyright 2018.

In Canada, the term **hospice palliative care**—defined in Chapter 6 as care aimed at improving the quality of life of patients with life-threatening illness and of their families through the relief of pain

and suffering—is used to recognize the convergence of hospice and palliative care into one movement that has the same principles of practice and continues to evolve in an effort to reflect changes in people's experience with illness and dying (CHPCA, 2013a). Advances in medical treatments have helped people live longer, now often many years with illness. The course of an illness and timing of death is becoming harder to predict as more treatments become available to extend life. Hospice palliative care is available to individuals and families throughout the illness experience, including end of life and bereavement, playing an increasingly significant role as the illness progresses. At the beginning of the illness, the primary focus is on therapy to treat or manage the illness and a lesser focus on hospice palliative care that aims to relieve suffering and improve quality of life (Figure 13-1). Over the course of an illness, the blend of therapies will vary, depending on the patient's and family's issues, their goals of care, and treatment priorities (CHPCA, 2013a; Figure 13-2).

FIGURE 13-1 One goal of end-of-life care is to improve the quality of the patient's remaining life. Source: JG Photography/Alamy Stock Photo.

Integrated Hospice Palliative Care Approach

The *Canada Health Act* (1984) is the overarching legislation covering Canada's national medicare program (Library of Parliament, 2005). This publicly funded health care system is administered on a provincial or territorial basis. Developing the integrated palliative approach to care is a health priority in Canada (CHPCA, 2013b).

More than 240 000 Canadians die each year, most in advanced age (Statistics Canada, 2011a). The number of Canadians dying each year is expected to increase by 38% to 332 000 by 2030 (Statistics Canada, 2010). Interestingly, the cause of death differs by age group. Among people aged 1 to 44 years, the leading cause of death is accidents, followed by cancer. Among people aged 45 to 64 years, most deaths are attributable to cancer and a smaller proportion to heart disease. People aged 65 and older are most likely to die from cancer or heart disease, followed by stroke, chronic lower respiratory diseases, and Alzheimer's disease (Statistics Canada, 2011a). Hospice palliative care and end-of-life care are best provided as an integral part of health care and should be available in all settings of care, including acute care facilities/hospitals, long-term/continuing care facilities, community care/individual homes, free-standing/residential hospices, and shelters (Quality End of Life Care Coalition of Canada [QELCCC], 2010).

An **integrated palliative approach** to care focuses on meeting a patient's and family's full range of needs—physical, psychosocial, and spiritual—at all stages of illness, not just at the end of life. It is a shared-care model: one that shifts hospice palliative care from being a specialized service to a more generalized integrated service available to people with life-limiting conditions regardless of where they live and receive care (CHPCA, 2013b). The primary care practitioners—physicians, nurses, home care nurses, personal support workers, long-term care staff, and hospital staff—continue to provide care with support of the expert hospice palliative care team. The expert hospice palliative care team takes the lead only when a patient has complex, intensive, or tertiary EOL needs, when normal medical management has not been able to relieve symptoms (CHPCA, 2015).

Because the provision of health care is a provincial or territorial responsibility, hospice palliative care services vary across the country. In an effort to develop a national standard of palliative care, the CHPCA has produced “The Way Forward” as a national vision (CHPCA, 2013b; Table 13-2).

TABLE 13-2

SUCCESS FACTORS FOR AN INTEGRATED PALLIATIVE APPROACH TO CARE

Vision
• Commitment to person-centred care • Focus on building capacity in the community • Focus on changing organizational structure • Senior management support
People
• Dedicated coordinators • Interprofessional teams • Strong role of and more support for family physicians • Support for providers in long-term care facilities • Key roles for nurses • Relationships, partnerships, and networks
Delivery of Care
• Integration of primary, secondary, and tertiary care • Cultural sensitivity • Single access point and case management • Round-the-clock community support and care • Advance care planning
Supportive Tools
• Common frameworks, standards, and assessment tools • Flexible approaches to education • Shared records • Research, evaluation, and quality improvement

End-of-Life Care

End-of-life (EOL) care refers to care given during the last months, weeks, or days of a patient's life. In June 2000, the Senate of Canada issued a report, "Quality End-of Life Care: The Right of Every Canadian" (Carstairs, 2000), which contained recommendations that would ensure access to high quality EOL care for all Canadians. The Quality End of Life Care Coalition of Canada (QELCCC, 2012) supported these recommendations that would ensure that Canadians are able to die with dignity, free of pain, and surrounded by their loved ones, in a setting of their own choice. There are well-

documented gaps between the EOL care that Canadians prefer and the care that they actually receive (Cook, Rocker, & Heyland, 2013).

Seriously ill individuals in hospitals and their family members have identified the following features of quality end-of-life care: trust in the treating physician, avoidance of unwanted life support, effective communication, continuity of care, and death with dignity (Cook, Rocker, & Heyland, 2013). Most people state that they would prefer to die at home (Holdsworth, Gage, Coulton, et al., 2015). However, much of the care of someone dying at home is left to the dying person's family and friends, who report feeling unprepared and lacking resources. The nature of some illnesses exceed the caregiver's ability to meet the needs of the dying individual in the home, which often results in an admission to hospital at the end of life. The freestanding/residential hospice is an alternative setting for patients who are unable to remain at home but do not require acute care (Cook, Rocker, & Heyland, 2013).

Death

For many years, society has debated the criteria for death, and this is particularly of concern in the context of organ failure support, organ replacement technology, and organ transplantation. Several major sequential events occur in the dying process of terminally ill individuals who experience a circulatory arrest, when cardiopulmonary resuscitation (CPR) is not medically indicated, and whose EOL care involves limiting or withdrawing life-sustaining therapies (Figure 13-3). The individual's circulation and breathing stop. Because no attempts to restore circulation are made, after approximately 2 to 5 minutes, cessation of breathing and circulation is permanent. The individual may be determined to be dead (Shemie, Hornby, Baker, et al., 2014). There is an inseparable link between circulation and brain function, and therefore the neurological and circulatory sequences are integrated in the dying process.

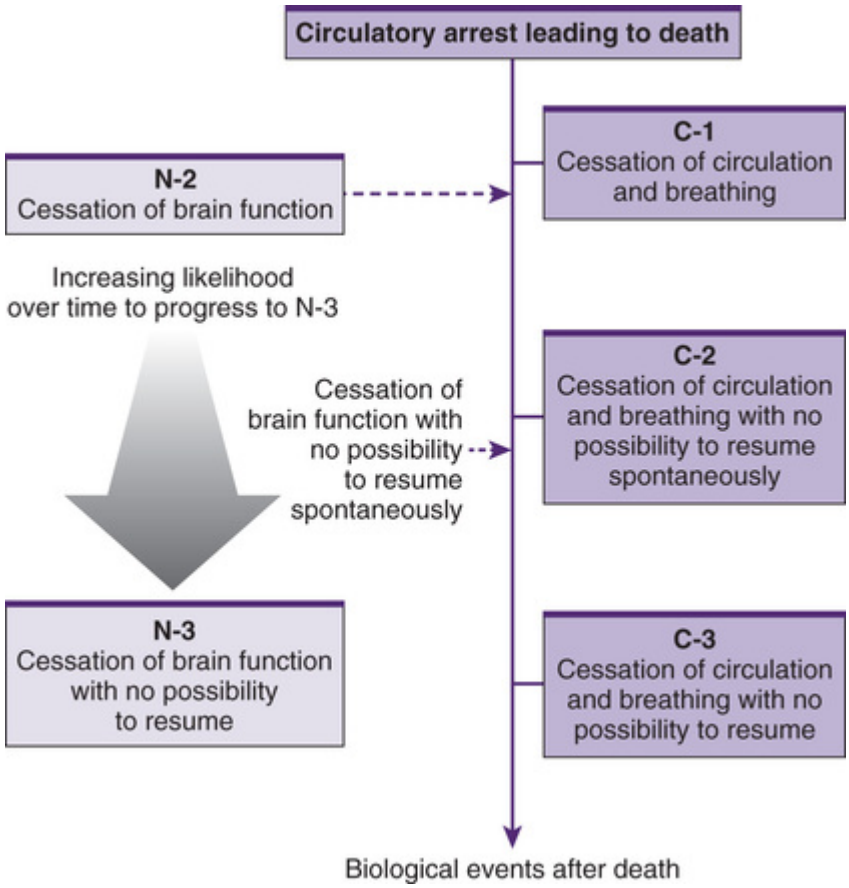

FIGURE 13-3 Physiological sequences in the dying process: integrated neurological and circulatory sequences (applies to cases of circulatory arrest). Source: Shemie, S. D., Hornby, L., Baker, A., et al. (2014). International guideline development for the determination of death. *Intensive Care Medicine, 40,* 788–797.

Death is the permanent loss of capacity for consciousness and all brainstem functions. This may result from permanent cessation of circulation or catastrophic brain injury. In the context of death determination, *permanent* refers to loss of function that cannot resume spontaneously and will not be restored through intervention. The minimum acceptable clinical standards to test for the cessation of circulatory function are (1) absence of palpable pulse, (2) absence of breath sounds, (3) absence of heart sounds, (4) absence of respiratory effort or chest wall motion, (5) loss of pulsatile arterial blood pressure according to noninvasive measurement, and (6) coma

and fixed pupils, observed continuously and confirmed after 2 to 5 minutes (Shemie, Hornby, Baker, et al., 2014). In individuals who have suffered a catastrophic brain injury, in which death follows the withdrawal of life-sustaining therapies, death entails a different sequence of events, which is beyond the scope of this discussion.

Physical Manifestations of the End of Life

As death approaches, metabolism is reduced and body functions gradually slow down until they all end. Respiratory changes are common at the end of life. Respirations may be rapid or slow, shallow, and irregular. Breath sounds may become wet and noisy, both audibly and on auscultation. Noisy, wet-sounding respirations, termed the **death rattle** or *terminal secretions,* are caused by mouth breathing and accumulation of mucus in the airways. **Cheyne-Stokes respiration** is a pattern of breathing characterized by alternating periods of apnea and deep, rapid breathing. When respirations cease, the heart stops beating within a few minutes. Physical manifestations of approaching death are listed in Table 13-3.

TABLE 13-3
PHYSICAL MANIFESTATIONS OF APPROACHING DEATH

System	Manifestations
Sensory system	
• Hearing	• Usually last sense to disappear
• Taste and smell	• Decreased with disease progression
• Sight	• Blurring of vision • Sinking and glazing of eyes • Blink reflex absent • Eyelids may remain half open
Cardiovascular system	• Increased heart rate; later slowing and weakening of pulse • Irregular rhythm • Decrease in blood pressure • Delayed absorption of drugs administered intramuscularly or subcutaneously
Respiratory system	• Increased respiratory rate • Cheyne-Stokes respiration (pattern of respiration characterized by alternating periods of apnea and deep, rapid breathing) • Inability to cough or clear secretions, which results in grunting, gurgling, or noisy congested breathing (death rattle or terminal secretions) • Irregular breathing, gradually slowing down to terminal gasps (may be described as "guppy breathing")
Urinary system	• Gradual decrease in urinary output • Incontinent of urine • Inability to urinate
Gastro-intestinal (GI) system	• Loss of appetite and thirst sensations • Slowing or cessation of GI function (may be attributed to opioid medications) • Accumulation of gas • Distension and nausea • Loss of sphincter control, which produces incontinence • Bowel movement before imminent death or at time of death
Musculo-skeletal system	• Increasing weakness • Gradual loss of ability to move • Sagging of jaw as a result of loss of facial muscle tone • Difficulty speaking • Possibly more difficulty with swallowing • Difficulty maintaining body posture and alignment • Loss of gag reflex • Jerking (myoclonus), seen in patients receiving large amounts of opioids
Integumentary system	• Mottling on hands, feet, arms, and legs • Cold, clammy skin • Cyanosis of nose, nail beds, and knees • "Waxlike" skin when death is very near

Although death in a hospice palliative care setting is anticipated, a significant minority of deaths (10%) are unexpected. A longer trajectory of illness is associated with unexpected death, and signs of impending death are observed less frequently (Bruera, Chisholm, Dos Santos, et al., 2015).

Psychosocial Manifestations of the End of Life

A variety of feelings and emotions can affect the dying patient and family at the end of life (Table 13-4). Most patients and families struggle with the news of a terminal diagnosis and the realization that there is no cure. The patient and family may feel overwhelmed, fearful, powerless, and fatigued. The family's response depends in part on the type and length of the illness and their relationship with the person.

TABLE 13-4

PSYCHOSOCIAL MANIFESTATIONS OF APPROACHING DEATH

- Altered decision making
- Anxiety about unfinished business
- Decreased socialization
- Fear of loneliness
- Fear of meaninglessness of one's life
- Fear of pain
- Helplessness
- Life review
- Peacefulness
- Restlessness
- Saying goodbyes
- Unusual communication
- Vision-like experiences
- Withdrawal

The patient's needs and wishes must be respected. Patients need time to think and express their feelings. Response time to questions may be sluggish because of fatigue, weakness, and confusion.

Grief and Bereavement

A*nticipatory grief* is a form of grieving that takes place before the actual death; in other words, in anticipation of the death. Patients nearing the end of life may also experience anticipatory grief. As a patient approaches the end of life, it is common to begin to think of what life will be like when the person has died. The extent to which loved ones have explored and experienced anticipatory grief has an influence on their grief after the actual death (National Cancer Institute, 2014).

Grief is a normal reaction to loss and may manifest itself in both psychological and physiological ways. Psychological responses may include anger, guilt, anxiety, sadness, depression, despair, or a combination of these. Physiological reactions may include disruption in sleep, changes in appetite, physical symptoms, and illness. These experiences may be quite intense immediately after the death and diminish over time. If they persist over a significant period of time, referral to a grief counsellor or health care provider should be considered.

Elisabeth Kübler-Ross (1969) was a pioneer in the recognition and description of grief. In her model of grief, she described five stages (Table 13-5). As other theorists built on this work, they realized that the stages are not linear. Indeed, not every person experiences all the stages of grieving. It is not uncommon to reach a stage and then revert to an earlier stage.

TABLE 13-5

KÜBLER-ROSS'S MODEL OF GRIEF

Stage	What a Person May Say	Characteristics
Denial	No, not me. It cannot be true.	Denying the loss has taken place and possibly withdrawing. This response may last minutes to months.
Anger	Why me?	Possibly being angry at the person who inflicted the hurt (even after death) or at the world for letting it happen. Possibly being angry with self for letting an event (e.g., car accident) take place, even if nothing could have stopped it.
Bargaining	Yes, me, but…	Making bargains with God, asking, "If I do this, will you take away the loss?"
Depression	Yes, me, and I am sad	Feeling numb, although anger and sadness may remain subconsciously.
Acceptance	Yes, me, but it is okay	Tapering off of anger, sadness, and mourning; accepting the reality of the loss.

Kübler-Ross's work was pioneering in that she was the first theorist to describe what she was observing in people who were grieving. Her "Stages of Grief" have been criticized as a model for therapy. William Worden further developed Kübler-Ross's work and began talking about "grief work." He developed a counselling model to assist people in the work of grief. Worden's (2009) model outlines "Four Tasks of Mourning" that must be accomplished in grief work (Figure 13-4).

FIGURE 13-4 Worden's tasks of mourning. Source: Worden, J. W. (2009). *Grief counselling and grief therapy: A handbook for the mental health practitioner.* Retrieved from *http://www.whatsyourgrief.com/wordens-four-tasks-of-mourning/.*

Bereavement is the period after the death of a loved one during which grief is experienced and mourning occurs. The time spent in bereavement depends on a number of factors, including cultural norms, the nature of the relationship with the deceased person, and the degree to which the surviving person was able to prepare for the loss before death. Bereavement and grief counselling are core components of patient- and family-centred hospice palliative care.

Spiritual Needs

Assessment of spiritual needs in EOL care is a key consideration (Table 13-6). **Spirituality** is defined as the beliefs, values, and practices that relate to the search for existential meaning and purpose. It may or may not include a belief in a higher power (Skalla & Ferrell, 2015; Figure 13-5). Some patients may choose to pursue a spiritual path; others may not. Nurses, however, must respect the patient's wishes with regard to spiritual guidance or pastoral care services and make referrals as appropriate.

TABLE 13-6
SPIRITUAL ASSESSMENT

1. Who or what provides you strength and hope?
2. Do you use prayer in your life?
3. How do you express spirituality?
4. How would you describe your philosophy of life?
5. What type of spiritual or religious support do you desire?
6. What is the name of your clergy, minister, chaplain, pastor, rabbi?
7. What does suffering mean to you?
8. What does dying mean to you?
9. What are your spiritual goals?
10. Is there a role of a church, synagogue, mosque, or temple in your life?
11. Has belief in God been important in your life?
12. How does your faith help you cope with illness?
13. How do you keep going day after day?
14. What helps you get through this health care experience?
15. How has illness affected you and your family?

Culturally Competent Care

At the End of Life

Although death is universal, the ways in which people understand and experience death vary across cultures. Yet variations in rituals within cultural groups, religious faiths, and individuals remind us of the importance of not overgeneralizing culturally attributed qualities (Oyebode & Owens, 2013). Although Canada's immigrants in the sixteenth to nineteenth centuries came from Europe, today's newcomers are more likely to be from Asia, the Middle East, Africa, the Caribbean, and Central and South America (Statistics Canada, 2011b).

Some cultural and religious experiences and expressions of death are subdued and intensely private, whereas for others the experience may involve the community as a whole and be a very public affair with public expressions of grief. Some cultures shield or protect the dying from information about their illness. Effective nurses seek to understand the cultural or religious practices and attitudes toward death that are specific to their patients (LoPresti, Dement, & Gold, 2014). This understanding must not only relate to the care of dying patients but also extend to practices or rituals concerning the care of the body upon and immediately after death.

Within Canada, people of Indigenous origin are the fastest growing populace. There was a 20.1% increase (232 385 people) between 2006 and 2011, in comparison with a 5.2% increase in the non-Indigenous population. The largest numbers live in Ontario, Manitoba, Saskatchewan, and British Columbia (Statistics Canada, 2011b).

Ontario has created a health program, Aboriginal Navigators, in an effort to increase Indigenous people's access to health care services by removing barriers and increasing cultural sensitivity among health care providers. This has taken the form of increasing understandings of the role of extended family, family gatherings for support, community leaders, healers, and medicine men and women within Indigenous culture. Furthermore, an openness within the

health care community to learn and understand about the connection to the spirit world, to ceremony, and to sacred and ceremonial items such as feathers, tobacco, sweet grass, cloth, and stones, as well as diet for healing, can all be respectfully incorporated into a patient's plan of care (Hampton, Baydale, Bourassa, et al., 2010). (Further considerations around culturally competent care are discussed in Chapter 2.)

Legal and Ethical Issues Affecting End-of-Life Care

Patients and families struggle with many questions related to a terminal illness and the dying experience. It is important to create a therapeutic relationship in which patients feel safe in exploring their fears and questions. Common questions may be related to how much control the patient may have over decisions about care: “What if my heart stops?” (resuscitation/mechanical ventilation), “Who would make decisions for me if I can't?” (advance directives/power of attorney), “If it's too much for me, can I decide when I want to die?” (physician-assisted dying), and “Can I donate my body to science?” (organ/tissue donation).

Ethical Dilemmas

End-of-Life Care

Situation

Suzanne Simard is a terminally ill 50-year-old woman with metastatic breast cancer. She has developed severe bone pain that is not adequately controlled by her current dosage of intravenous (IV) morphine. She moans at rest and verbalizes severe pain from any movement to reposition her. Even though she appears to sleep at intervals, she requests pain medicine frequently, and her family is demanding additional pain medicine for her. At the interdisciplinary team conference, the nurses have discussed the need for more effective pain control but are concerned that additional pain medicine could hasten her death.

Important Points for Consideration

- Adequate pain relief is an important outcome for all patients, but in particular for patients who are terminally ill. The *principle of beneficence* imposes the obligation to provide the necessary care to benefit the patient.
- One goal of treatment of the terminally ill is to provide adequate pain control to alleviate suffering. This goal is based on the *principle of nonmaleficence:* preventing or reducing harm to the patient. The secondary effect of hastening the patient's death is ethically justified. This is referred to as the principle of *double effect*.
- Adequate pain relief at the end of life continues to be a major concern of health care providers and consumers.

Clinical Decision-Making Questions

1. In Ms. Simard's situation, what type of discussion needs to occur among members of the health care team, the patient, and the family as this phase of the care of the terminally ill is approached?
2. Distinguish between palliative sedation and physician-assisted death, and the promotion of comfort and relief of pain in dying patients.

Advance Care Planning and Advance Directives

Legislation pertaining to advance care planning in Canada is specific to each province or territory. However, the principles underlying advance care planning are common across the country: the intrinsic value and uniqueness of each person, the person's right to self-determination, and autonomous decision making.

Health care providers always speak with patients about their health care and treatment options. The intent of an *advance care plan* is that when the patient is no longer able to give direction or consent, the patient's substitute decision maker or advance care plan, or both, will ensure the patient's wishes are known. Each province and

territory has its own legislation outlining who may be designated as a substitute decision maker.

Advance care planning is a process of a patient's thinking about and sharing his or her wishes for future health and personal care. It is a means by which an individual can tell others what would be important if he or she were ill and unable to communicate. An individual may choose a substitute decision maker and identify this person through a written document such as a power of attorney (or similar document).

An individual may express his or her wishes or directions as generally or as specifically as he or she wishes through an advance care plan (formerly known as a *living will*). When **advance directives**—legal documents specifying an individual's decisions regarding end-of-life care and specifying alternative decision makers as required—are written, they should be made available to the health care providers and to the substitute decision maker. The CHPCA has led a national initiative promoting and educating the general public, as well as health care providers, on the importance of advance care planning. The "Speak Up" website lists a variety of tools, workbooks, and other information (see the Resources at the end of this chapter).

In all cases, a substitute decision maker must act on a patient's prior expressed wishes, if known, and in a manner that would be consistent with what the patient would have done when capable.

Nurses play an important role in educating individuals about their health condition and in providing factual information about the probable risks and benefits of treatment options. Patients are then encouraged to consider this information in the context of the steps to the development of an advance care plan (Table 13-7).

TABLE 13-7
DEVELOPING AN ADVANCE CARE PLAN

Steps	Important Considerations
Learn about your condition and medical treatment: Some may improve your quality of life, whereas others may only keep you alive longer. **Think about you:** What are your values, wishes, beliefs, and understanding about your care and specific medical treatments? **Talk about your wishes:** It is important to discuss your wishes with your loved ones, your family physician, and your health care team. **Choose a substitute decision maker:** Choose someone who would honour and follow your wishes if you cannot speak for yourself. **Record your wishes:** It is a good idea to write down or make a recording of your wishes. Give a copy to your health care provider and substitute decision maker.	• What makes each day worthwhile? • What makes you happy? • How do your decisions about your illness, your care, and your treatment affect your loved ones? Does this change the way you feel about treatment? • Do you have fears or worries regarding your treatment? • Do you have a preference regarding location of care (for example, at home, in a health care institution) if your condition gets worse? • Is there anything that feels "undone" about your life? • Whom can you rely on to help you through any challenges? • Do your religious, cultural, or personal beliefs affect your decisions?

Resuscitation

Do-not-resuscitate (DNR) decisions are unique instructions that have developed in acute care hospitals since the 1970s. Because cardiopulmonary resuscitation (CPR) is the default response to respiratory or cardiac arrest, a DNR decision requires informed consent (Jalkin & Olver, 2011). This is a very specific example of an event that can often be anticipated and addressed in an advance care directive.

A physician's DNR order is required and should be specific enough to reflect the patient's expressed wishes, whether through direct discussion with the patient, through the advance directives, or from the patient's substitute decision maker. It is now common for a physician to reflect this understanding of the patient's wishes with a written order of "comfort measures only," meaning that treatment associated with pain control and symptom management are carried out, but the natural physiological progression to death is not delayed

or interrupted. The use of this type of language means that care is not withheld but rather is supportive while allowing nature to take its course. It is meant to promote comfort and dignity at the end of life. Alberta Health Services has designed "Goals of Care Designations" to facilitate conversations and documentation of an individual's values and wishes related to medical care, resuscitative care, and comfort care (see the Resources at the end of this chapter).

Physician-Assisted Dying

The issue of physician-assisted dying has been debated in Canada for decades, and several cases have been before the Supreme Court of Canada. On February 6, 2015, the Supreme Court of Canada, in its decision in *Carter v. Canada (Attorney General),* unanimously struck down the Criminal Code prohibitions against assisted dying under certain specific circumstances (Ontario Ministry of Health and Long Term Care & Attorney General, 2015). Accordingly, the federal government, as well as provincial and territorial governments, were given 1 year to draft any necessary legislation and regulations pertinent to physician-assisted dying. As an interesting sidebar, on January 15, 2016, the Supreme Court of Canada granted a 4-month extension at the request of Canada's newly elected government, so that April 2016 became the date for such legislation to be in place (Supreme Court of Canada, 2016).

In November 2015, a report titled "Provincial–Territorial Advisory Group on Physician-assisted Dying" (Ontario Ministry of Health and Long-Term Care & Attorney General, 2015) was published; it offered policymakers recommendations directed toward a uniquely Canadian approach to this critical social policy issue.

Palliative Sedation

Physician-assisted dying should not be confused with palliative sedation. *Palliative sedation* is an infrequent and extraordinary intervention that necessitates interprofessional expertise. Rigorous guidelines are strictly followed to intentionally produce sedation in order to relieve intractable symptoms in the last days of a patient's life (Alberta Health Services, 2015). The intent of palliative sedation

is to control refractory symptoms and suffering, not to shorten life or to hasten death (Abarshi, Papavasiliou, Preston, et al., 2014), as is the case with physician-assisted death.

Promoting the relief of suffering is a nurse's ethical obligation, and it may include appropriate administration of medications (e.g., opioids) that have the potential to cause sedation. The *principle of double effect* justifies the use of medications that cause sedation as an adverse effect, an unintended harm, as its primary role is to relieve suffering and that are not intended to hasten death. Careful titration of medication, which is based on the patient's response, can improve the likelihood that the patient will receive the correct proportion of medication and minimize the potential for harm (Abarshi, Papavasiliou, Preston, et al., 2014).

The use of opioids for symptom management at the end of life is often misunderstood and feared by patients, families, and some health care providers. For this reason, many patients do not receive adequate medication, which may lead to physical and emotional suffering from uncontrolled pain and symptoms. This is an opportunity for the nurse to educate the patient and family about physical dependence on and tolerance of medications. A terminally ill patient should not be concerned with physical dependence when the goal of treatment is comfort until death. (Pain management is discussed in Chapter 10.)

Organ and Tissue Donation

In Canada, oversight and administration of health services, including organ donation, are the responsibility of provincial and territorial governments. Deceased donor services are managed by organ procurement organizations, and living donor services are managed by individual hospitals (Gill, Klarenbach, Barnieh, et al., 2014). All people who are 16 years of age or older and are competent may choose organ and tissue donation. Only patients who have sustained a nonrecoverable injury and are on life support may donate organs. However, all patients have the potential to donate tissue (e.g., eyes, bones, heart valves, and skin) after death (Ontario Trillium Gift of Life Network).

Nurses should be aware of ethical and legal issues and the patient's wishes. Advance directives and organ donor information should be located in the patient's medical record and identified on that record or in the nursing care plan. All caregivers responsible for the patient need to know the patient's wishes. In addition, nurses are responsible for becoming familiar with provincial or territorial, local, and agency procedures related to documentation of EOL care. (Altered Immune Response and Transplantation is discussed in Chapter 16.)

Nursing Management End of Life

Nurses spend more time with patients near the end of the patient's lives than do any other health care providers. Nursing care of terminally ill and dying patients is holistic and encompasses all psychosocial and physical needs. Respect, dignity, and comfort are important for the patient and family. Although there is no cure for the person's disease, the treatment plan still consists of assessment, planning, implementation, and evaluation. The main difference is that the focus of care is on the management of the symptoms of the disease, not necessarily the disease itself. In addition, nurses who care for the dying need to recognize their own needs when dealing with grief and dying.

Nursing Assessment

Assessment of a terminally ill or dying patient varies with the patient's diagnosis, life expectancy, and rate of decline. Depending on the reason for admission, the assessment might be comprehensive or limited to essential data. Nurses must be sensitive and not impose repeated, unnecessary assessments on a dying patient. When possible, health history data that are available in the medical record should be used in the nursing assessment. The nurse documents the specific event or change in condition that caused the patient to enter the health care facility. The patient's medical diagnoses, medication profile, and allergies are recorded.

A comprehensive symptom assessment according to the acronym *OPQRSTUV* (**o**nset, **p**rovoking/**p**alliating, **q**uality, **r**egion/**r**adiation, **s**everity, **t**reatment, **u**nderstanding/effect on the examiner, and **v**alues; Fraser Health Authority, 2009) and a physical assessment should be completed so that prompt interventions can be initiated. In addition, comorbid conditions or acute episodes of problems such as diabetes mellitus or headache should be evaluated and managed. The nurse should elicit information about the patient's abilities, food and fluid intake, patterns of sleep and rest, and response to the stress of terminal illness; assess the patient's ability to cope with the diagnosis and prognosis of the illness; and determine the family's

capacity to manage the needed care and to cope with the illness and its consequences. (Health history and physical assessment are discussed in Chapter 3.)

The physical assessment is abbreviated and focuses on changes that accompany terminal illness and the specific disease process (Hui, Dos Santos, Chisholm, et al., 2015). The frequency of assessment depends on the patient's stability, but a full assessment is completed at least every 8 hours in the institutional setting. For patients cared for in their homes, assessment may occur weekly. As changes occur, assessment and documentation may have to be completed more frequently. If the patient is in the final hours of life, the physical assessment may be limited to gathering essential data (e.g., level of distress).

Key elements of a social assessment include determining the relationships and patterns of communication among the family members. If multiple family members are present, the nurse should listen to varying concerns from different members. Differences in expectations and interpersonal conflict can result in family disruptions during the dying process and after the death of the loved one. Social assessment also includes evaluating the goals of the patient and family.

As the patient nears death, the nurse should monitor the patient for multiple systems that often are failing during the EOL period. This requires vigilance and attention to physical changes that are often subtle. Neurological assessment is especially important and includes evaluation of level of consciousness, presence of reflexes, and pupil responses. Evaluation of vital signs, skin colour, and temperature helps detect changes in circulation. The nurse should monitor and describe respiratory status, character and pattern of respirations, and characteristics of breath sounds. Nutritional and fluid intake, urine output, and bowel function should also be monitored because they provide assessment data for renal and gastrointestinal functioning. Skin condition should be assessed on an ongoing basis because skin becomes fragile and may easily break down.

In the last hours of life, assessments should be limited to only those that are needed to determine the patient's comfort. Assessment

of pain and respiratory status may be the most important during this time. It may be more peaceful and comforting to the patient and family to refrain from overstimulation that may occur from certain types of assessments, such as measuring blood pressure or checking for pupillary response. As the patient's death approaches, the nurse's efforts may be better spent providing emotional support to the patient and family rather than performing tasks that will have no effect on the patient's physical care. (Tools for practice can be found at the Canadian Virtual Hospice and Pallium Canada websites, listed in the "Resources" section at the end of this chapter.)

Nursing Diagnoses

Several nursing diagnoses deal with psychosocial manifestations (Table 13-8) and physical manifestations (Table 13-9) associated with EOL care.

TABLE 13-8

NURSING DIAGNOSES
Psychosocial Manifestations of the End of Life

- *Anxiety, death*
- *Confusion, acute*
- *Confusion, chronic*
- *Coping, ineffective*
- *Denial, ineffective*
- *Family processes, interrupted*
- *Fear*
- *Grieving, risk for complicated*
- *Grieving, complicated*
- *Hopelessness*
- *Loneliness, risk for*
- *Sleep pattern, disturbed*
- *Social interaction, impaired*
- *Social isolation*
- *Sorrow, chronic*
- *Spiritual distress*
- *Spiritual well-being, readiness for enhanced*
- *Verbal communication, impaired*

TABLE 13-9

NURSING DIAGNOSES
Physical Manifestations of the End of Life

- *Airway clearance, ineffective*
- *Aspiration, risk for*
- *Bed mobility, impaired*
- *Bowel incontinence*
- *Breathing pattern, ineffective*
- *Cardiac output, decreased*
- *Constipation*
- *Diarrhea*
- *Fatigue*
- *Gas exchange, impaired*
- *Infection, risk for*
- *Injury, risk for*
- *Nausea*
- *Nutrition, imbalanced: less than body requirements*
- *Oral mucous membrane, impaired*
- *Pain, acute*
- *Pain, chronic*
- *Physical mobility, impaired*
- *Self-care deficits*
- *Skin integrity, impaired*
- *Swallowing, impaired*
- *Thermoregulation, ineffective*
- *Tissue integrity, impaired*
- *Tissue perfusion, ineffective*
- *Incontinence, functional urinary*

Planning

The patient and family need to be involved in planning and coordinating EOL care. In some cases, a family conference may be helpful to develop a coordinated plan of care.

The nurse develops a comprehensive plan to support, teach, and evaluate patients and families. Nursing care goals during the last stages of life involve comfort and safety measures and care of the patient's emotional and physical needs. These goals may also include determining where the patient would prefer to die and whether this is possible. For example, the patient may prefer to die at home, but the family may not be in favour. Many factors contribute to the decision of the patient and family. Interprofessional EOL care should include the physician, nurse, social worker, and chaplain, as well as other members of the hospice palliative care team. The nurse should

advocate for the patient so that his or her wishes are met as much as possible.

Nursing Implementation

Psychosocial care and physical care are interrelated for both the dying patient and the family. Support and education are important components of EOL care. Patients and families need ongoing information regarding the disease, the dying process, and any care that will be provided. They need information on how to cope with the many issues during this period of their lives. Anxiety and grief may be barriers to learning and understanding at the end of life for both the patient and the family. (Tools for practice can be found at the Canadian Virtual Hospice and Pallium Canada websites, listed in the "Resources" section at the end of this chapter.)

Psychosocial Care.

As the patient's death approaches, the nurse should encourage the family to respond appropriately to the psychosocial manifestations of the end of life. Table 13-10 discusses management of psychosocial manifestations near death.

TABLE 13-10

NURSING MANAGEMENT
Psychosocial Care at the End of Life

Characteristic	Nursing Management
Withdrawal	
Patient near death may seem withdrawn from the physical environment; however, the patient may be able to hear but unable to respond.	• Converse as though the patient were alert, using a soft voice and gentle touch.
Unusual Communication	
This may indicate that an unresolved issue is preventing the dying person from letting go. Patient may become restless and agitated or perform repetitive tasks (may also indicate terminal delirium).	• Encourage the family to talk with and reassure the dying person.
Vision-Like Experiences	
The patient may talk to people who are not there or see places and objects not visible. Vision-like experiences assist the dying person in coming to terms with meaning in life and transition from it.	• Affirm the dying person's experience as a part of transition from this life.
Saying Goodbyes	
It is important for the patient and family to acknowledge their sadness, mutually forgive one another, and say goodbye.	• Encourage the dying person and family to verbalize their feelings of sadness, loss, and forgiveness and to touch, hug, and cry. • Allow the patient and family privacy to express their feelings and comfort one another.
Spiritual Needs	
The patient or family may request spiritual support, such as the presence of a chaplain.	• Assess spiritual needs. Allow patient to express his or her spiritual needs. • Encourage visit by appropriate spiritual care service provider, chaplain, or family member.

Anxiety and Depression.

Patients often exhibit signs of anxiety and depression during the EOL period. Anxiety is an uneasy feeling whose cause is not easily identified. Anxiety is frequently related to fear.

Causes of anxiety and depression may include uncontrolled pain and dyspnea, psychosocial factors related to the disease process or impending death, altered physiological states, and drugs used in high dosages. Encouragement, support, and teaching decrease some of the anxiety and depression. Management of anxiety and depression may include both medications and nonpharmacological interventions. Relaxation strategies such as relaxation breathing,

muscle relaxation, music, and imagery may be useful. (Complementary and alternative therapies are discussed in Chapter 12.)

Anger.

Anger is a common and normal response in the grief process. A grieving person cannot be forced to accept loss. The surviving family members may be angry with the dying loved one who is leaving them. The nurse should encourage the expression of feelings, but at the same time realize how difficult it is to come to terms with loss. The nurse may be the target of the anger; however, it is critical to understand the source of the expressed emotion and not to react on a personal level.

Hopelessness and Powerlessness.

Feelings of hopelessness and powerlessness are common during the EOL period. The nurse should encourage realistic hope within the limits of the situation. The patient and family should be allowed to deal with what is within their control, and the nurse should help them to recognize what is beyond their control. When possible, the patient's involvement in decision making about care should be supported, to foster a sense of control and autonomy.

Fear.

Fear is a common emotion associated with dying. Four specific fears associated with dying are fear of pain, fear of shortness of breath, fear of loneliness and abandonment, and fear of meaninglessness.

Fear of Pain.

Many people assume that pain always accompanies dying and death. Physiologically, there is no absolute indication that death is always painful. Psychologically, pain may result from the anxieties and separations related to dying. Terminally ill patients who do experience physical pain should have pain-relieving medications available around the clock (Pereira, 2013). Nurses must assure the patient and family that drugs will be given promptly when needed and that adverse effects of drugs can and will be managed.

Reassessment of pain after medications are given is an important nursing action. Patients can participate in their own pain relief by discussing pain relief measures and their effects. Most patients want their pain relieved without the adverse effects of grogginess or sleepiness. Pain relief measures do not have to deprive the patient of the ability to interact with others.

Fear of Shortness of Breath.

Respiratory distress and dyspnea occur in some patients near the end of life. The sensation of breathlessness results in anxiety for both the patient and family. Current therapies include opioids, bronchodilators, and oxygen, depending on the cause of the dyspnea. Anxiety-reducing medications (anxiolytics) may help produce relaxation.

Fear of Loneliness and Abandonment.

Most terminally ill and dying people fear loneliness and do not want to be alone. Many dying patients are afraid that loved ones who are unable to cope with the patient's imminent death will abandon them. The simple presence of someone provides support and comfort (Figure 13-6). Holding hands, touching, and listening are important nursing interventions. Providing companionship allows the dying person a sense of security.

FIGURE 13-6 Dying patients typically want someone whom they know and trust to stay with them. Source: © Can Stock Photo/jgroup.

Fear of Meaninglessness.

Fear of meaninglessness leads most people to review their lives. They review their intentions during life, examining actions and expressing regrets about what might have been. *Life review* helps patients recognize the value of their lives. Nurses can assist patients and their families in identifying the positive qualities of the patient's life. Practical ways of helping may include looking at photo albums or collections of important mementos. Sharing thoughts and feelings may enhance spirituality and provide comfort for the patient at this time. A patient may wish to leave a legacy through writing letters to read or making a video to be viewed at future events when they will no longer be present (Waldrop & Meeker, 2014). Nurses must respect and accept the practices and rituals associated with the patient's life review while remaining nonjudgemental.

Communication.

No two conversations are the same, inasmuch as they are shaped by the unique circumstances, coping styles, and personalities of the individuals involved. Difficult discussions include any information that adversely affects one's expectations for the future. How the person experiences and processes difficult news is dependent on not only the words used but also how the message is delivered (Boles, 2015). Nurses may use several approaches to difficult conversations that share common features. Suggested approaches are "ask–tell–ask," "tell me more," responding to emotions with the NURSE protocol (**n**aming, **u**nderstanding, **r**especting, **s**upporting, and **e**xploring) and the SPIKES six-step protocol (**s**etup, **p**erception, **i**nvitation, **k**nowledge, **e**mpathize, and **s**ummarize and **s**trategize; Back, Arnold, Baile, et al., 2005).

Effective communication techniques used in conversations among the interprofessional team, patient, and family are essential at the end of the patient's life. Empathy and active listening are essential communication components in EOL care (Figure 13-7). Empathy is the identification with and understanding of another person's situation, feelings, and motives. Active listening, an active process required in the development of empathy toward another person's feeling, is paying attention to what is said, observing the patient's nonverbal cues, and not interrupting.

FIGURE 13-7 Therapeutic communication is an important aspect of end-of-life nursing care. Source: © Can Stock Photo/diego_cervo.

There may also be silence. Silence is frequently related to the overwhelming feelings experienced at the end of life. Silence can also allow time to gather thoughts. Listening to the silence sends a message of acceptance and comfort. Communication also must be respectful of the patient's ethnic, cultural, and religious backgrounds.

Patients and family members may have difficulties expressing themselves emotionally. The nurse must allow time for them to express their feelings and thoughts, making time to listen and interact in a sensitive way to enhance the relationship among the nurse, the patient, and the family. A family conference is one way to create a environment more conducive to large group conversations.

Family members must be prepared for changes in emotional and cognitive function that occur at end of the patient's life. Unusual communication by the patient may take place at the end of life. The patient's speech may become confused, disoriented, or garbled.

Patients may speak to or about family members or others who have predeceased them, give instructions to those who will survive them, or speak of projects yet to be completed. Active, careful listening allows for the identification of specific patterns in the dying person's communication and decreases the risk for inappropriate labelling of behaviours.

Physical Care.

Nursing management related to physical care at the end of life focuses on symptom management and comfort rather than treatments for curing a particular disease or disorder (Table 13-11). The priority is meeting the patient's physiological and safety needs. Physical care addresses the needs for oxygen, nutrition, pain relief, mobility, elimination, and skin care. People who are dying deserve and require the same physical care as do patients who are expected to recover. If possible, it is important to discuss with the patient and family the goals of care before treatment begins. Documentation of the discussion regarding wishes and preferences may take the form of an advance directive or simply recorded in the medical chart to clearly communicate with the interdisciplinary team.

TABLE 13-11

NURSING MANAGEMENT
Physical Care at the End of Life

Characteristics	Nursing Management
Pain	
• May be a major symptom associated with terminal illness and is the one most feared • Can be acute or chronic • Possible causes of bone pain: metastases, fractures, arthritis, and immobility • Aggravated by physical and emotional stressors	• Assess pain thoroughly and regularly to determine the quality, intensity, location, and contributing and alleviating factors. • Minimize possible irritants such as wet skin, heat or cold, and pressure. • Administer medications around the clock in a timely manner and on a regular basis to provide constant relief, rather than waiting until the pain is unbearable and then trying to relieve it. • Provide complementary and alternative therapies such as guided imagery, massage, and relaxation techniques as needed (see Chapter 12). • Evaluate effectiveness of pain relief measures frequently to ensure that the patient is on a correct, adequate drug regimen. • Do not delay or deny pain relief measures to a terminally ill patient.
Delirium	
• A state characterized by confusion, disorientation, restlessness, clouding of consciousness, incoherence, fear, anxiety, excitement, and often hallucinations • May be misidentified as depression, psychosis, anger, or anxiety • May be caused by use of opioids or corticosteroids, as well as by their withdrawal • May be exacerbated by underlying disease process • Generally considered a reversible process	• Perform a thorough assessment for reversible causes of delirium, including pain, constipation, and urinary retention. • Provide a room that is quiet, well lit, and familiar to reduce the effects of delirium. • Reorient the dying person with delirium to person, place, and time with each encounter. • Administer ordered benzodiazepines and sedatives as needed. • Stay physically close to a frightened patient. Reassure in a calm, soft voice with touch and slow strokes of the skin. • Provide family with emotional support and encouragement in their efforts to cope with the behaviours associated with delirium.
Anxiety/Restlessness	
• May occur as death approaches and cerebral metabolism slows • May occur with tachypnea, dyspnea, or sweating	• Assess for previous anxiety disorder. • Assess for spiritual distress or concerns related to death as causes of restlessness and agitation. • Assess for urinary retention and stool impaction. • Do not restrain. • Use soothing music; slow, soft touch; and calm, soft voice. • Limit the number of people at the patient's bedside.
Dysphagia	

Characteristics	Nursing Management
• May occur because of extreme weakness and changes in level of consciousness • Difficulty swallowing • Aspiration of liquids or solids, or both • Drooling/inability to swallow secretions	• Identify the least invasive alternative routes of administration for drugs needed for symptom management. • If necessary, use alternative (rectal, buccal, transdermal) medication routes. • Suction orally as needed. • Modify diet as tolerated/desired (soft, pureed, chopped meats). • Hand feed small meals. • Elevate the patient's head for meals and for at least 30 minutes after. • Discontinue nonessential medications. • Discuss risk of aspiration with patient/family.
Weakness and Fatigue	
• Expected at the end of life • Exacerbated by metabolic demands related to disease process	• Assess the patient's tolerance for activities. • Time nursing interventions to conserve the patient's energy. • Help the patient identify and complete valued or desired activities. • Provide support as needed to maintain patient's positions in bed or chair. • Provide frequent rest periods for the patient.
Dehydration	
• May occur during the last days of life • Hunger and thirst rare in the last days of life • Tendency for dying patients to take in less food and fluid	• Assess mucous membranes frequently for dryness, which can lead to discomfort. • Maintain complete, regular oral care to provide for comfort and hydration of mucous membranes. • Encourage consumption of ice chips and sips of fluids, or use moist cloths to provide moisture to the mouth. • Use moist cloths and swabs for an unconscious patient to prevent aspiration. • Apply lubricant to the lips and oral mucous membranes as needed. • Do not force the patient to eat or drink. • Teach the family that hunger and thirst are rare in the last days of life. • Reassure the family that cessation of food and fluid intake is a natural part of the process of dying.
Dyspnea	
• Subjective symptom • Accompanied by fear of suffocation and anxiety • Can be exacerbated by underlying disease process • Progressive difficulty with coughing and expectorating secretions	• Assess respiratory status regularly. • Elevate the patient's head, or position the patient on one side to improve chest expansion. • Use a fan or air conditioner to facilitate movement of cool air. • Teach and encourage the use of pursed-lip breathing. • Administer supplemental oxygen as ordered. • Suction as necessary to remove accumulation of mucus from the airways. Suction cautiously when a patient is in the terminal phase. • Administer expectorant as ordered.
Myoclonus	

Characteristics	Nursing Management
• Mild to severe jerking or twitching, sometimes associated with use of high dose of opioids • Possible complaints of involuntary twitching of extremities	• Assess for initial onset, duration, and any discomfort or distress experienced by patient. • If myoclonus is distressing or becoming more severe, discuss possible drug therapy modifications with the health care provider. • Changes in opioid medication may alleviate or decrease myoclonus.
Skin Breakdown	
Difficulty maintaining skin integrity at the end of life Risk for development increased by immobility, urinary and bowel incontinence, dry skin, nutritional deficits, anemia, friction, and shearing forces Skin integrity possibly impaired by disease and other processes As death approaches, decrease of circulation to the extremities; become cool, mottled, and cyanotic	• Assess skin for signs of breakdown. • Implement protocols to prevent skin breakdown by controlling drainage and odour and by keeping the skin and any wound areas clean. • Perform wound assessments as needed. • Follow appropriate nursing management protocol for dressing wounds. • Follow appropriate nursing management protocol for a patient who is immobile, but consider realistic outcomes of skin integrity in relation to maintenance of comfort. • Follow appropriate nursing management to prevent skin irritations and breakdown from urinary and bowel incontinence. • Use blankets to cover for warmth. Never apply heat. • Prevent the effects of shearing forces.
Bowel Patterns	
• Constipation possibly caused by immobility, use of opioid medications, depression, lack of fibre in the diet, and dehydration • Diarrhea possible as muscles relax or as a result of fecal impaction related to the use of opioids and immobility	• Assess bowel function. • Assess for and remove fecal impactions. • Encourage movement and physical activities as tolerated. • Encourage fibre in the diet if appropriate. • Encourage fluid intake if appropriate. • Use suppositories, stool softeners, laxatives, or enemas if ordered. • Assess patient for confusion, agitation, restlessness, and pain, which may be signs of constipation.
Urinary Incontinence	
• May result from disease progression or changes in the level of consciousness • Relaxation of perineal muscles soon before death	• Assess urinary function. • Use absorbent pads for urinary incontinence. • Follow appropriate nursing protocol for the consideration and use of indwelling or external catheters. • Follow appropriate nursing management to prevent skin irritations and breakdown from urinary incontinence.
Anorexia, Nausea, and Vomiting	

Characteristics	Nursing Management
• May be caused by complications of disease process • Nausea exacerbated by drugs • All exacerbated by constipation, impaction, and bowel obstruction	• Assess the patient for complaints of nausea or vomiting. • Assess possible contributing causes of nausea or vomiting. • Have family provide the patient's favourite foods. • Discuss modifications to the drug regimen with the health care provider. • Provide antiemetics before meals if ordered. • Offer and provide frequent meals with small portions of favourite foods. • Offer culturally appropriate foods. • Provide frequent mouth care, especially after the patient vomits. • Ensure uninterrupted mealtimes. • If ordered, administer medications (e.g., megestrol, corticosteroids) to increase appetite. • Teach family that appetite naturally decreases at the end of life.
Candidiasis	
• White, cottage cheese–like oral plaques • Fungal overgrowth in the mouth as a result of chemotherapy, immunosuppression, or both	• Administer oral antifungal nystatin if ordered. • Clean dentures and other dental appliances to prevent re-infection. • Provide oral hygiene, and use a soft toothbrush.

Postmortem Care.

The **pronouncement of death** is not a reserved act or a delegated medical function, and is within the scope of nursing practice, for an expected death related to a terminal illness (College of Registered Nurses of British Columbia, 2015, p. 10). Although the death is anticipated, the pronouncement of death should be made with certainty and compassion. Death is considered to have occurred when cardiac and respiratory functions have ceased. The pronouncement of death is verification of an absence of an apical pulse and respirations and that the pupils are fixed and dilated. A **certification of death**—a legal medical document stating that the patient is dead—is usually required within 24 hours of a death. This function is in the purview of a physician or medical examiner, who is required to both sign the document and indicate the cause of death (College & Association of Registered Nurses of Alberta, 2011).

After the patient is pronounced dead, prepare or delegate preparation of the body for immediate viewing by the family with consideration for cultural customs and in accord with employer policies and procedures. In some cultures, it may be important to

allow the family to prepare or assist in caring for the body. In general, the nurse should close the eyes, replace dentures, wash the body as needed (placing pads under the perineum to absorb urine and feces), and remove tubes and dressings (if appropriate). The body is straightened, the pillow is positioned to support the head, and a small rolled towel is placed under the chin to hold the mouth closed.

The family should be allowed privacy and as much time as they need with the deceased person. In the case of an unexpected or unanticipated death, preparation of the patient's body for viewing or release to a funeral home depends on provincial law and employer policies and procedures. The deceased person should never be referred to as “the body.” Care of and discussion related to the person should continue to be respectful even after death.

Special Needs of Caregivers in End-of-Life Care

Special Needs of Family Caregivers

Family caregivers are important in meeting the patient's physical and psychosocial needs. The role of caregivers includes working and communicating with the patient and other family members, supporting the patient's concerns, and helping the patient resolve any unfinished business. Families often face emotional, physical, and economic consequences as a result of caring for a family member who is dying. The caregiver's responsibilities do not end when the person is admitted to an acute care, inpatient hospice, or long-term care facility.

An understanding of the grieving process as it affects both the patient and family is important. Being present during a family member's dying process can be highly stressful. The nurse should recognize signs and behaviours among family members who may be at risk for abnormal grief reactions, and be prepared to intervene if necessary. Warning signs may include dependency and negative feelings about the dying person, inability to express feelings, sleep disturbances, a history of depression, difficult reactions to previous losses, perceived lack of social or family support, low self-esteem, multiple previous bereavements, alcoholism, or substance abuse. Caregivers with concurrent life crises (e.g., divorce) will be especially at risk.

Family caregivers and other family members need encouragement to continue their usual activities as much as possible. They need to discuss their activities and maintain some control over their lives. The nurse should inform caregivers about appropriate resources for support, including respite care. Resources such as community counselling and local support may assist some people in working through their grief.

The nurse should encourage caregivers to build a support system of extended family, friends, faith community, and clergy. The

caregivers should have people to call on at any time to express any feelings they are experiencing.

Special Needs of Nurses

Many nurses who care for dying patients do so because they are passionate about providing high-quality EOL care. Caring for patients and their families at the end of life is challenging and rewarding but also intense and emotionally charged (Sliter, Sinclair, Yuan, et al., 2014). A bond or connection may develop between the nurse and the patient or family. The nurse should be aware of how grief personally affects him or her. When the nurse provides care for terminally ill or dying patients, he or she is not immune to feelings of loss. It is common to feel helpless and powerless when dealing with death. The nurse may need to express feelings of sorrow, guilt, and frustration. It is important to recognize one's own values, attitudes, and feelings about death.

Interventions are available that may help ease the nurse's physical and emotional stress. The nurse should be aware of what he or she can and cannot control. Recognizing personal feelings allows openness in exchanging feelings with the patient and family. Realizing that it is okay to cry with the patient or family during the end of life may be important for the nurse's well-being.

To meet the nurse's personal needs, she or he should focus on interventions that will help decrease stress. The nurse can get involved in hobbies or other interests, schedule time for her- or himself, ensure time for sleep, maintain a peer support system, and develop a support system beyond the workplace (Wittenberg-Lyles, Goldsmith, & Reno, 2014). Specialized hospice palliative care teams can help the nurse cope through professionally assisted groups, informal discussion sessions, and flexible time schedules.

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. The client is in the terminal stages of lung cancer. On assessment, it is noted that the client has alternating periods of apnea and deep, rapid breathing. Which of the following is the correct terminology to use in documenting this assessment data?
   a. Tachypnea
   b. Stertorous respirations
   c. Dyspnea
   d. Cheyne-Stokes respirations
2. The client has inoperable pancreatic cancer. Until recently, they have been very active in a book club, but no longer wants to attend. Which common end of life psychological manifestation is the client demonstrating?
   a. Decreased socialization
   b. Decreased disease progression
   c. Decreased sense of helplessness
   d. Decreased perception of pain and touch
3. A client died 2 years ago but his wife refuses to donate his belongings to charity. She often sits in the bedroom, crying and talking to her long-dead husband. What type of grief is the wife experiencing?
   a. Adaptive grief
   b. Disruptive grief
   c. Anticipatory grief
   d. Prolonged grief
4. A female client, in the terminal stages of a disease, experiences choking when she given food or fluids. The family is concerned that the client is starving. What is the most helpful response from the nurse? *(Select all that apply)*

a. “Allow me to show you how to moisten her mouth.”

b. “If you give her food, she will choke to death.”

c. “I can order you a tray and you can try to feed her if you like.”

d. “People who are dying usually don't experience hunger or thirst.”

5. The client did not have an advance directive when he suffered a serious stroke. Who is responsible for identifying end-of-life measures to be instituted when the patient cannot communicate his or her specific wishes?

   a. Adult children

   b. Notary and attorney

   c. Physician and family

   d. Physician and nursing staff

6. When a male client was diagnosed with renal failure, his new wife asked his children from a previous marriage to help with their father's care. Each of the children refused to help and his wife cared for him without help until his death. Which factors may predispose the children to an abnormal grief reaction? *(Select all that apply)*

   a. Negative feelings about the deceased person

   b. Lack of experience with other deaths in the family

   c. Difficulties with substance misuse

   d. Residing geographically far away

7. The nurse has been working full time with terminally ill clients for 3 years. The nurse has been experiencing irritability and mixed emotions when expressing sadness since four clients died on the same day. What should the nurse change to optimize the quality of her nursing care?

   a. Full-time work schedule

   b. Past feelings toward death

   c. Patterns for dealing with grief

   d. Demands for involvement in care

1. d; 2. a; 3. d; 4. a, d; 5. c; 6. a, b, c, d; 7. c.

SECTION 2

Pathophysiological Mechanisms of Disease

OUTLINE

Introduction

Source: BGSmith/Shutterstock.com.

CHAPTER 14

Inflammation and Wound Healing

Written by, Sharon L. Lewis

Adapted by, Beth Clarke

LEARNING OBJECTIVES

1. Explain the mechanisms that enable the cell to adapt to sublethal injury.
2. Describe the causes and mechanisms of lethal cell injury.
3. Differentiate among types of cell necrosis.
4. Describe the components and functions of the mononuclear phagocyte system.
5. Describe the inflammatory response, including vascular and cellular responses and exudate formation.
6. Explain local and systemic manifestations of inflammation and their physiological bases.
7. Describe the pharmacological, dietary, and nursing management of inflammation.
8. Differentiate between healing by primary, secondary, and tertiary intention.
9. Describe the factors that delay wound healing and common complications of wound healing.
10. Describe the risk assessment process for pressure injuries.
11. Discuss measures to prevent the development of pressure injuries.
12. Explain the causes and clinical manifestations of pressure injuries.
13. Discuss collaborative and nursing management of a patient with pressure injuries.

sublethal injury, p. 223
wet gangrene, p. 225

Cell Injury

Cell injury can be sublethal or lethal. **Sublethal injury** alters function without causing cell destruction. The changes caused by this type of injury are potentially reversible if the harmful stimulus is removed. **Lethal injury** is an irreversible process that causes cell death.

Cell Adaptation to Sublethal Injury

Cell adaptations to sublethal injuries are common and are part of many normal physiological processes, but they may also result from pathological changes. For example, prolonged exposure to sunlight stimulates melanin production, which provides protection of deeper skin layers; increased melanin production causes tanning of the skin. Lack of muscular activity can lead to atrophy and decreased tone of muscles. Adaptive processes of the cell include hypertrophy, hyperplasia, atrophy, and metaplasia. Other responses, which are considered maladaptive, are dysplasia and anaplasia.

Hypertrophy.

Hypertrophy is an expansion in the size of cells, which results in increased tissue mass without cell division. *Physiological hypertrophy* results from increased workload on an organ or tissue that is not caused by disease. Examples include an increase in the muscle mass that occurs during weight training, uterine expansion during pregnancy from hormonal stimulation, and enlargement of the sex organs during puberty. *Pathological hypertrophy* occurs as a result of disease: for example, enlargement and thickening of the heart ventricle in a person with severe hypertension in response to increased cardiac workload. *Compensatory hypertrophy* occurs in response to increased workload caused by reduced function: for example, when a kidney is removed, the remaining kidney enlarges as a result of increased work demand.

Hyperplasia.

Hyperplasia is a multiplication of cells as a result of increased cellular division. *Physiological hyperplasia* is an adaptive response to normal body changes. For example, cells of the uterus undergo hyperplasia during pregnancy, and the female breast undergoes hyperplasia during puberty and lactation. Examples of *pathological hyperplasia* are endometrial hyperplasia, caused by excessive estrogen secretion, and acromegaly, caused by excessive production of growth hormone. *Compensatory hyperplasia* is a process whereby cells of certain organs regenerate. For example, if portions of the liver are removed, the remaining cells undergo increased mitosis to compensate.

Atrophy.

Atrophy is a decrease in the size of a tissue or organ as a result of a reduction in the number or size of individual cells. It is frequently caused by disease (e.g., musculo-skeletal disease), lack of blood supply (e.g., thrombus formation), the natural aging process (e.g., atrophy of ovaries after menopause), inactivity (e.g., decreased muscle size), or nutritional deficiency.

Metaplasia.

Metaplasia is the transformation of one cell type into another in response to a change in physiological condition or an external irritant. An example of *physiological metaplasia* is the change of circulating monocytes to macrophages as they migrate into inflamed tissues. An example of *pathophysiological metaplasia* is the change of normal pseudostratified columnar epithelium of the bronchi to squamous epithelium in response to chronic cigarette smoking. These squamous cells can later become cancerous.

Dysplasia.

Dysplasia is an abnormal differentiation of dividing cells that results in changes in their size, shape, and appearance. Minor dysplasia is found in some areas of inflammation. Dysplasia is potentially reversible

if the stimulus for the change is removed. Dysplasia is frequently a precursor of malignancy, as in cervical dysplasia.

Anaplasia.

Anaplasia is cell differentiation to a more immature or embryonic form. Malignant tumours are often characterized by anaplastic cell growth.

Causes of Lethal Cell Injury

Many different agents and factors can cause lethal cell injury (Table 14-1). The mechanisms of actual cell death may include deterioration of the nucleus, such as pyknosis (nuclear condensation and shrinking), karyolysis (dissolution of nucleus and contents), disruption of cell metabolism, and rupture of the cell membrane. Microbial invasion often results in cell injury and death. Infection occurs when pathogens invade and multiply in body tissue.

TABLE 14-1
CAUSES OF LETHAL CELL INJURY

Cause	Effect on Cell
Hypoxia or ischemic injury	Compromised cell metabolism, acute or gradual cell death
Physical agents	
• Heat	Denaturation of protein, acceleration of metabolic reactions (see Chapter 27)
• Cold	Decreased blood flow from vasoconstriction, slowed metabolic reactions, thrombosis of blood vessels, freezing of cell contents that forms crystals and can cause cell to burst (see Chapter 71)
• Radiation	Alteration of cell structure and activity, alteration of enzyme systems, mutations (see Chapter 18)
• Electrothermal injury	Interruption of neural conduction, fibrillation of cardiac muscle, coagulative necrosis of skin and skeletal muscle (see Chapter 27)
• Mechanical trauma	Transfer of excess kinetic energy to cells, causing rupture of cells, blood vessels, tissue; examples include the following: *Abrasion:* scraping of skin or mucous membrane *Laceration:* severing of vessels and tissue *Contusion (bruise):* crushing of tissue cells, causing hemorrhage into skin *Puncture:* piercing of body structure or organ *Incision:* surgical cutting
Chemical injury	Alteration of cell metabolism, interference with normal enzymatic action within cells (see Chapter 27)
Microbial injury	
• Viruses	Taking over of cell metabolism and synthesis of new particles that may cause cell rupture; cumulative effect may produce clinical disease
• Bacteria	Destruction of cell membrane or cell nucleus, production of lethal toxins
Immunological*	
• Antigen–antibody response • Autoimmune response	Release of substances (histamine, complement) that can injure and damage cells Activation of complement, which destroys normal cells and produces inflammation (see Chapter 16)
Neoplastic growth	Cell destruction from abnormal and uncontrolled cell growth (see Chapter 18)
Normal substances (e.g., digestive enzymes, uric acid)	Release into abdomen, causing peritonitis and crystallization of excess accumulation in joints and renal tissue

*See Chapter 16 for a more detailed discussion.

Cell Apoptosis and Necrosis

Apoptosis and necrosis are the two fundamental types of cell death. Programmed cell death **(apoptosis)** is a normal, anticipated event that occurs in some regenerating tissues to create homeostasis, such as bone marrow, skin, and gut epithelium. In contrast, **necrosis** is tissue death that occurs as a result of a traumatic injury, infection, or exposure to a toxic chemical that causes a local inflammatory response, which results from the release of intracellular contents after the rupture of the outer membrane of the dead cells. Various types of tissue necrosis occur in different organs or tissues (Table 14-2; Figure 14-1).

TABLE 14-2

TYPES OF NECROSIS

Type	Description
Coagulative necrosis	Caused by ischemia. Ischemia results in decreased levels of adenosine triphosphate (ATP), increased levels of cytosolic Ca^{2+}, and free radical formation, each of which eventually causes membrane damage. A myocardial infarct is an example of a localized area of coagulative necrosis.
Liquefactive necrosis	Usually caused by focal bacterial infections because they can attract polymorphonuclear leukocytes (PMNs). The enzymes in the PMNs are released to fight the bacteria but also dissolve the tissues nearby, which causes pus to accumulate and the tissue to liquefy. An abscess is an example of a liquefactive necrotic process.
Caseous necrosis	A distinct form of coagulative necrosis that occurs in mycobacterial infections (e.g., tuberculosis) or in tumour necrosis, in which the coagulated tissue no longer resembles the cells but is in chunks of unrecognizable debris.
Gangrene	Necrosis of an appendage (usually the limbs). The term may also be used to describe necrosis of an appendix or gallbladder. This form of necrosis applies to ischemic necrosis, usually with superimposed bacterial action (wet gangrene) but sometimes in toes without bacterial effects (dry gangrene or mummification).

Source: Adapted from Krafts, K. (2012). *A quick summary of six types of necrosis*. Retrieved from *http://www.pathologystudent.com/?p=5770*.

FIGURE 14-1 Gangrene of the toes. Gangrenous necrosis 6 weeks after frostbite injury. Source: Courtesy of Cameron Bangs, MD. From Auerbach, P. S. (2007). *Wilderness medicine* (6th ed., p. 201). St. Louis: Elsevier.

Dry gangrene can result from degenerative changes that occur with certain chronic diseases, such as atherosclerosis or diabetes, when the blood supply to the lower extremities is gradually reduced (see Figure 14-1). **Wet gangrene**, which can quickly become fatal, occurs as the result of a sudden rapid elimination of blood flow, such as that seen in a severe burn or traumatic crush injury. It is malodorous because of extensive tissue liquefaction, which makes the affected area soft, and the odour is often indicative of a bacterial infection.

Defence Against Injury

To protect against injury and infection, the body has various defence mechanisms: (a) the skin and mucous membranes (see Chapter 25); (b) the mononuclear phagocyte system; (c) the inflammatory response; and (d) the immune system (see Chapter 16).

Mononuclear Phagocyte System

The *mononuclear phagocyte system* consists of monocytes and macrophages and their precursor cells. In the past, the mononuclear phagocyte system was called the *reticuloendothelial system*. However, it is not a body system with distinctly defined tissues and organs. Rather, it consists of phagocytic cells located in various tissues and organs. The phagocytic cells are either fixed or free (mobile). The macrophages of the liver, spleen, bone marrow, lungs, lymph nodes, and nervous system are fixed phagocytes. The monocytes in blood and the macrophages found in connective tissue are mobile, or wandering, phagocytes.

Monocytes and macrophages originate in the bone marrow. Monocytes spend a few days in the blood and then enter tissues and change into macrophages. Tissue macrophages are larger and more phagocytic than monocytes.

The functions of the macrophage system include recognition and phagocytosis of foreign material such as microorganisms, removal of old or damaged cells from circulation, and participation in the immune response (see Chapter 16).

Inflammatory Response

The **inflammatory response** is a biological response to cell injury caused by pathogens, irritants, or chronic health conditions. Through this response, the inflammatory agent is neutralized and diluted, necrotic materials are removed, and an environment suitable for healing and repair is established. The term *inflammation* should not be confused with *infection*. Infections almost always cause inflammation, but not all inflammations are caused by infections. Furthermore, neutropenic individuals may not mount an inflammatory response to infection. An infection involves invasion of tissues or cells by microorganisms such as bacteria, fungi, and viruses. Inflammation can also be caused by heat, radiation, trauma, chemicals, allergens, or an autoimmune reaction (see Table 14-1). Under these conditions, the presence of an infection represents a superimposed invasion of microorganisms.

The mechanism of inflammation is basically the same regardless of the injuring agent. The intensity of the response depends on the extent and the severity of injury and on the reactive capacity of the injured person. The inflammatory response can be divided into a vascular response, a cellular response, formation of exudate, and healing. Figure 14-2 illustrates the vascular and cellular responses to injury.

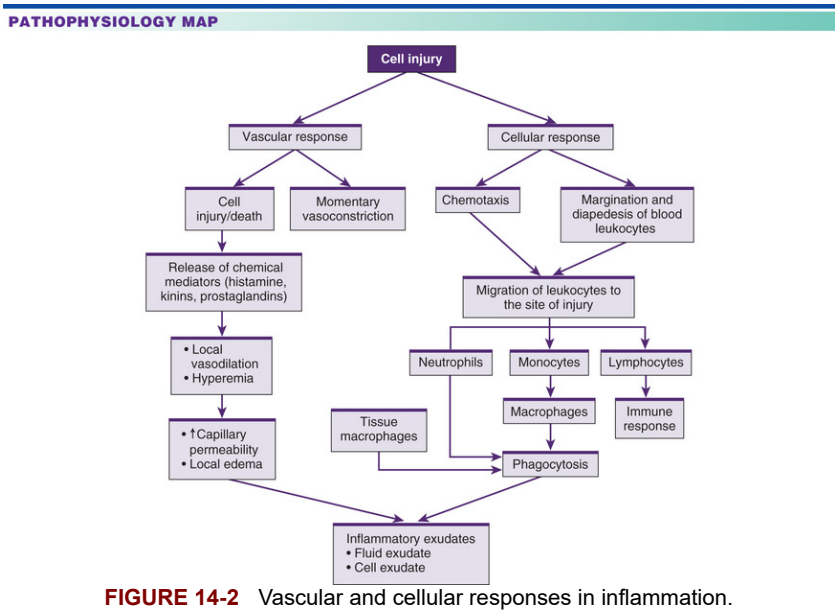

FIGURE 14-2 Vascular and cellular responses in inflammation.

Vascular Response.

After cell injury, arterioles in the area briefly undergo transient vasoconstriction, which is stimulated by the sympathetic nervous system. Platelets adhere to vessels and aggregate to seal the injured area, forming a fibrin-platelet clot, and they release proinflammatory mediators such as histamine, which cause vasodilation. This results in *hyperemia* (increased blood flow in the area) in which filtration pressure increases, causing endothelial cell retraction and an increase in capillary permeability. Movement of fluid from capillaries into tissue spaces is thus facilitated. Initially composed of serous fluid, this inflammatory exudate later contains plasma proteins, primarily albumin, which exerts oncotic pressure that further draws fluid from blood vessels, and the tissue become edematous.

As the plasma protein fibrinogen leaves the blood, it is activated by the products of the injured cells to become fibrin. Fibrin strengthens the blood clot formed by platelets. In tissue, the clot functions to trap bacteria, prevent their spread, and serve as a framework for the healing process. Platelets release growth factors that begin the healing process.

Cellular Response.

Phagocytes produce nitric oxide, whose role in the inflammatory response is to inhibit vascular smooth muscle contraction and growth, platelet aggregation, and leukocyte adhesion to endothelium. Cytokines are released by macrophages, which causes endothelial cells to express cellular adhesion molecules: **selectins** (cell surface carbohydrate-binding proteins that mediate cell adhesion, involved in leukocyte extravasation during the immune response) and **integrins** (cell receptors that mediate attachment between endothelial cells and surrounding tissues, also involved in leukocyte extravasation during the immune response). The blood flow through capillaries in the area slows as fluid is lost and viscosity increases. Neutrophils and monocytes move to the inner surface of the capillaries (margination) and then, in ameboid manner, through the capillary wall *(diapedesis)* to the site of injury.

Chemotaxis is the directional migration of white blood cells (WBCs) along a concentration gradient of chemotactic factors, which are substances that attract WBCs to the site of inflammation. Chemotaxis is the mechanism for ensuring accumulation of neutrophils and monocytes at the site of injury.

Neutrophils.

Neutrophils are the first leukocytes to arrive at the site of inflammation (within 6 to 12 hours). They phagocytize (engulf) bacteria, other foreign material, and damaged cells. Because of their short lifespan

(24 to 48 hours), dead neutrophils soon accumulate. In time, a mixture of dead neutrophils, digested bacteria, and other cell debris collect as a creamy substance *(pus).*

To keep up with the demand for neutrophils, the bone marrow releases more neutrophils into circulation. This results in an elevated WBC count, especially the neutrophil count. Sometimes the demand for neutrophils increases to the extent that the bone marrow releases immature forms of neutrophils (bands) into circulation. (Mature neutrophils are called *segmented neutrophils.*) The finding of increased numbers of band neutrophils in circulation is called *a shift to the left* and is commonly observed in patients with acute bacterial infections. (See Chapter 32 for a discussion of neutrophils.)

Monocytes.

Monocytes are the second type of phagocytic cells that migrate from circulating blood. They are attracted by chemotactic factors and usually arrive at the site within 3 to 7 days after the onset of inflammation. On entering the tissue spaces, monocytes transform into macrophages. Together with the tissue macrophages, they assist in phagocytosis of the inflammatory debris. The macrophage role is important in cleaning the area before healing can occur. Macrophages have a long lifespan; they may stay in the damaged tissues for weeks and multiply, and they are important in orchestrating the healing process.

In some cases, macrophages perform tasks other than phagocytosis. They may accumulate and fuse to form a *multinucleated giant cell.* The giant cell attempts to phagocytize particles too large for macrophages and is then encapsulated by collagen, which leads to the formation of a granuloma. A classic example of this process occurs in tuberculosis of the lung. Although the *Mycobacterium* bacillus is walled off, a chronic state of inflammation exists. The granuloma formed is a cavity of necrotic tissue.

Lymphocytes.

Lymphocytes arrive later at the site of injury. Their primary role is related to humoral and cell-mediated immunity (see Chapter 16).

Eosinophils and Basophils.

Eosinophils and basophils have a more selective role in inflammation. Eosinophils are released in large quantities during an allergic reaction. They release chemicals that act to control the effects of histamine and serotonin. They are also involved in phagocytosis of the allergen-antibody complex. Eosinophils contain highly caustic chemicals that are capable of destroying a parasite's cell surfaces. The histamine and heparin that basophils carry in their granules are released during inflammation.

Chemical Mediators.

Mediators of the inflammatory response are listed in Table 14-3.

TABLE 14-3

MEDIATORS OF INFLAMMATION

Mediator	Source	Mechanisms of Action
Histamine	Stored in granules of basophils, mast cells, platelets	Causes vasodilation and increased vascular permeability by stimulating contraction of endothelial cells and creating widened gaps between cells
Serotonin	Stored in platelets, mast cells, enterochromaffin cells of GI tract	Causes vasodilation and increased vascular permeability by stimulating contraction of endothelial cells and creating widened gaps between cells; stimulates smooth muscle contraction
Kinins (e.g., bradykinin)	Produced from precursor factor kininogen as a result of activation of Hageman factor (XII) of clotting system	Cause contraction of smooth muscle and dilation of blood vessels; result in stimulation of pain
Complement components (C3a, C4a, C5a)	Anaphylatoxic agents generated from complement pathway activation	Stimulate histamine release; stimulate chemotaxis
Fibrinopeptides	Produced from activation of the clotting system	Increase vascular permeability; stimulate chemotaxis for neutrophils and monocytes
Prostaglandins and leukotrienes	Produced from arachidonic acid	Prostaglandins E_1 and E_2 cause vasodilation; leukotriene B_4 stimulates chemotaxis
Cytokines	Secreted by white blood cells and other cells For more information on cytokines, see Table 16-3	Act as messengers between cell types; instruct cells to alter their proliferation differentiation, secretion, or activity

GI, gastrointestinal.

Complement System.

The complement system is an enzymatic cascade consisting of pathways to mediate inflammation and destroy invading pathogens. Major functions of the complement system are enhanced phagocytosis, increased vascular permeability, chemotaxis, and cellular lysis. All of these activities are important in the inflammatory response.

When the complement system is activated, the components are generated in the sequential order of C1, C4, C2, C3, C5, C6, C7, C8, and C9. The numbering reflects the order of their discovery. Some components have subparts designated by lowercase letters, such as C3a, C3b, and C5a. The primary pathway for activation of the complement system is through fixation of component C1 to an antigen–antibody complex. Immunoglobulins G and M are responsible for fixing complement. Each activated complex can act on the next component, which creates a cascade effect.

In an alternative pathway, C3 is activated without prior antigen–antibody fixation. Bacterial products, lipopolysaccharides, and neutrophil proteases can stimulate the complement sequence, beginning with C3 and with activation of C5 through C9.

Complement activation increases phagocytosis through opsonization and chemotaxis. *Opsonization* occurs when the antigen, in combination with complement factor C3b and immunoglobulin, sticks to the surface of phagocytic cells. This leads to more rapid phagocytosis. In addition, complement component C5a promotes chemotaxis.

The components C3a, C5a, and C4a are termed *anaphylatoxins* and bind to receptors on mast cells and basophils, thus triggering histamine release. Histamine causes smooth muscle contraction, vasodilation, and an increase in vascular permeability.

The entire complement sequence of C1 to C9 must be activated for cell lysis to occur. The final components (C8, C9) act on the cell surface, causing rupture of the cell membrane and lysis. In autoimmune disorders, healthy tissue can be damaged by complement activation and the resulting inflammatory response. Examples of this include rheumatoid arthritis and systemic lupus erythematosus.

Prostaglandins and Leukotrienes.

Prostaglandins are substances that can be synthesized from the phospholipids of cell membranes of most body tissues, including blood cells. On stimulation by chemotactic factors or phagocytosis or after cell injury, phospholipids can be converted to arachidonic acid, which is then oxidized by two different pathways.

The *cyclo-oxygenase metabolic pathway* leads to the production of prostaglandins of the D, E, F, and I series and of thromboxanes (formed on activation of platelets). Prostaglandins of the E and I series are potent vasodilators and inhibit platelet and neutrophil aggregation. Prostaglandin E_2 (PGE_2) can also sensitize pain receptors to arousal by stimuli that would normally be painless. PGE_2 is also a potent pyrogen, acting on the temperature-regulating area of the hypothalamus. Thromboxane A_2 is a potent vasoconstrictor and platelet-aggregating agent. Prostaglandins are generally considered proinflammatory, contributing to increased blood flow, edema, and pain. Metabolism of arachidonic acid by the lipoxygenase pathway leads to the production of leukotrienes. Leukotriene B_4 is a potent chemotactic factor. Leukotrienes C_4, D_4, and E_4 form the slow-reacting substance of anaphylaxis, which constricts smooth muscles of bronchi and increases capillary permeability.

Drugs that inhibit prostaglandin synthesis are useful clinically. Nonsteroidal anti-inflammatory drugs (NSAIDs) are used to treat many acute and chronic inflammatory conditions. Acetylsalicylic acid blocks platelet aggregation; it also has anti-inflammatory action. Prostacyclin (prostaglandin I_2) has been used to prevent platelet deposition in extracorporeal systems, such as hemodialysis and heart–lung bypass oxygenators.

Another group of drugs that inhibit prostaglandins is the corticosteroids. They are valuable in the treatment of asthma because they inhibit leukotriene production and thus prevent bronchoconstriction. (Other mediators of the inflammatory response are described in Table 14-3.)

Exudate Formation.

Exudate consists of fluid and leukocytes that move from the circulation to the site of injury. The nature and quantity of exudate depend on the type and the severity of the injury and the tissues involved

(Table 14-4).

TABLE 14-4

TYPES OF INFLAMMATORY EXUDATE

Type	Description	Examples
Serous	Results from fluid that has low cell and protein content; seen in early stages of inflammation or when injury is mild	Skin blisters, pleural effusion
Catarrhal	Found in tissues in which cells produce mucus; mucus production is accelerated by inflammatory response	Runny nose in association with upper respiratory tract infection
Fibrinous	Occurs with increasing vascular permeability and fibrinogen leakage into interstitial spaces; excessive amounts of fibrin coating of tissue surfaces may cause tissues to adhere	Adhesions
Purulent (pus)	Consists of WBCs, microorganisms (dead and alive), liquefied dead cells, and other debris	Furuncle (boil), abscess, cellulitis (diffuse inflammation in connective tissue)
Hemorrhagic	Results from rupture or necrosis of blood vessel walls; consists of RBCs that escape into tissue	Hematoma

RBCs, red blood cells; *WBCs*, white blood cells.

Clinical Manifestations.

The local manifestations of inflammation include redness, heat and swelling, and pain (Table 14-5). Systemic manifestations of inflammation include leukocytosis with a shift to the left, malaise, nausea and anorexia, increased pulse and respiratory rate, and fever. The causes of these systemic changes may be related to complement activation and the release of cytokines from stimulated WBCs. Three of these cytokines—interleukin-1, interleukin-6, and tumour necrosis factor—are important in causing the generalized symptoms of inflammation, such as malaise, as well as inducing fever. An increase in pulse and respiration follows the rise in metabolism as a result of a rise in body temperature. (Cytokines are discussed in Chapter 16.)

TABLE 14-5

LOCAL MANIFESTATIONS OF INFLAMMATION

Manifestations	Cause
Redness	Hyperemia from vasodilation
Heat	Increased metabolism at inflammatory site
Pain	Change in pH; nerve stimulation by chemicals (e.g., histamine, prostaglandins); pressure from fluid exudate
Swelling	Fluid shift to interstitial spaces; fluid exudates accumulation

Fever.

The release of cytokines initiates metabolic changes in the temperature-regulating centre of the hypothalamus, thus causing fever (Figure 14-3). The synthesis of PGE_2 is the most critical metabolic change because it acts directly to increase the thermostatic set point. The hypothalamus then activates the autonomic nervous system to stimulate increased muscle tone and shivering and decreased perspiration and blood flow to the periphery. Epinephrine released from the adrenal medulla increases the metabolic rate. The net result is fever.

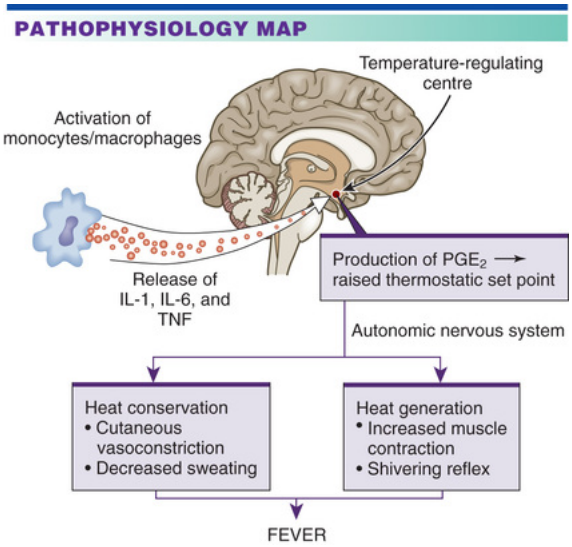

FIGURE 14-3 Production of fever. When monocytes or macrophages are activated, they secrete cytokines such as interleukin-1 (IL-1), interleukin-6 (IL-6), and tumour necrosis factor (TNF), which reach the hypothalamic temperature-regulating centre. These cytokines promote the synthesis and secretion of prostaglandin E_2 (PGE_2) in the anterior hypothalamus. PGE_2 increases the thermostatic set point, and the autonomic nervous system is stimulated, which results in shivering, muscle contraction, and peripheral vasoconstriction.

With the physiological thermostat fixed at a higher-than-normal temperature, the rate of heat production is increased until the body temperature reaches the new set point. As the set point is raised, the hypothalamus signals an increase in heat production and conservation to raise the body temperature to the new level. At this point, the affected individual feels chilled and shivers. The shivering response is the body's way of raising its temperature until the new set point is reached. The body is hot, and yet the individual paradoxically piles on blankets and may go to bed to get warm. When the circulating body temperature reaches the set point of the core body temperature, the chills and warmth-seeking behaviour cease (Dinarello & Porat, 2015). The febrile response is classified into four stages, described in Table 14-6.

TABLE 14-6

STAGES OF THE FEBRILE RESPONSE

Stage	Characteristics
Prodrome	Nonspecific complaints such as mild headache, fatigue, general malaise, muscle aches
Chill	Cutaneous vasoconstriction, "goose pimples," pale skin; feeling of being cold; generalized, shaking chill; shivering that causes body to reach new temperature set by control centre in hypothalamus
Flush	Sensation of warmth throughout body; cutaneous vasodilation; warming and flushing of skin
Defervescence	Sweating; decrease in body temperature

The released cytokines and the fever they trigger activate the body's defence mechanisms. Beneficial aspects of fever include increased killing of microorganisms, increased phagocytosis by neutrophils, and increased proliferation of T cells. Higher body temperatures may also enhance the activity of interferon, the body's natural virus-fighting substance (see Chapter 16).

Types of Inflammation.

The basic types of inflammation are acute, subacute, and chronic. In *acute inflammation,* the healing occurs in 2 to 3 weeks and usually leaves no residual damage. Neutrophils are the predominant cell type at the site of inflammation. A *subacute inflammation* has the features of the acute process but lasts longer. For example, infective endocarditis is a smouldering infection with acute inflammation, but it persists for weeks or months (see Chapter 39).

Chronic inflammation lasts for weeks, months, or even years. The injurious agent persists or repeatedly injures tissue. The predominant cell types present at the site of inflammation are lymphocytes and

macrophages. Examples of chronic inflammation include rheumatoid arthritis, osteomyelitis, and tuberculosis. The prolongation and chronicity of any inflammation may be the result of an alteration in the immune response (e.g. autoimmune disease). C-reactive protein is an acute-phase protein whose plasma concentration increases in response to inflammation, and thus it can be a useful inflammatory marker.

Healing Process.

The final phase of the inflammatory response is healing. Healing includes two major components: regeneration and repair. **Regeneration** is the replacement of lost cells and tissues with cells of the same type. **Repair** is healing as a result of lost cells being replaced by connective tissue. Repair is the more common type of healing and usually results in scar formation.

Regeneration.

The ability of cells to regenerate depends on the cell type (Table 14-7). Labile cells—such as cells of the skin, lymphoid organs, bone marrow, and mucous membranes of the gastrointestinal, urinary, and reproductive tracts—divide constantly. Injury to these organs is followed by rapid regeneration.

TABLE 14-7
REGENERATIVE ABILITY OF DIFFERENT TYPES OF TISSUES

Tissue Type	Regenerative Ability
Epithelial	
Skin, linings of blood vessels, mucous membranes	Cells readily divide and regenerate.
Connective Tissue	
Bone	Active tissue heals rapidly.
Cartilage	Regeneration is possible but slow.
Tendons and ligaments	Regeneration is possible but slow.
Blood	Cells actively regenerate.
Muscle	
Smooth	Regeneration is usually possible (particularly in GI tract).
Cardiac	Damaged muscle is replaced by connective tissue.
Skeletal	Connective tissue replaces severely damaged muscle; in moderately damaged muscle, some regeneration occurs.
Nerve	
Neurons	Cells of these tissues are generally nonmitotic; they do not replicate or replace themselves if irreversibly damaged.
Glial	Cells regenerate; scar tissue often forms when neurons are damaged.

GI, gastrointestinal.

Stable cells retain their ability to regenerate but do so only if the organ is injured. Examples of stable cells are liver, pancreas, kidney, and bone cells.

Permanent cells such as neurons of the central nervous system and cardiac muscle cells do not regenerate. Damage to these cells can lead to permanent loss. Healing occurs by repair with scar tissue.

Repair.

Repair is a more complex process than is regeneration. Most injuries heal by connective tissue repair. Repair healing occurs by primary, secondary, or tertiary intention (Figure 14-4).

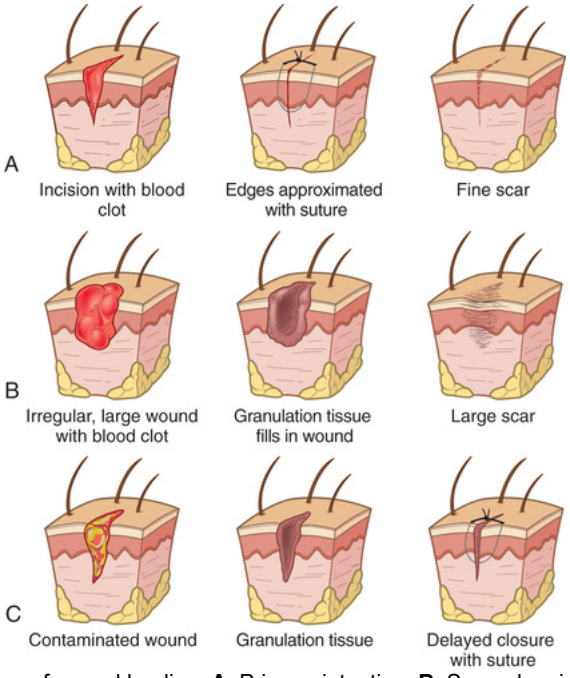

FIGURE 14-4 Types of wound healing. **A,** Primary intention. **B,** Secondary intention. **C,** Tertiary intention.

Primary Intention.

Primary intention healing takes place when wound margins are neatly approximated, as in a surgical incision or a paper cut. A continuum of processes is associated with primary healing (Table 14-8). These processes include three phases: the initial (inflammatory) phase, the granulation (proliferative/reconstructive) phase, and the maturation phase and scar contraction.

TABLE 14-8

PHASES IN PRIMARY INTENTION HEALING

Phase	Activity
Initial (3 to 5 days)	Approximation of incision edges; migration of epithelial cells; clot serving as meshwork for starting capillary growth
Granulation (5 days to 4 weeks)	Migration of fibroblasts; secretion of collagen; abundance of capillary buds; fragility of wound
Scar contracture (7 days to several months)	Remodelling of collagen; strengthening of scar

Initial (Inflammatory) Phase.

The initial phase lasts for 3 to 5 days. The edges of the incision are aligned and sutured (or stapled) in place. The incision area fills with blood from the cut blood vessels, and blood clots form and platelets release growth factors to begin the healing process. This forms a matrix for WBC migration and an acute inflammatory reaction occurs.

The area of injury is composed of fibrin clots, erythrocytes, neutrophils (dead and dying), and other debris. Macrophages ingest and digest cellular debris, fibrin fragments, and red blood cells. Extracellular enzymes from macrophages and neutrophils help digest fibrin. As the wound debris is removed, the fibrin clot serves as a framework for future capillary growth and migration of epithelial cells.

Granulation (Proliferative/Reconstructive) Phase.

The *granulation phase* is the second step and lasts from 5 days to 3 weeks. The components of granulation tissue include proliferating fibroblasts; proliferating capillary sprouts (angioblasts); various types of WBCs; exudate; and loose, semifluid, ground substance.

Fibroblasts are immature connective tissue cells that migrate into the healing site and secrete collagen. In time, the collagen is organized and restructured to strengthen the healing site. At this stage, it is termed *fibrous* or *scar tissue.*

During the granulation phase, the wound is pink and vascular. Numerous red granules (young budding capillaries) are present. At this point, the wound is friable, at risk for dehiscence, and resistant to infection.

Surface epithelium at the wound edges begins to regenerate. In a few days, a thin layer of epithelium migrates across the wound surface in a one-cell thick layer until it contacts cells spreading from the opposite direction. The epithelium thickens and begins to mature, and the wound now closely resembles the adjacent skin. In a superficial wound, re-epithelialization may take 3 to 5 days.

Maturation Phase and Scar Contraction.

The *maturation phase*, in which scar contraction occurs, overlaps with the granulation phase. It begins 7 days after the injury and continues for several months or years, during which time collagen fibres are further organized, and the remodelling process occurs. Fibroblasts disappear as the scar becomes stronger. The active movement of the myofibroblasts causes contraction of the healing area, helping to close the defect and bring the skin edges closer together to form a mature scar. In contrast to granulation tissue, a mature scar is virtually avascular and pale.

Secondary Intention.

Wounds with wide or irregular wound margins that cannot be approximated will heal by *secondary intention.* Examples include chronic wounds, such as venous ulcers, and wounds caused by trauma or pressure. The inflammatory reaction that occurs is often greater than in primary healing, which creates more debris, cells, and exudate. The debris may have to be cleaned away (debrided) before healing can take place.

In some instances, a surgical incision may become infected, which creates additional inflammation. The wound may reopen (dehiscence), and healing by secondary intention must then take place.

The process of healing by secondary intention is essentially the same as that of healing by primary intention. The major differences are the larger defect and the gaping wound edges. Healing and granulation take place from the edges inward and from the bottom of the wound upward until the defect is filled. There is more granulation tissue, and the result is a much larger scar.

Tertiary Intention.

Tertiary intention (delayed primary intention) healing occurs when a wound is intentionally left open because if the wound is closed immediately, healing could be impaired by contamination (e.g., animal bite or foreign body), infection/high risk of infection, edema, or poor circulation. The wound is later closed surgically after the problem is controlled or resolved. Healing by tertiary intention usually results in a larger and deeper scar than does healing by primary or secondary intention.

Wound Classification.

Correctly classifying a wound requires identifying the underlying cause. Wounds can be categorized by cause (surgical or nonsurgical), duration (acute or chronic), level of contamination, or depth of tissue affected (superficial, partial thickness, or full thickness). A superficial wound involves only the epidermis. Partial-thickness wounds extend into the dermis. Full-thickness wounds cause destruction to the deepest layer of tissue because they involve the subcutaneous tissue and sometimes even extend into the fascia and underlying structures such as muscle, tendon, or bone (see Figure 27-3). Pressure injuries are the only type of wound that are staged (Wound, Ostomy and Continence Nurses Society, 2016; see Table 14-13 later in this chapter).

Another system that is sometimes used clinically to categorize open wounds is based on the colour of the wound (red, yellow, black) rather than on the depth of tissue destruction (Figure 14-5). It can be used to describe any wound allowed to heal by secondary or tertiary intention. When a wound contains two or three colours at the same time, it should be classified according to the least desirable colour present (e.g., if there is any black in the wound, the wound is deemed “black”).

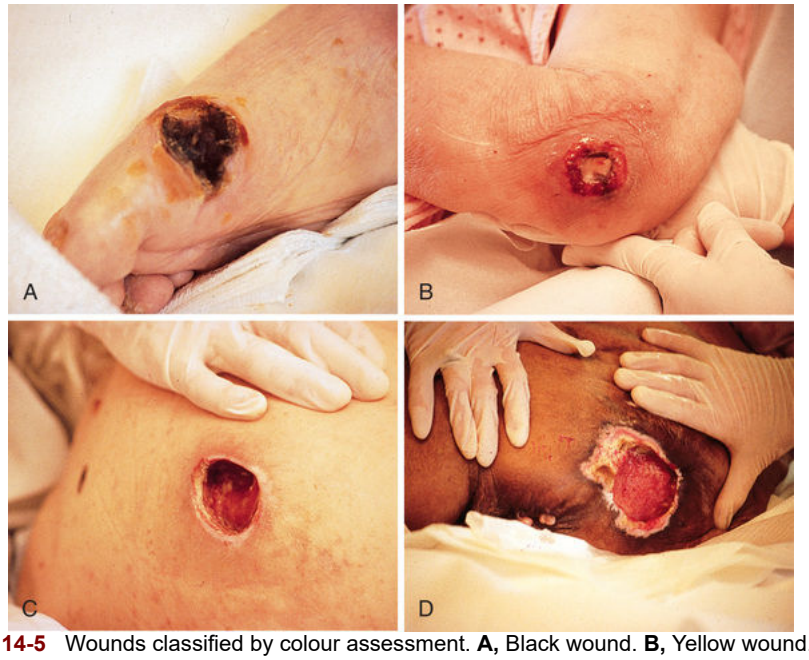

FIGURE 14-5 Wounds classified by colour assessment. **A,** Black wound. **B,** Yellow wound. **C,** Red wound. **D,** Mixed-colour wound. Source: Courtesy Molnlyche Health Care, Eddystone, PA. In Potter, P. A., & Perry, A. G. (2009). *Fundamentals of nursing* (8th ed., p. 1285). St. Louis: Elsevier.

Delay of Healing.

In a healthy person, wounds heal at a normal, predictable rate. Little can be done to accelerate this process. However, some factors delay wound healing. These are summarized in Table 14-9.

TABLE 14-9
FACTORS DELAYING WOUND HEALING

Factor	Effect on Wound Healing
Nutrition	
• Vitamin C deficiency	Delays formation of collagen fibres and capillary development
• Protein deficiency	Decreases supply of amino acids for tissue repair
• Zinc deficiency	Impairs epithelialization
Inadequate blood supply	Decreases supply of nutrients to injured area, decreases removal of exudative debris, inhibits inflammatory response
Smoking	Nicotine is a potent vasoconstrictor and impedes blood flow to healing areas, which results in tissue ischemia and impairs wound healing
Corticosteroid drugs	Impair phagocytosis by WBCs, inhibit fibroblast proliferation and function, depress formation of granulation tissue, inhibit wound contraction
Infection	Increases inflammatory response and tissue destruction
Anemia	Reduces supply of oxygen to tissues
Advanced age	Slows collagen synthesis by fibroblasts, impairs circulation, imposes need for longer time for epithelialization of skin, alters phagocytic and immune responses
Obesity	Decreases blood supply in fatty tissue
Diabetes mellitus	Decreases collagen synthesis, retards early capillary growth, impairs phagocytosis (result of hyperglycemia), reduces supply of O_2 and nutrients as a result of vascular disease
Poor general health	Causes generalized absence of factors necessary to promote wound healing
Mechanical friction on wound	Destroys granulation tissue, prevents apposition of wound edges
Cold temperature	Decreases cellular activity and fibroblast proliferation
Excessive moisture	Promotes formation of hypergranulation tissue, which prevents the migration of epithelial cells

WBCs, white blood cells.

Complications of Healing.

Complications of wound healing may include adhesions, contractures, dehiscence and evisceration, excess granulation tissue, fistula formation, infection, hemorrhage, and formation of hypertrophic scars and keloids.

Adhesions.

Adhesions are bands of scar tissue that form between or around organs. They may develop in the abdominal cavity or between the lungs and pleura. Adhesions in the abdomen may cause an intestinal obstruction. Those between the lungs and the pleura necessitate decortication, or stripping of pleura, to enable normal ventilation.

Contractures.

Wound contraction is an important part of healing. This process may become abnormal when contraction is excessive, which results in deformity, or *contracture.* Shortening of muscle or scar tissue, especially over joints, results from excessive fibrous tissue formation. Contractures frequently occur in burn injuries, when extensive skin and subcutaneous tissue are lost (see Chapter 27).

Dehiscence and Evisceration.

Dehiscence is the separation and disruption of previously joined wound edges. It usually occurs when a primary healing site bursts open (Figure 14-6). Dehiscence has three possible contributing causes. First, an infection may cause an inflammatory process. Second, the granulation tissue may not be strong enough to withstand the forces imposed on the wound: for example, if a fluid pocket (seroma or hematoma) develops between the tissue layers. Third, obese individuals are at a high risk for dehiscence because adipose tissue has less blood supply, which can slow healing. **Evisceration** occurs when wound edges separate to the extent that intestines protrude through the wound.

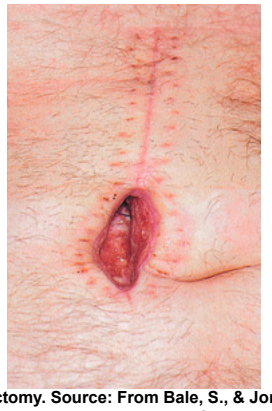

FIGURE 14-6 Dehiscence after a cholecystectomy. Source: From Bale, S., & Jones, V. (2006). ***Wound care nursing: A patient-centered approach*** (2nd ed., p. 20). St. Louis: Mosby.

Excess Granulation Tissue.

Excess granulation tissue or hypergranulation tissue ("proud flesh") may protrude above the surface of the healing wound. If the granulation tissue is cauterized or cut off, healing continues in a normal manner.

Fistula Formation.

A **fistula** is an abnormal passage that forms between organs or a hollow organ and the skin. For example, a connection between the bowel and the skin would be referred to as an *enterocutaneous fistula;* a connection between the bowel and the bladder would be referred to as an *enterovesical fistula.*

Infection.

A wound has an increased risk of *infection* when it contains necrotic tissue, when the blood supply is decreased, when the immune function is depressed, or if a patient is malnourished, has multiple stressors, or is diabetic.

Hemorrhage.

Bleeding is normal immediately after tissue injury and ceases with clot formation. *Hemorrhage* occurs as abnormal internal or external blood loss caused by suture failure, clotting abnormalities, dislodged clot, infection, or erosion of a blood vessel by a foreign object (tubing, drains) or infection process.

Formation of Hypertrophic Scars and Keloids.

Hypertrophic keloid scars form when the body produces excess collagen. A **hypertrophic scar** is inappropriately large, red, raised, and hard (Figure 14-7). However, it remains confined to the wound edges and regresses in time. In contrast, a **keloid** is a protrusion of scar tissue that extends beyond the wound edges and may form tumour-like masses of scar tissue (Figure 14-8). Keloids are permanent, without any tendency to subside. A person with keloids often feels tenderness, pain, and hyperesthesia in the area of the scar, particularly in the early stages of development. Keloid formation is thought to be hereditary and occurs more often in dark-skinned people, particularly Black individuals. Neither complication is life-threatening, but both can have serious cosmetic implications.

Nursing Management Inflammation and Healing

Nursing Implementation

Health Promotion.

The best management of inflammation is the prevention of infection, trauma, surgery, and contact with potentially harmful agents. This is not always possible; for example, a simple mosquito bite causes an inflammatory response. Because occasional injury is inevitable, concerted efforts to minimize inflammation and infection are needed.

Adequate nutrition is essential so that the body has the necessary factors to promote healing when injury occurs. Individuals at risk for wound-healing complications are those with malabsorption problems (e.g., Crohn's disease, gastrointestinal surgery, liver disease), deficient intake or high energy demands (e.g., malignancy, major trauma or surgery, sepsis, fever), or diabetes. An individual should always be considered at risk for delayed wound healing if the following have occurred: (a) loss of 20% or more of total body weight in the preceding 6 months or (b) 10% loss of total body weight in the preceding 2 months.

Special nutritional measures facilitate wound healing. Fluid intake must be high to replace fluid loss from perspiration and exudate formation. An increased metabolic rate intensifies water loss. For every 1°C increase in body temperature above 37.8°C, metabolism increases by 13%. A diet high in protein, carbohydrate, and vitamins with moderate fat intake is necessary to promote healing. Protein is needed to correct the negative nitrogen balance that results from the increased metabolic rate. Protein is also necessary for synthesis of immune factors, leukocytes, fibroblasts, and collagen. Carbohydrate is needed for the increased metabolic energy required for inflammation and healing. If carbohydrate intake is deficient, the body breaks down protein for the needed energy. Fats are also a necessary component in the diet to help in the synthesis of fatty acids and triglycerides, which are part of the cellular membrane. Vitamin C is needed for capillary synthesis, capillary formation, and resistance to infection. The B-complex vitamins are necessary as coenzymes for many metabolic reactions. If a vitamin B deficiency develops, metabolism of protein, fat, and carbohydrate is disrupted. Vitamin A is also needed in healing because it aids in the process of epithelialization. It increases collagen synthesis and tensile strength of the healing wound. Patients are sometimes given vitamin A to counteract the effects of steroids on wound healing.

If the patient is unable to eat, enteral feedings and supplements should be the first choice if the gastrointestinal tract is functional. Parenteral nutrition is indicated when enteral feedings are contraindicated or not tolerated. (Enteral nutrition and parenteral nutrition are discussed in Chapter 42.)

The manifestations of inflammation and infection must be recognized early so that appropriate treatment can begin. Treatment may be rest, drug therapy, or specific care of the injured site. Immediate treatment may prevent the extension and complications of prolonged inflammation.

Acute Intervention

Observation and Vital Signs.

The ability to recognize the clinical manifestations of inflammation is important. In a patient who is immunosuppressed (e.g., taking corticosteroids or receiving chemotherapy), the classic manifestations of inflammation may be masked. In such a patient, early symptoms of inflammation may be malaise or "just not feeling well."

Observation and recording of wound characteristics are essential. The consistency, colour, and odour of any drainage should be recorded and reported if abnormal. *Staphylococcus* and *Pseudomonas* organisms commonly cause purulent drainage. Exudate from wounds colonized with *Pseudomonas* often has a distinctive bright "highlighter" yellow or green appearance.

Vital signs are important to note with any inflammation, especially when an infectious process is present. When infection is present, temperature may rise, and pulse and respiration rates may increase. If a wound infection develops in a postoperative patient, vital signs change within 3 to 5 days after surgery.

Fever.

Although fever is usually regarded as harmful, an increase in body temperature is an important host defence mechanism. Steps are frequently taken to lower body temperature to relieve the anxiety of the patient and medical personnel. Because a mild fever does little harm, imposes no great discomfort, and may benefit host defence mechanisms, antipyretic drugs are rarely essential for patient welfare. Moderate fevers (up to 39.5°C) usually produce few problems in most patients. However, if the patient is very young or very old, is extremely uncomfortable, or has a significant medical problem (e.g., severe cardiopulmonary disease, brain injury), the use of antipyretics should be considered. Fever in an immunosuppressed patient should be treated rapidly and antibiotic therapy begun because infections can rapidly progress to septicemia. (Neutropenia is discussed in Chapter 33.)

Fever (especially if the temperature exceeds 40°C) can be damaging to body cells, and delirium and seizures can occur. At temperatures higher than 41°C, regulation by the hypothalamic temperature control centre becomes impaired, and many cells, including those in the brain, can be damaged.

Older adults have a blunted febrile response to infection (Dinarello & Porat, 2015). The body temperature may not rise to the level expected for a younger adult, or the onset of fever may be delayed. The blunted response can delay diagnosis and treatment. By the time fever (as defined for younger adults) is present, the illness may be severe.

Several drugs are commonly used to lower the body temperature set point in the hypothalamus (Table 14-10). Aspirin specifically blocks prostaglandin synthesis in the hypothalamus and elsewhere in the body. Acetaminophen acts on the heat-regulating centre in the hypothalamus. Some NSAIDs (e.g., ibuprofen [Motrin, Advil]) have antipyretic effects. Corticosteroids are antipyretic through the dual mechanisms of inhibiting interleukin-1 production and preventing prostaglandin synthesis. The action of these drugs results in dilation of superficial blood vessels, increased skin temperature, and sweating.

TABLE 14-10
DRUG THERAPY
Inflammation and Healing

Drug	Mechanisms of Action
Antipyretic Drugs	
Salicylates (Aspirin)	Lower temperature by action on heat-regulating centre in hypothalamus, resulting in peripheral dilation and heat loss; interfere with formation and release of prostaglandins; selectively depress CNS
Acetaminophen (Tylenol)	Lowers temperature by action on heat-regulating centre in hypothalamus
NSAIDs (e.g., ibuprofen [Motrin, Advil])	Inhibit synthesis of prostaglandins
Anti-inflammatory Drugs	
Salicylates (Aspirin)	Inhibit synthesis of prostaglandins, reduce capillary permeability
Corticosteroids (e.g. prednisone)	Interfere with tissue granulation, induce immunosuppressive effects (decreased synthesis of lymphocytes), prevent liberation of lysosomes
NSAIDs (e.g., ibuprofen [Motrin], naproxen [Naprosyn], celecoxib [Celebrex])	Inhibit synthesis of prostaglandins
Vitamins	
Vitamin A	Accelerates epithelialization
Vitamin B complex	Acts as coenzymes
Vitamin C	Assists in synthesis of collagen and new capillaries
Vitamin D	Facilitates calcium absorption

CNS, central nervous system; *NSAIDs*, nonsteroidal anti-inflammatory drugs.

Antipyretics should be given around the clock to prevent acute swings in temperature. These agents cause a sharp decrease in temperature. When the antipyretic wears off, the body may initiate a compensatory involuntary muscular contraction (i.e., chill) to raise the body temperature back up to its previous level. To prevent this unpleasant adverse effect, these agents should be administered regularly at 2- to 4-hour intervals. Although sponge baths increase evaporative heat loss, there is no evidence that they decrease the body temperature unless antipyretic drugs have been given to lower the set point; otherwise, the body will initiate compensatory mechanisms (e.g., shivering) to restore body heat. The same principle applies to the use of cooling blankets; they are most effective in lowering body temperature when the set point has also been lowered. The nursing care of the patient with a fever is presented in Nursing Care Plan 14-1, available on the Evolve website.

RICE.

Rest, ice, compression, and elevation (RICE) constitute a key concept in the treatment of soft tissue injuries and related inflammation.

Rest.

Rest helps the body use its nutrients and oxygen for the healing process. The repair process is facilitated when fibrin and collagen are allowed to form across the wound edges with little disruption.

Ice and Heat.

At the time of initial trauma, cold application is usually appropriate to promote vasoconstriction and decreases swelling, pain, and congestion from increased metabolism in the area of inflammation. Heat may be used later (e.g., after 24 to 48 hours) and when swelling has subsided to promote healing by increasing the circulation to the inflamed site and subsequent removal of debris. Heat is also used to localize the inflammatory agents. Warm, moist heat may help debride the wound site if necrotic material is present.

Compression and Immobilization.

Compression counters vasodilation and development of edema after an injury. Compression by direct pressure over a laceration occludes blood vessels to stop bleeding. Compression bandages provide support to injured joints that have tendons and muscles unable to provide support on their own. Distal pulses and capillary refill should be assessed before and after application of compression to assess whether compression has compromised circulation (e.g., as evidenced by pale colour of skin or loss of sensation).

Immobilization of the inflamed area promotes healing by decreasing the tissues' metabolic need. Immobilization with a cast, splint, or bandage supports fractured bones and prevents further tissue injury from sharp bone fragments that could sever nerves or blood vessels (causing hemorrhage).

Elevation.

Elevation of an injured extremity reduces the edema at the inflammatory site by increasing venous and lymphatic return. Elevation helps reduce pain associated with blood engorgement at the injured site. Elevation may be contraindicated in patients with significantly reduced arterial circulation.

Wound Management.

The type of wound management and dressings required depend on the type, extent, and characteristics of the wound and the phase of healing (Registered Nurses' Association of Ontario [RNAO], 2016). The purposes of wound management include (a) cleaning and debriding the wound to remove debris and dead tissue from the wound bed, (b) controlling inflammation and treating infection to prepare the wound for healing, and (c) providing moisture balance for healable wounds, and moisture reduction for nonhealable and maintenance wounds (Sibbald, Elliott, Ayello, et al., 2015). Treatment of pressure injuries is discussed in more detail later in this chapter.

For wounds that heal by primary intention, it is common to cover the incision with a dry, sterile dressing that is removed as soon as the drainage stops or in 2 to 3 days. Protective sprays or wipes that form a transparent film on the skin may be used for dressings on a clean incision or injury. Sometimes a surgeon leaves a surgical wound uncovered or removes the dressing within 48 hours after surgery (Lisy, 2014).

Evidence-Informed Practice

Research Highlight

What Is the Effect of Tap Water on Wound Cleansing?

Clinical Question

In patients with an infected wound (P), what is the effect of tap water (I) versus normal saline or no cleansing (C) on infection and healing rates (O)?

Best Available Evidence

Randomized controlled trials and quasi-randomized controlled trials

Critical Appraisal and Synthesis of Evidence

- Ten trials (n = 35 to 705 per trial) involving people who had acute infected wounds. In seven trials, researchers compared infection and healing rates between wounds treated with water and those treated with normal saline. In three trials, investigators compared wound cleansing (with various solutions) with no cleansing at all.
- No significant differences were found in infection rate and healing between wounds cleansed with tap water and those not cleansed at all.
- Tap water was more effective than saline in reducing wound infection rate.

Conclusion

- Using tap water to cleanse acute wounds does not increase infection rate and, in some cases, it may reduce infection.

Implications for Nursing Practice

- The option of using tap water should be carefully considered when other wound cleansing solutions are not accessible.
- Water quality, type of wound, and the patient's overall health should be evaluated before tap water is used.
- If potable tap water is not available, boiled water that is cooled or distilled water may be used in wound cleansing.

P, Patient population of interest; *I,* intervention or area of interest; *C,* comparison of interest or comparison group; *O,* outcomes of interest (see Chapter 1).

Fernandez R, Griffiths R. Water for wound cleansing. *Cochrane Database Syst Rev*. 2012;(2) [CD003861].

Wound healing management by secondary intention depends on the cause of the wound and the type of tissue in the wound. The red-yellow-black concept of wound care (see Figure 14-5) can be used to describe the wound, and dressing selection depends on the characteristics of the wound. Examples of wound dressing types are presented in Table 14-11.

TABLE 14-11

TYPES OF WOUND DRESSINGS

Type	Description	Examples
Gauze	Provides absorption of exudate. Supports debridement if applied and kept moist. Can be used to maintain moistness of wound surface. Can be used as filler dressings in sinus tracts.	Nu Gauze (numerous products available)
Nonadherent dressing	Woven or nonwoven dressings may be impregnated with petrolatum or antimicrobial drugs. Minimally absorbent. Used on minor wounds or skin tears.	Adaptic, Jelonet, Bactigras, Inadine
Transparent film	Semipermeable membrane that permits gaseous exchange between wound bed and environment. Minimally absorbent so that environment is kept moist in presence of exudate. Bacteria do not penetrate membrane. Used for dry, noninfected wounds, wounds with minimal drainage, or stage 1 pressure injuries to help prevent friction and shear.	Bioclusive, OpSite, Tegaderm, Mefilm
Acrylic clear	Used for superficial and partial-thickness wounds with light drainage.	Tegaderm Absorbent
Hydrocolloid dressing	Occlusive dressing does not allow O_2 to diffuse from atmosphere to wound bed. Occlusion does not interfere with wound healing and supports debridement. Used for superficial and partial-thickness wounds with light to moderate drainage.	Comfeel, DuoDERM, Restore, Tegasorb
Foam	Product comes in many shapes and sizes. Absorbs moderate to heavy amount of exudate. Used for partial- or full-thickness wounds or infected wounds.	Allevyn, Hydrasorb, Lyofoam, Mepilex, Biatain, Tegaderm Foam
Alginate, calcium alginate, and hydrofibre dressings	Large volume of exudate can be absorbed. Dressing forms a gel-like substance that supports autolytic debridement and maintains moistness of wound surface. Fills wound cavities and obliterates dead space. Available in rope or sheet form. For partial- or full-thickness wounds or infected wounds with heavy drainage. Dressing should not be used for lightly draining or dry wounds because it can desiccate the wound bed. A secondary dressing is required.	Aquacel, Kaltostat, Tegagen, Seasorb, Fibracol, Algisite, Algisite M, Melgisorb
Hypertonic dressing	Sheet, ribbon, or gel impregnated with sodium chloride concentrate. Should not be used on dry wounds (which should be treated with a hydrogel). May be painful on sensitive tissue.	Mesalt, Hypergel
Hydrogel	Gently eliminates necrotic tissue by autolytic debridement. Maintains moistness of wound surface. Provides limited absorption of exudate. Available as sheet, gel, and impregnated gauze. A secondary dressing is required. Used for partial- or full-thickness wounds with minimal drainage, and necrotic wounds. Has a cooling effect on the wound and thus is effective in managing pain.	IntraSite Gel, DuoDERM Hydroactive Gel, Normlgel, Nu-Gel, Tegagel, Tegaderm Hydrogel wound filler
Charcoal dressing	Dressing that contains odour-absorbent charcoal layered within the product. Some products contain silver to enhance antimicrobial capability.	Actisorb, Carbonet, CarboFlex
Antimicrobial dressing	Broad spectrum against bacteria. Silver, polyhexamethylene biguinide (PHMB), cadexomer iodine, methylene blue/crystal violet, or honey with vehicle for delivery: sheets, foams, alginates, ribbons, gels, or paste. Products are not to be used on patients with known hypersensitivity to any product components.	Acticoat, AMD Antimicrobial Foam, Iodosorb, Allevyn Ag, Mepilex Ag, Aquacel Ag, Contreet, Silvercel, SilvaSorb, Tegaderm Ag Mesh, Hydrofera Blue, Medihoney
Biological dressing	Living human fibroblasts provided in sheets at ambient or frozen temperatures. Extracellular matrix. Collagen-containing preparations. Hyaluronic acid. Not to be used on wounds with infections, sinus tracts, or excessive exudate, or on patients with hypersensitivity to any of the product components.	Apligraf, Dermagraft, Oasis Wound Matrix, Promogran, Tegaderm Matrix

Source: Information on antimicrobials and biological dressings from Sibbald, G., Orsted, H., Coutts, P., & Keast, D. (2006). Best practice recommendations for preparing the wound bed: Update 2006. *Wound Care Canada, 4*(1), 309–405.

Red Wound.

A *red wound* can be superficial or deep and is clean and red or pink in appearance. Examples include skin tears, pressure injuries, partial-thickness or second-degree burns, and wounds created surgically that are allowed to heal by secondary intention. The goal of treatment is gentle cleansing and protection of the wound (LeBlanc & Baranoski, 2014). Wounds should be cleaned with normal saline, potable or sterile water, or noncytotoxic wound cleansers (RNAO, 2016). Clean wounds that are granulating and re-epithelializing should be kept slightly moist and protected from further trauma until they heal naturally (Ayello & Baranoski, 2014). A dressing that keeps the wound surface clean and slightly moist is optimal in promoting epithelialization. Unnecessary manipulation during dressing changes may destroy new granulation tissue and break down fibrin formation.

Yellow Wound.

A *yellow wound* has nonviable necrotic tissue, which creates an ideal environment for bacterial growth. The goal of treatment is absorption of excessive drainage and removal of nonviable tissue (described in the next section). Topical antimicrobials and bactericidals (e.g., povidone-iodine, sodium hypochlorite [Dakin's solution], hydrogen peroxide, acetic acid, and chlorhexidine) may be used to cleanse wounds containing debris that are highly colonized or infected. They should never be used to treat clean granulating wounds (RNAO, 2016).

Black Wound.

A *black wound* is covered with thick, dry, necrotic tissue called *eschar* that is black, brown, or grey. Examples of black wounds include third-degree burns and gangrenous ulcers. The risk of wound infection increases in proportion to the amount of necrotic tissue present. The immediate treatment is removal of the nonviable eschar. The debridement method used depends on the amount of debris and the condition of the wound tissue (Wilcox, Carter, & Covington, 2013). There are several approaches to debridement:

1. *Surgical debridement.* This fast and cost-effective method of debridement is indicated when large amounts of tissue are nonviable and the patient has sepsis. Sharp surgical debridement is selective and can be performed in the operating room or at the patient's bedside, depending on the extent of necrotic material (Woo, Keast, Parsons, et al., 2015). Only wounds that have an adequate blood supply and are considered "healable" should be debrided surgically.
2. *Mechanical debridement.* This method is used when debris is minimal. One example is wet-to-dry dressings, in which open-mesh gauze is moistened with normal saline, packed into the wound surface, and allowed to dry. Wound debris adheres to the dressing. When the dressing is removed, the debris is trapped in the gauze and is mechanically separated from the wound bed. One disadvantage to this method is that it is nonselective and destroys some healthy tissue. Mechanical debridement can be painful, and the patient should receive appropriate pain management before the removal of a wet-to-dry dressing. Another method of mechanical debridement is pressurized wound irrigation, in which water is delivered at high or low pressure to remove bacteria, foreign matter, and necrotic tissue from the wound. It is important to ensure that the pressure is not too high, as this could drive bacteria and debris deeper into the wound and damage granulation tissue. Whirlpool is another method of mechanical debridement that can be effective at loosening and removing surface wound debris, but it should be used with caution because it can cause tissue maceration and bacterial cross-contamination. Mechanical debridement should not be used for clean granulating wounds.
3. *Autolytic debridement.* Hydrogels, semiocclusive dressings, or occlusive dressings (see Table 14-11) may be used to promote softening of dry eschar by autolysis. This is a slow but selective and painless process that enables the body's own endogenous enzymes to selectively rehydrate, soften, and liquefy necrotic tissue. These types of dressings are used in noninfected wounds with necrotic tissue and adequate circulation. The use of a skin protectant around the wound helps prevent maceration.
4. *Enzymatic debridement.* In this method, a topical ointment containing proteolytic enzymes is applied to the necrotic tissue in the wound and then covered with a moist dressing such as saline-moistened gauze and changed daily. Santyl collagenase is the only product in this category currently available in Canada. The wound pH must be between 6 and 8 for optimal enzyme activity; therefore, cleansing products containing detergents or heavy metals such as mercury or silver should not be used.
5. *Biosurgical debridement.* In this debridement method, medical grade maggots are applied directly to a wound in a controlled and contained environment. The maggots clean the wound by digesting dead tissue with their proteolytic, digestive enzymes. They also kill bacteria by ingesting them and can destroy biofilm.

Negative-Pressure Wound Therapy.

This therapy involves the application of negative pressure (suction) to the wound bed. The vacuum creates continuous or intermittent negative pressure at the wound base to remove fluid, exudate, and infectious material and to promote blood flow. The wound is cleansed, and the periwound area is

protected with a skin protectant and transparent film. Then a foam or gauze dressing (depending on the manufacturer) is cut to the dimensions of the wound. A large occlusive dressing is applied over the top, and a small hole is made over the dressing where the tubing is attached (Figure 14-9). Wound types suitable for this therapy include chronic, acute, traumatic, and dehisced wounds; partial-thickness burns; diabetic ulcers; stage 3 and stage 4 pressure injuries; flaps; and grafts. Contraindications include malignancy, untreated osteomyelitis, fistula, eschar, and active bleeding. It is important to count and document the number of pieces of foam or gauze used in the wound. For further information on negative-pressure wound therapy, refer to the Ontario Ministry of Health and Long-Term Care document *Negative Pressure Wound Therapy* (see the Resources at the end of this chapter).

Source: From Abai, B., Zickler, R. W., Pappas, P. J, et al. (2007). Lymphorrhea responds to negative pressure wound therapy. *Journal of Vascular Surgery, 45*(3),610–613. doi:http://dx.doi.org/10.1016/j.jvs.2006.10.043.

Hyperbaric Oxygen Therapy.

Hyperbaric oxygen therapy is the systemic delivery of oxygen at increased atmospheric pressures. The patient is placed in an enclosed chamber in which 100% oxygen is administered at 1.5 to 3.0 times the normal atmospheric pressure. This form of therapy accelerates granulation tissue formation and wound closure by increasing blood and tissue oxygen content in hypoxic tissues, which stimulates fibroblast proliferation and collagen synthesis.

Electrical Stimulation.

With this therapy, a generator connected to electrodes is attached to the periwound skin, and an electrical charge is delivered to the wound tissues to produce a physiological response. Electrical stimulation may be used as an adjunct to regular wound care to promote healing and wound closure with stalled but healable stage 2, 3, and 4 pressure injuries that have not responded to other interventions. It should not be used if a patient has osteomyelitis, cancer, an implanted electronic device, or a blood clot in the leg. It should never be applied over a pregnant uterus, dressings with metallic or ionic components, or excitable tissues.

Psychological Implications.

The patient may be distressed at the thought or sight of an incision or wound because of fear of scarring or disfigurement. Drainage from a wound may also cause alarm. The patient needs to understand the healing process and the normal changes that occur as the wound heals. When a nurse is changing a dressing, inappropriate facial expressions can alert the patient to problems with the wound or the nurse's ability to care for it. Wrinkling of the nose by the nurse may convey disgust to the patient. A nurse should also be careful not to focus on the wound to the extent that the patient is not treated as a total person.

Ambulatory and Home Care.

Because patients are being discharged earlier after surgery and many undergo surgery as outpatients, it is important that the patient, the family, or both know how to care for the wound and perform dressing

changes. Wound healing may not be complete for 4 to 6 weeks or longer. Adequate rest and good nutrition are essential. Physical and emotional stress should be minimized. The wound should be observed for complications such as infection. The patient should be able to recognize the signs and symptoms of infection and note changes in wound colour and the amount of drainage. The health care provider should be notified of any signs of abnormal wound healing.

Medications are often taken for a period after recovery from an acute infection. Drug-specific adverse effects should be reviewed with the patient, and he or she should be instructed to contact the health care provider if any of these effects occur. The patient must be taught the necessity to continue the drugs for the specified time. For example, a person who is instructed to take an antibiotic for 10 days may stop taking the drug after 5 days because symptoms disappear. However, if a full course of antibiotic is not taken, the infection may not be entirely eliminated, and remaining organisms may also become resistant to the antibiotic.

Pressure Injuries

Causes and Pathophysiological Features

A **pressure injury** is a localized injury to the skin or underlying soft tissue, usually over a bony prominence or related to a medical or other device as a result of pressure or pressure in combination with shear, friction, or both. Pressure injuries are generally considered an indicator of the quality of care, and most are regarded as avoidable. However, there are instances in which skin breakdown can be considered unavoidable: in the case of patients who have limited movement because of hemodynamic instability; inability to provide nutrition and fluids; or at the end of life (Edsberg, Langemo, Baharestani, et al., 2014).

According to the Canadian Institute for Health Information, pressure injuries are a financial burden to the health care system, in addition to the effect they have on mortality, morbidity, and quality of life. The prevalence of pressure injuries in Canada was reported as 0.4% in acute care, 2.4% in home care, 14.1% in complex continuing care, and 6.7% in long-term care (Canadian Institute for Health Information, 2013). The most common sites for pressure injury development are the sacrum, ischium, trochanter, coccyx, heels, and malleolus. Factors that influence the development of pressure injuries include the intensity and duration of the pressure, as well as the ability of the patient's tissue to tolerate the externally applied stress (Doughty & McNichol, 2016). Besides pressure, **shearing force** (pressure exerted on the skin when it adheres to the bed and the underlying skin layers slide in the direction of body movement), *friction* (two surfaces rubbing against each other), and *excessive moisture* (incontinence or perspiration) contribute to pressure injury formation (RNAO, 2016). Factors that increase a patient's risk for the development of pressure injuries are presented in Table 14-12. A pressure injury risk assessment and comprehensive skin assessment should be conducted within 8 hours of the patient's admission and with any change in patient condition. A risk-based prevention plan should then be developed (National Pressure Ulcer Advisory Panel [NPUAP], 2014).

TABLE 14-12

RISK FACTORS FOR PRESSURE INJURIES

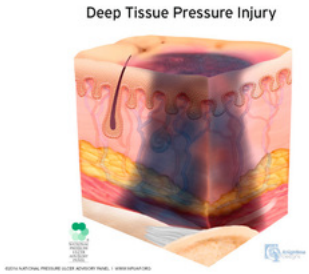
- Advanced age
- Anemia
- Contractures
- Diabetes mellitus
- Elevated body temperature
- Immobility
- Impaired circulation
- Incontinence
- Low diastolic blood pressure (<60 mm Hg)
- Mental deterioration
- Neurological disorders
- Nutritional deficiencies
- Obesity
- Pain
- Prolonged surgery
- Prolonged use of steroids
- Vascular disease

Clinical Manifestations

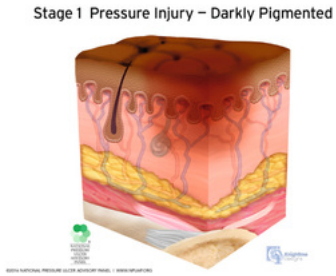
The clinical manifestations of pressure injuries depend on the extent of the tissue that is involved. They are staged according to their deepest level of tissue damage. Table 14-13 illustrates the pressure injury stages according to the NPUAP (2016) guidelines. When slough or necrotic eschar is present, it is not possible to stage the ulcer until the devitalized tissue is removed by debridement. Clinicians describe such pressure injuries as *unstageable* (RNAO, 2016).

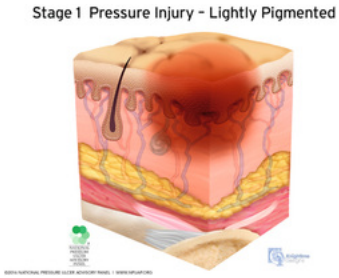
TABLE 14-13
STAGING OF PRESSURE INJURIES

Deep Tissue Pressure Injury
Intact or nonintact skin with localized area of persistent nonblanchable, deep red, maroon, purple discoloration or epidermal separation revealing a dark wound bed or blood filled blister. Pain and temperature change often precede skin colour changes. Discoloration may appear differently in darkly pigmented skin. This injury results from intense or prolonged pressure and shear forces at the bone–muscle interface. The wound may evolve rapidly to reveal the actual extent of tissue injury, or it may resolve without tissue loss. If necrotic tissue, subcutaneous tissue, granulation tissue, fascia, muscle, or other underlying structures are visible, the injury is a full-thickness pressure injury (unstageable, stage 3, or stage 4). The *term deep tissue pressure injury* does not describe vascular, traumatic, neuropathic, or dermatological conditions.

Diagram	**Clinical Presentation***	
		


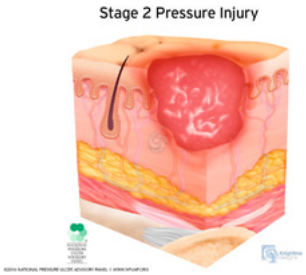
Stage 1		
Intact skin with a localized area of nonblanchable erythema, which may appear differently in darkly pigmented skin. Presence of blanchable erythema or changes temperature, or firmness may precede visible changes. Colour changes do not include purple or maroon discoloration; these may indicate deep tissue pressure inj		

Diagram	**Clinical Presentation**
	
	


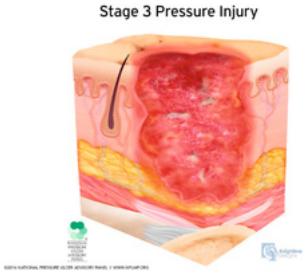


Stage 2	
Partial-thickness loss of skin with exposed dermis. The wound bed is viable, pink or red, moist, and may also appear as an intact or ruptured serum-filled blister. Neither adipose (fat) nor deeper tissues are visible. Granulation tissue, slough, and eschar are not present. These injuries commonly result from adverse microclimate and shear in the skin over the pelvis and shear in the heel. This stage should not be used to describe moisture-associated skin damage, including incontinence-associated dermatitis, intertriginous dermatitis, medical adhesive–related skin injury, or traumatic wounds (skin tears, burns, abrasions).	

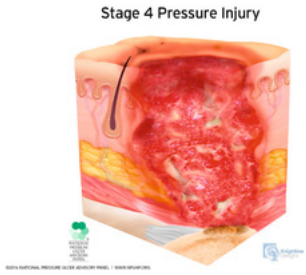
Diagram	**Clinical Presentation**

Diagram	Clinical Presentation	
		


Stage 3		
Full-thickness loss of skin, in which adipose (fat) is visible in the ulcer and granulation tissue and epibole (rolled wound edges) are often present. Slough or eschar be visible. The depth of tissue damage varies by anatomical location; deep wounds can develop in areas of significant adiposity. Undermining and tunnelling may muscle, tendon, ligament, cartilage, and bone are not exposed. If slough or eschar obscures the extent of tissue loss, the injury is considered an unstageable pressu		

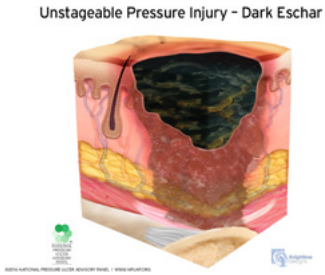
Diagram	Clinical Presentation	
		


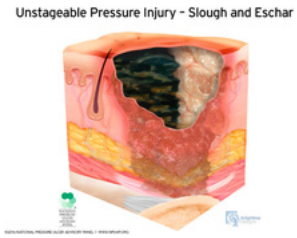
Stage 4		
Full-thickness skin and tissue loss with exposed or directly palpable fascia, muscle, tendon, ligament, cartilage, or bone in the ulcer. Slough, eschar, or both may b Epibole (rolled edges), undermining, or tunnelling, or a combination of these, often occurs. Depth varies by anatomical location. If slough or eschar obscures the e loss, the injury is considered an unstageable pressure injury.		

Diagram	Clinical Presentation	
		


Unstageable		
Full-thickness skin and tissue loss in which the extent of tissue damage within the ulcer cannot be confirmed because it is obscured by slough or eschar. If slough removed, a stage 3 or stage 4 pressure injury is revealed. Stable eschar (i.e., dry, adherent, intact without erythema or fluctuance) on the heel or ischemic limb shou softened or removed.		

Diagram	Clinical Presentation†‡

Diagram	Clinical Presentation†‡	
		
		




Medical Device–Related Pressure Injury Medical device–related pressure injuries result from the use of devices designed and applied for diagnostic or therapeutic purposes. The resultant pressure injury the pattern or shape of the device. The injury should be staged according to the staging system just described.		
Example		
Mucosal Membrane Pressure Injury Mucosal membrane pressure injury is found on mucous membranes on which a medical device has been in use at the location of the injury. Because of the anatom injuries cannot be staged.		

Diagram	Clinical Presentation§

Note: For additional information regarding the staging of pressure injuries, refer to the Registered Nurses' Association of Ontario. (2016). *Assessment and management of pressure injuries for the interprofessional team. (3rd edition.)*. Available at

http://rnao.ca/bpg/guidelines/pressure-injuries.

Source: Descriptions, drawings, and photos (with exceptions noted as follows) of pressure injury stages copyrighted by National Pressure Ulcer Advisory Panel (NPUAP) website. (2016). *Educational and clinical resources.* Available at *http://www.npuap.org/resources/educational-and-clinical-resources*. Used with permission.

When full-thickness pressure injuries heal, fat, muscle, and dermis are replaced with granulation tissue, and the original integrity of the tissue is lost. Reverse staging—for example, stating that a stage 3 ulcer has healed into a stage 2 ulcer—is thus not appropriate. Rather, the ulcer would be known as a "healing stage 3 ulcer." It is important to note the location of previously healed pressure injuries in an initial admission assessment because history of a pressure injury is a risk factor for recurrence.

Nursing and Collaborative Management Pressure Injuries

Management of a patient with a pressure injury encompasses not only care of the wound itself but also support measures for the whole person, such as adequate nutrition, pain management, control of other medical conditions, and pressure relief. Evidence-informed practice is to keep a pressure injury slightly moist, rather than dry, to enhance re-epithelialization. In addition to the nurse, other members of the health care team, such as the physician, the dietitian, the physiotherapist, and the occupational therapist, can provide valuable input into the complex treatment necessary to prevent and manage pressure injuries. Both conservative and surgical strategies are used in the treatment of pressure injuries, depending on the stage and the condition of the injury. Therapeutic and nursing management are discussed together because the activities are interrelated.

Nursing Assessment

Patients should be assessed for pressure injury risk initially on admission to the hospital and at periodic intervals thereafter on the basis of the patient's condition and the care setting. The nurse should conduct a thorough head-to-toe skin assessment on admission to identify and document pressure injuries. The skin and wounds should be reassessed on an ongoing basis and the treatment plan modified accordingly (RNAO, 2016).

Safety Alert

- In acute care, the patient should be reassessed every 24 hours.
- In long-term care, a resident should be reassessed weekly for the first 4 weeks after admission and at least monthly or every 3 months thereafter.
- In home care, the patient should be reassessed at each nurse visit.

Risk assessment should be performed with a validated assessment tool such as the Braden scale (Table 14-14). To obtain a patient's pressure injury risk assessment score on the Braden scale, the nurse adds the numerical scores for the factors in each of the six subscales (sensory perception, moisture, activity, mobility, nutrition, and friction and shear). Scores can range from 6 to 23. The lower the numerical score on the Braden scale, the higher is the patient's predicted risk of developing a pressure injury. Incremental changes in the score indicate the level of risk: no risk (19 to 23), at risk (15 to 18), at moderate risk (13 to 14), at high risk (10 to 12), and at very high risk (≤9). Knowing the level of risk can help the health care provider determine how aggressive the preventive measures should be. The Braden scale has also been modified (Braden Q scale) for use with the pediatric population (Manning, Gauvreau, & Curley, 2015).

TABLE 14-14
BRADEN SCALE FOR PREDICTING PRESSURE INJURY RISK

Patient's Name _____
Evaluator's Name _____
Date of Assessment _____

Point Value				
1	**2**	**3**	**4**	**Score**
Sensory Perception: Ability to Respond Meaningfully to Pressure-Related Discomfort				
Completely limited: Unresponsive (does not moan, flinch, or grasp) to painful stimuli, due to diminished level of consciousness or sedation or limited ability to feel pain over most of body	Very limited: Responds only to painful stimuli; cannot communicate discomfort except by moaning or restlessness or has a sensory impairment that limits the ability to feel pain or discomfort over half of body	Slightly limited: Responds to verbal commands, but cannot always communicate discomfort or the need to be turned or has some sensory impairment that limits ability to feel pain or discomfort in one or two extremities	No impairment: Responds to verbal commands; has no sensory deficit that would limit ability to feel or to voice pain or discomfort	
Moisture: Degree to Which Skin Is Exposed to Moisture				
Constantly moist: Skin is kept moist almost constantly by perspiration, urine, and so on; dampness is detected every time patient is moved or turned	Very moist: Skin is often, but not always, moist; linen must be changed at least once per shift	Occasionally moist: Skin is occasionally moist, necessitating an extra linen change approximately once per day	Rarely moist: Skin is usually dry; linen requires changing [only] at routine intervals	
Activity: Degree of Physical Activity				
Bedfast: Confined to bed	Chairfast: Ability to walk [is] severely limited or nonexistent; cannot bear own weight or must be assisted into chair or wheelchair	Walks occasionally: Walks occasionally during day, but for very short distances, with or without assistance; spends most of each shift in bed or chair	Walks frequently: Walks outside room at least twice per day and inside room at least once every 2 hours during waking hours	
Mobility: Ability to Change and Control Body Position				
Completely immobile: Does not make even slight changes in body or extremity position without assistance	Very limited: Makes occasional slight changes in body or extremity position but unable to make frequent or significant changes independently	Slightly limited: Makes frequent though slight changes in body or extremity position independently	No limitation: Makes major and frequent changes in position without assistance	
Nutrition: Usual Food Intake Pattern				
Very poor: Never eats a complete meal; rarely eats more than half of any food offered; eats two servings or less of protein (meat or dairy products) per day; takes fluids poorly; does not take a liquid dietary supplement or is NPO and/or maintained on clear liquids or [IV supplements] for more than 5 days	Probably inadequate: Rarely eats a complete meal and generally eats only about half of any food offered; protein intake includes only three servings of meat or dairy products per day; occasionally will take a dietary supplement or receives less than optimum amount of liquid diet or tube feeding	Adequate: Eats over half of most meals; eats four servings of protein (meat or dairy products) per day; occasionally will refuse a meal, but will usually take a supplement when offered or is on a tube feeding or total parenteral nutrition regimen that probably meets most of nutritional needs	Excellent: eats most of every meal; never refuses a meal; eats four or more servings of protein (meat or dairy products); occasionally eats between meals; does not require supplementation	
Friction and Shear				
Problem: Requires moderate to maximum assistance in moving; complete lifting without sliding against sheets is impossible; frequently slides down in bed or chair, necessitating frequent repositioning with maximum assistance; spasticity, contractures, or agitation leads to almost constant friction	Potential problem: Moves feebly or requires minimum assistance; during a move, skin probably slides to some extent against sheets, chair, restraints, or other devices; maintains relatively good position in chair or bed most of the time but occasionally slides down	No apparent problem: Moves in bed and in chair independently and has sufficient muscle strength to lift up completely during move; maintains good position in bed or chair		

IVs, intravenous nutrition; *NPO,* nothing by mouth (status).

Source: From Braden, B., & Bergstrom, N. (1994). Predictive validity of the Braden scale for pressure sore risk in a nursing home population. *Research in Nursing & Health,* 17, 459. Copyright, Braden and Bergstrom, 1988. Reprinted with permission. All rights reserved.

Identification of stage 1 pressure injuries may be difficult in patients with dark skin. Table 14-15 presents techniques to help assess darker skin. Subjective and objective data that should be obtained from a person with a pressure injury are presented in Table 14-16.

TABLE 14-15
ASSESSING PATIENTS WITH DARK SKIN

To assess patients with dark skin, the nurse should:
- Look for changes in skin colour, such as skin that is darker (purplish, brownish, bluish) than surrounding skin.
- Use natural light or a halogen light source to accurately assess the skin colour. Fluorescent light casts blue light, which can make skin assessment difficult.
- Assess the skin temperature of the area by using his or her hand. The area may feel warm initially and then cooler.
- Touch the skin to feel its consistency. Boggy or edematous observation may indicate a stage 1 pressure injury.
- Ask the patient if he or she has any pain or itchy sensation.

TABLE 14-16

NURSING ASSESSMENT
Pressure Injuries

Subjective Data

Important Health Information

Past health history: Stroke, spinal cord injury; prolonged bed rest or immobility; circulatory impairment; poor nutrition; altered level of consciousness; history of previous pressure injury; immunological abnormalities; advanced age; diabetes; anemia; trauma
Medications: Use of opioids, hypnotics, systemic corticosteroids, nicotine
Surgery or other treatments: Recent surgery

Symptoms

Incontinence of urine, feces, or both; weakness, debilitation, inability to turn and position body; pain or altered cutaneous sensation in injured area; decreased awareness of pressure on body areas; decreased fluid, calorie, or protein intake; vitamin or mineral deficiencies

Objective Data

General

Obesity; emaciation; clinically significant malnutrition as indicated by low serum albumin level, decreased total lymphocyte count, and decreased body weight (15% less than ideal body weight); contractures

Integumentary

Diaphoresis, edema, and discoloration, especially over bony areas such as sacrum, hips, elbows, heels, knees, ankles, shoulders, and ear rims, progressing to increased tissue damage characteristic of ulcer stages*

Possible Findings

Leukocytosis if infection present, positive cultures for microorganisms from pressure injury

*See Table 14-13.

Nursing Diagnoses

Nursing diagnoses for the patient with a pressure injury may include, but are not limited to, the following:

- *Impaired skin integrity* related to *pressure over bony prominence*
- *Impaired tissue integrity* related to *inadequate nutrition*

Planning

The overall goals are that the patient with a pressure injury will (a) have no deterioration of the ulcer stage, (b) reduce or eliminate the factors that lead to pressure injuries, (c) have improved nutritional status, (d) have increased mobility, (e) not develop an infection in the pressure injury, (f) have healing of pressure injuries, and (g) have no recurrence.

Nursing Implementation

Health Promotion.

Nurses are responsible for identifying patients at risk for the development of pressure injuries (see Tables 14-12 and 14-14). Once a patient has been identified as being at risk for pressure injury development, prevention strategies should be implemented. Prevention remains the best treatment for pressure injuries (Houghton, Campbell, & Clinical Practice Guidelines Panel, 2013; Paul, McCutcheon, Tregarthen, et al., 2014; Roe & Williams, 2014).

Safety Alert

- The patient should be repositioned frequently to prevent pressure injuries.
- Devices to reduce pressure and shearing force (e.g., alternating pressure mattresses, foam mattresses, lift sheets, wheelchair cushions, padded commode seats, heel boots [foam, air]) should be used, as appropriate.
- These devices are not adequate substitutes for frequent repositioning.

Evidence-Informed Practice

Translating Research Into Practice

The nurse is caring for Sarjana Wali, an obese 86-year-old woman with a history of diabetes, hypertension, and chronic kidney disease. Ms. Wali spends most of her time in bed or in a wheelchair and now has a stage 1 pressure injury on her sacral area. The nurse is delivering discharge teaching to the patient's daughter, who is her primary caregiver. The nurse explains the importance of preventing further skin breakdown and that the daughter needs to reposition her mother every 2 to 4 hours during the night. Ms. Wali's daughter tells the nurse that at night, she will reposition her mother only if her mother wakes up to use the commode; otherwise, she must have uninterrupted sleep because she watches her two young grandchildren during the day.

Best Available Evidence	Clinician Expertise	Patient Preferences and Values
Repositioning remains the primary method of reducing risk for pressure injuries. Pressure-reducing devices (e.g., foam mattress, padded commode seats) can also be used but should not be a substitute for repositioning.	Patients with pressure injuries should be repositioned at least every 2 to 4 hours while in bed and should shift weight every 15 minutes when in a chair. Stage 1 pressure injuries can rapidly deteriorate to stage 2 if proper care is not taken.	Ms. Wali's caregiver expresses the need to have a certain amount of uninterrupted sleep to maintain multiple family responsibilities. The caregiver states that she will reposition her mother at least every 2–4 hours while she is in bed during the day and every 15 minutes when she is in a wheelchair. Ms. Wali's caregiver states she will purchase a foam mattress, wheelchair cushion, and padded commode seat to help prevent further skin issues.

Decision and Action

The nurse discusses the importance of repositioning as the primary method to prevent pressure injuries and decrease the progression of existing pressure injuries to more serious ones. Ms. Wali's daughter reiterates that she will not be able to reposition her mother every 2 to 4 hours during the night. The nurse can understand her decision and document this discussion in the patient's discharge teaching record.

National Pressure Ulcer Advisory Panel, European Pressure Ulcer Advisory Panel, & Pan Pacific Pressure Injury Alliance (Haesler, E., Ed.). *Prevention and treatment of pressure ulcers: Quick reference guide*. Cambridge Media: Perth, Australia; 2014 [Retrieved from] http://www.npuap.org/wp-content/uploads/2014/08/Updated-10-16-14-Quick-Reference-Guide-DIGITAL-NPUAP-EPUAP-PPPIA-16Oct2014.pdf.

Acute Intervention.

Once a pressure injury has developed, the nurse should initiate interventions that are based on the ulcer characteristics (e.g., stage, size, location, amount of exudate, type of wound, presence of infection or pain) and the patient's general status (e.g., nutritional state, level of mobility).

Measuring the Wound.

The size of the pressure injury should be carefully documented. A wound-measuring tape can be used to note the ulcer's maximum length and width in centimetres (Figure 14-10). To find the depth of the ulcer, gently place a sterile cotton-tipped applicator into the deepest part of the ulcer. The length of the portion of the applicator that probed the ulcer can then be measured.

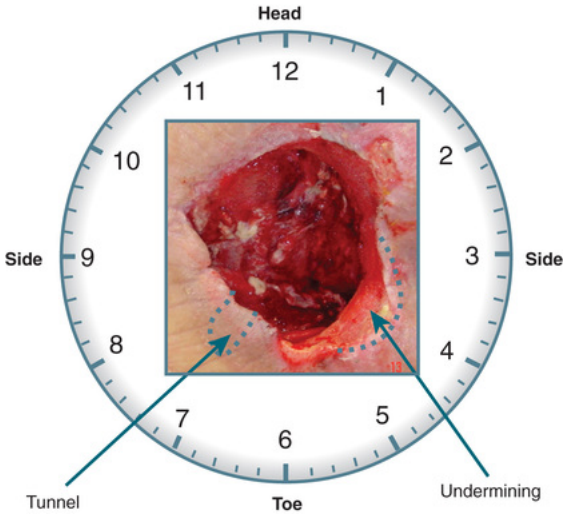

FIGURE 14-10 Wound measurements are made in centimetres. The first measurement is oriented from head to toe, the second is from side to side, and the third is the depth (if any). Any tunnelling (when a cotton-tipped applicator is placed in the wound, the applicator moves) or undermining (when a cotton-tipped applicator is placed in wound, there is a "lip" around the wound) is charted like a clock, the 12 o'clock position being toward the patient's head. This wound would be charted as a full-thickness, red wound, 7 cm × 5 cm × 3 cm, with a 3-cm tunnel at the 7 o'clock position and 2-cm undermining from the 3 o'clock to 5 o'clock positions. Source: Courtesy Robert B. Babiak, RN, BSN, CWOCN, San Antonio, TX.

Documentation.

Healing of the wound can be documented with several available pressure injury healing tools such as the NPUAP Pressure Ulcer Scale of Healing (PUSH) tool. Some employers require that pictures of the pressure injury be taken initially and at regular intervals during the course of treatment. See the "Informatics in Practice" box for suggestions on digital imaging.

Informatics in Practice

Digital Images

To monitor wound progress, use digital photography.
For the best images:

- Include a ruler with date, length, width, and depth of the wound in each photo.
- Position the patient the same way for each photo.
- Take the photo from the same angle each time. Pointing perpendicularly at the wound is best.
- Use natural light, without flash, whenever possible.
- Show the wound on a solid background, avoiding shiny underpads.

Wound Irrigation.

Pressure injuries should be cleaned with 100 to 150 mL of a noncytotoxic solution, such as normal saline, that does not damage fibroblasts. It is important to use enough irrigation pressure (4 to 15 psi) to clean the area adequately without causing trauma or damage to the wound, which can be accomplished with the use of a 100-mL saline squeeze bottle or a 30-mL syringe with an 19-gauge angiocatheter (RNAO, 2016).

Local Wound Care.

After the pressure injury has been cleansed, it should be covered with an appropriate dressing. Some factors to consider in selecting a dressing are maintenance of a moist environment, prevention of wound desiccation (drying out), ability to absorb the wound drainage, location of the wound, amount of caregiver time, cost of the dressing, presence of infection, and the setting of care delivery. For further information on preparing the wound bed and localized wound care, refer to the Canadian Association of Wound Care website (see the Resources at the end of this chapter). (Dressings are discussed in Table 14-11.)

Stage 2 through stage 4 pressure injuries are considered contaminated or colonized with bacteria. For patients with chronic wounds or who are immunocompromised, the clinical signs of infection (purulent exudate, odour, erythema, induration, warmth, tenderness, edema, pain, fever, and elevated WBC count) may not be present even though the wound is infected.

The maintenance of adequate nutrition is an important nursing responsibility for the patient with a pressure injury (RNAO, 2016). Many such patients are debilitated and have a poor appetite as a result of inactivity. Clinically significant malnutrition is defined as a serum albumin level lower than 30 g/L, a total lymphocyte count lower than 1.8×10^9/L, or a body weight decrease of more than 5% over a 6- to 12-month period. Oral feedings must be adequate in calories, proteins, fluids, vitamins, and minerals to meet the patient's nutritional requirements. The intake needed to correct and maintain a nutritional balance may be 30 to 35 calories per kilogram per day and 1.25 to 1.50 g of protein per kilogram per day. Nasogastric feedings can be used to supplement the oral feedings. Parenteral nutrition consisting of amino acid and glucose solutions is administered when oral and nasogastric feedings are inadequate. (Parenteral and enteral nutrition are discussed in Chapter 42.) Nursing Care Plan 14-2 (available on the Evolve website) outlines the care for the patient with a pressure injury.

An appropriate support surface for both bed and chair or wheelchair should relieve pressure and keep the patient off of the damaged area. In some circumstances, reconstruction of the pressure injury site by operative repair, including skin grafting, skin flaps, musculo-cutaneous flaps, or free flaps, may be necessary.

Ambulatory and Home Care.

Pressure injuries affect the quality of life of patients and their caregivers. Because recurrence is common, the education of both the patient and the care provider in prevention techniques is extremely important. The care provider needs to know the causes of pressure injuries, prevention techniques, early signs, nutritional support, and best practice for wound management. Because many patients with a pressure injury require extensive care for other health problems, it is important that the nurse support the caregiver in confronting the added responsibility of pressure injury treatment.

Evaluation

Expected outcomes for the patient with a pressure injury are presented in Nursing Care Plan 14-2 on the Evolve website.

Case Study

Inflammation and Infection

Source: © Kristiina Paul.

Patient Profile

Mr. Fred Roger, a 58-year-old man, is admitted to the hospital emergency department with partial-thickness burns that involved his face, neck, and upper trunk. He also has a lacerated right leg. His injuries occurred about 36 hours earlier, when he fell out of a tree onto his gas grill (which was lit) while he was trying to get his cat.

Subjective Data

- Complains of slightly hoarse voice and irritated throat
- States that he tried to treat himself because he does not regularly see the same primary care health provider
- Has been coughing up sooty sputum
- Complains of severe pain in left hip

Objective Data

Physical Examination

- Leg wound is gaping and looks infected; temperature is 38.4°C
- Radiographs reveal a fractured right tibia and a fractured left hip

Laboratory Studies

- WBC count is 26.4 × 10^9/L with 80% neutrophils (10% bands)

Collaborative Care

- Surgery is performed to repair the left hip

Discussion Questions

1. What clinical manifestations of inflammation did Mr. Roger exhibit, and what are their pathophysiological mechanisms?
2. What type of exudate formation developed?
3. What is the basis for the elevated temperature?
4. What is the significance of his WBC count and differential?
5. Because his wound was gaping, primary tissue healing was not possible. How might healing take place? What complications could he develop?
6. What are Mr. Roger's risk factors for developing a pressure injury?
7. ***Priority Decision:*** On the basis of the assessment data provided, what are the priority nursing diagnoses? Are there any collaborative problems?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. In which context is physiological hyperplasia commonly found?
   a. A distended urinary bladder
   b. The female breast during lactation
   c. The bronchi of a chronic cigarette smoker
   d. An enlarged myocardium in heart failure
2. When radiation therapy is used in the treatment of cancer, how does it achieve the desired effect, which is death of cancer cells?
   a. Altering cellular metabolism and activity
   b. Producing mutations that interfere only with cancer cell function
   c. Accelerating metabolic reactions to reduce the normal life span of cells
   d. Stimulating synthesis of new particles that cause cell rupture and death
3. Which of the following is an example of coagulation necrosis?
   a. Autophagocytosis
   b. Myocardial infarction
   c. Malignant brain tumour
   d. Peripheral vascular disease
4. Which of the following will be experienced by a client with an impaired mononuclear phagocyte system?
   a. Increased circulation of histamine
   b. Decreased susceptibility to infection
   c. Decreased vascular response to cell injury
   d. Decreased surveillance for damaged or mutated cells
5. One day after abdominal surgery a client has incisional pain, 37.5°C temperature, slight erythema at the incision margins, and 30 mL of serosanguineous drainage in the Jackson-Pratt drain. On the basis of this assessment, what conclusion would the nurse make?
   a. The abdominal incision shows signs of an infection.
   b. The client is having a normal inflammatory response.
   c. The abdominal incision shows signs of impending dehiscence.
   d. The client's physician must be notified about her condition.
6. The nurse assessing a client with a chronic leg wound finds local signs of erythema and pain at the wound site. What would the nurse anticipate being ordered to assess the client's systemic response?
   a. Serum protein analysis
   b. WBC count and differential
   c. Punch biopsy of centre of wound
   d. Culture and sensitivity testing of the wound
7. A client in the unit has a 39.8°C temperature. Which intervention would be most effective in restoring normal body temperature?
   a. Use a cooling blanket while the client is febrile.
   b. Administer antipyretics on an around-the-clock schedule.
   c. Provide increased fluids and instruct the unlicensed assistive personnel to give sponge baths.
   d. Give prescribed antibiotics and provide warm blankets for comfort.

8. A nurse is caring for a client who has a pressure injury that is treated with debridement, irrigations, and moist gauze dressings. How should the nurse anticipate healing to occur?
   a. Tertiary intention
   b. Secondary intention
   c. Regeneration of cells
   d. Remodelling of tissues

9. A nurse is caring for a client with diabetes who is scheduled for amputation of his necrotic left great toe. The client's WBC count is 15.0×10^9/L, and he has coolness of the lower extremities, weighs 34 kg more than his ideal body weight, and smokes two packs of cigarettes per day. Which priority nursing diagnosis addresses the primary factor affecting the client's ability to heal?
   a. *Readiness for enhanced nutrition*
   b. *Impaired tissue integrity* related to *insufficient knowledge about protecting tissue integrity*
   c. *Ineffective peripheral tissue perfusion* related to sedentary lifestyle
   d. *Ineffective coping* related to *ineffective tension release strategies*

10. An 89-year-old client with end-stage renal disease is assessed to have a score of 16 on the Braden scale. On the basis of this information, how should the nurse plan for this client's care?
   a. Implement a 1-hour turning schedule with skin assessment
   b. Place a hydrocolloid on the client's sacrum to prevent breakdown
   c. Elevate the head of bed to 90 degrees when the client is supine
   d. Continue with weekly skin assessments with no additional special precautions

11. A 65-year-old client who has had a stroke and has limited mobility has a purple area of suspected deep tissue injury on the left greater trochanter. Which nursing diagnoses are most appropriate? *(Select all that apply)*
   a. *Acute pain* related to *physical injury agent*
   b. *Impaired skin integrity* related to *pressure over bony prominence*
   c. *Impaired tissue integrity* related to *insufficient knowledge about protecting tissue integrity*
   d. *Risk for infection* as evidenced by *malnutrition*

12. An 82-year-old man is being cared for at home by his family. A pressure injury on his right buttock measures 1 × 2 × 0.8 cm in depth, and pink subcutaneous tissue is completely visible on the wound bed. Which stage would the nurse document on the wound assessment form?
   a. Stage 1
   b. Stage 2
   c. Stage 3
   d. Stage 4

13. Which one of the orders should a nurse question in the plan of care for an elderly client who is immobile as the result of a stroke and has a stage 3 pressure injury?
   a. Cover the ulcer with a foam dressing.
   b. Turn and position the client every hour.
   c. Clean the ulcer every shift with Dakin's solution.
   d. Assess for pain and medicate before dressing change.

1. b; 2. a; 3. b; 4. d; 5. b; 6. b; 7. b; 8.b; 9.b; 10. a; 11. b, c; 12. c; 13. c.

CHAPTER 15

Genetics

Written by, Sharon L. Lewis

Adapted by, George S. Charames

With contributions from, Kelly Metcalfe

LEARNING OBJECTIVES

1. Describe the significance of the Human Genome Project for nurses and the field of health care.
2. Define common terms related to genetics and genetic disorders: *autosome, carrier, heterozygous*, *homozygous*, *mutation*, *recessive*, and *sex-linked.*
3. Compare and contrast the most common categories of genetic disorders.
4. Describe taking a family history or pedigree using the common nomenclature.
5. Identify the common types of genetic testing.
6. Outline the role of the nurse in working with patients and families with possible or actual genetic conditions.
7. Explore the complex ethical and social implications of genetic testing.

KEY TERMS

translation, p. 251

Genomics (the study of genomes) is a central science for all nursing practice because essentially all diseases and conditions have a genetic or genomic component. Health care for all people will increasingly include genetic and genomic information along the pathways of prevention, screening, diagnostics, prognostics, selection of treatment, and monitoring of treatment effectiveness (Consensus Panel on Genetic/Genomic Nursing Competencies, 2009).

Genetics has a great impact on health and disease; therefore, the study of genetics has become increasingly important for health care providers. Common disorders such as heart disease and most cancers arise from a complex interplay among multiple genes and between genes and factors in the environment (World Health Organization, 2016).

The molecular basis of more than 4 600 disorders is now known (Online Mendelian Inheritance in Man [OMIM], 2017). This identification of a genetic basis for many diseases has affected the study of genetics and genomics and their relevance to nurses and, accordingly, has directly influenced the care of patients at risk for or diagnosed with such a disease. Nurses need to know the basic principles of genetics, be familiar with the impact that genetics has on health and disease, and be prepared to assist the patient and family in dealing with genetics issues (Calzone, Jenkins, Nicol, et al., 2013; Munro, 2015). In addition, nurses must become knowledgeable regarding the application of genetic discoveries to clinical care and assume leadership in preparing to meet patients' needs for the future (Daack-Hirsch, et al., 2013). Nurses are at the interface of translating

new human genome research discoveries into clinical practice and will increasingly care for individuals and families who have a genetic condition or a health issue with a genetic component.

Human Genome Project

The Human Genome Project (HGP) is one of the most significant health-related advances of modern times. The HGP began in 1990 as an international effort to analyze the structure of human DNA and determine the location on chromosomes of all human genes. It involved more than 2 000 scientists from 20 institutions in six countries. The human genome was completely sequenced by 2003, with the sequence of more than 3 billion DNA bases determined. An estimated 20 000 genes exist in the human genome. The HGP has enabled the characterization of more than 15 000 genes to date (OMIM, 2017).

The contribution of the HGP has helped to improve the diagnosis of genetic-related diseases, allowed for earlier detection through improved surveillance methods, and offered improved targeted therapies, and continues to play a critical role in determining personal and familial risks. A comprehensive website covering the topic of the HGP can be found at Human Genome Project Information (see the Resources at the end of this chapter).

Basic Principles of Genetics

Genetics is the study of inheritance. Table 15-1 presents a glossary of terms commonly used in the study of genetics.

TABLE 15-1

GLOSSARY OF GENETIC TERMS

Term	Definition
Allele	One of two or more alternative forms of a gene that can occupy a particular chromosomal locus
Autosome	Any chromosome that is not a sex chromosome
Carrier	An individual who carries a copy of a mutated gene for a recessive disorder
Chromosome	A gene-carrying structure in the nucleus of all human cells that consists of DNA and protein
Codominance	Two dominant versions of a trait that are both expressed in the same individual
Congenital disorder	Condition present at birth
Dominant allele	Gene that is expressed in the phenotype of a heterozygous individual
Gene	Unit of hereditary information located on a specific part of a chromosome
Genome	An organism's complete set of genetic material present in a cell
Hereditary	A disease or condition being transmitted from parent to offspring
Heterozygous	Having two different alleles for one given gene
Homozygous	Having two identical alleles for one given gene
Locus	Position of a gene on a chromosome
Mutation	A change in the DNA sequence of a gene, affecting the expression of the gene (changing the original manner of expression)
Oncogene	Gene that is able to initiate and contribute to the conversion of normal cells to cancer cells
Pedigree	Family tree that contains the genetic characteristics and disorders of that particular family
Phenotype	Clinically expressed traits of an individual
Proto-oncogenes	Normal cellular genes that are important regulators of normal cellular processes; mutations can activate them to become oncogenes
Recessive allele	An allele that has no noticeable effect on the phenotype in a heterozygous individual
Sex-linked gene	A gene located on a sex chromosome
Trait	Physical characteristic that one inherits, such as hair and eye colour

Chromosomes, Genes, and DNA

An individual's heritable collection of genetic material is called the **genotype**. The physical and observable characteristics of an individual (e.g., eye colour, weight) are called *phenotypes.* The phenotypes may or may not be caused by the genotype. Genetic material is mostly packaged into threadlike structures called *chromosomes,* and chromosomes are located within the cell nucleus (Figure 15-1). Humans have two sets of 23 chromosomes (46 in total) in nearly every cell in the human body except the gametes (egg and sperm cells), which have only one set of 23

chromosomes. Two sets of chromosomes is termed *diploid,* while one set of chromosomes is termed *haploid*. One set is inherited from the mother, and one set is inherited from the father during conception. Twenty-two pairs of chromosomes, called *autosomes,* are the same in both men and women. The twenty-third pair is referred to as the sex chromosomes. A male has an X and a Y chromosome, and a female has two X chromosomes. The genetic material on each of the non-sex chromosome pairs is *homologous* to each other, meaning that they have the same position and order (Figure 15-2).

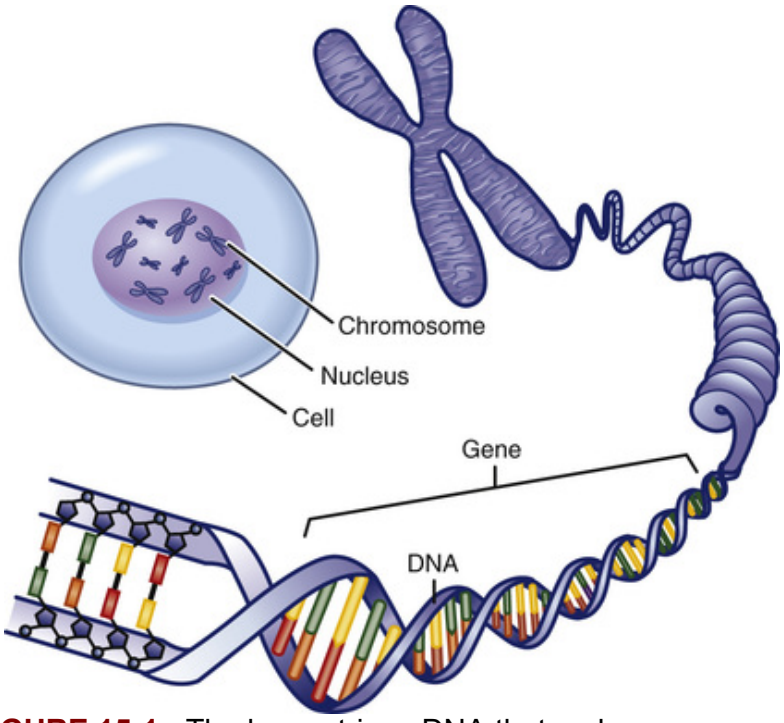

FIGURE 15-1 The long, stringy DNA that makes up genes is spooled within chromosomes inside the nucleus of a cell. (Note that a gene would actually be a much longer stretch of DNA than what is shown here.) Source: National Institute of General Medical Science. National Institutes of Health, U.S. Department of Health and Human Services (2010). *The new genetics.* Retrieved from https://publications.nigms.nih.gov/thenewgenetics/thenewgenetics.pdf.

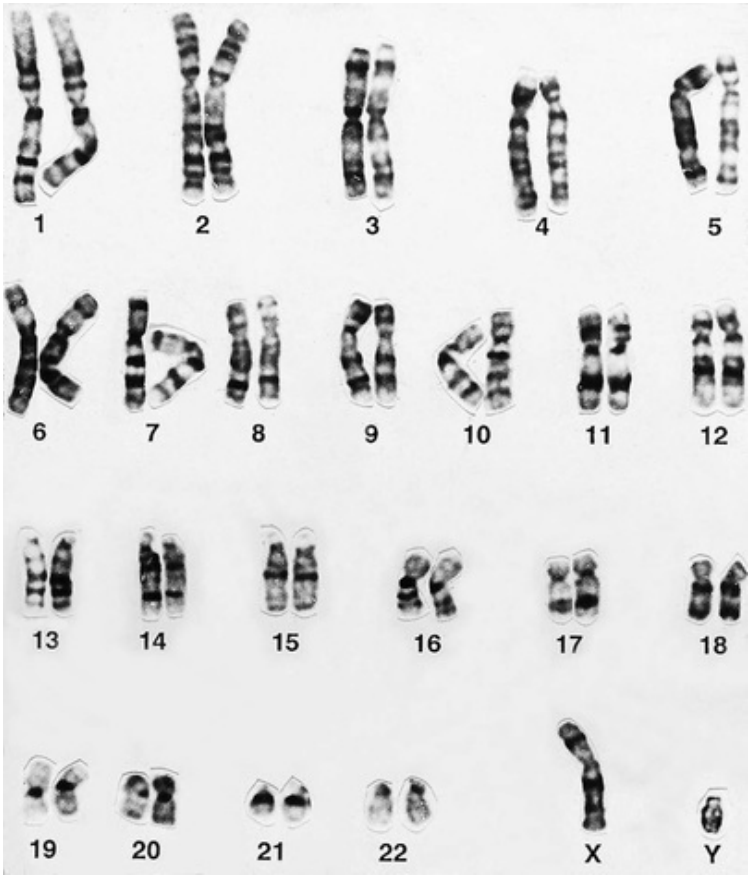

FIGURE 15-2 Human chromosomes. Source: Turnpenny, P. D. (2007). *Emery's elements of medical genetics* (13th ed., p. 34). Edinburgh/Philadelphia: Churchill Livingstone/Elsevier.

Chromosomes are composed of proteins and a long, thin molecule called **deoxyribonucleic acid (DNA)**. DNA is the hereditary material (meaning it can be passed on to daughter cells and subsequent generations) in cells that contains the instructions that drive most cellular processes, typically through making functional proteins. The segments of DNA that contain these instructions are called *genes.* Although most DNA is contained within the nucleus, some DNA can be found outside the nucleus (e.g., mtDNA is in the mitochondria).

The specific structure of DNA is a double helix in which two strands (polynucleotide chains) run in opposite directions (Figure 15-3). The two strands are held together by hydrogen bonds between pairs of bases: adenine (A), thymine (T), guanine (G), and cytosine (C). DNA is composed of a sugar (deoxyribose), a phosphate group, and one of the four nitrogenous bases. One unit, a sugar group combined with a phosphate group and one of the four bases, is called a *nucleotide*. The bases on each strand of DNA are paired in a specific manner. Adenine always pairs with

thymine, and guanine pairs with cytosine. The specific nature of the genetic information encoded in the human genome lies in the nucleotide sequence within the DNA.

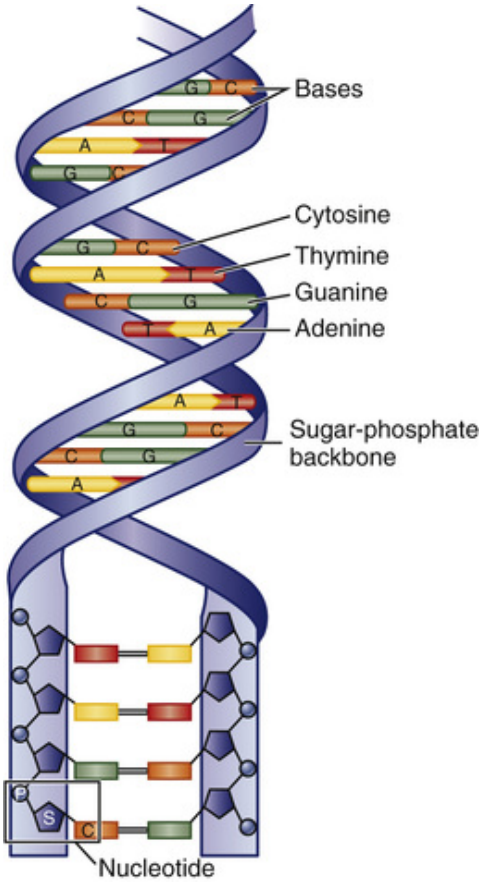

FIGURE 15-3 DNA consists of two long, twisted chains made up of nucleotides. Each nucleotide contains one base, one phosphate molecule *(P)*, and the sugar molecule deoxyribose *(S)*. The bases in DNA nucleotides are adenine *(A)*, thymine *(T)*, cytosine *(C)*, and guanine *(G)*. Source: Adapted from *The new genetics* (2010). National Institute of General Medical Science. National Institutes of Health. U.S. Department of Health and Human Services.

How Proteins Are Made

DNA must undergo replication, transcription, and translation before a functional protein is made. A new DNA strand must be synthesized before cell division. In order for synthesis to occur, the two DNA strands separate and unwind and become templates for new strands. DNA is formed and

replicated in the cell nucleus, whereas protein synthesis takes place in the cytoplasm of the cell. Transcription and translation, the latter following the former, take place when the genetic code is transported from the cell nucleus to the cytoplasm (Figure 15-4). **Ribonucleic acid (RNA)** is the nucleic acid that is involved in these processes. RNA is similar to DNA; however, it is composed of only one strand (as opposed to two strands in DNA), and the nitrogenous base thymine (T) is replaced with uracil (U). **Transcription** takes place when RNA is synthesized from the DNA template. Genes are made up of coding (exons) and noncoding (introns) regions. In transcription, the noncoding regions (introns) are removed, or spliced out. As a result, a messenger RNA (mRNA) is created and can move across the nuclear membrane into the cytoplasm. This is where, based on the sequence of the mRNA, the protein is manufactured in a process called **translation**. In translation, the mRNA sequence acts as a template for the formation of a chain of amino acids. Three successive nucleotides (e.g., CCG) are termed a *codon,* and one codon specifies the production of one amino acid. Proteins are made up of many amino acids. Translation is accomplished by a cytoplasmic particle called the *ribosome.*

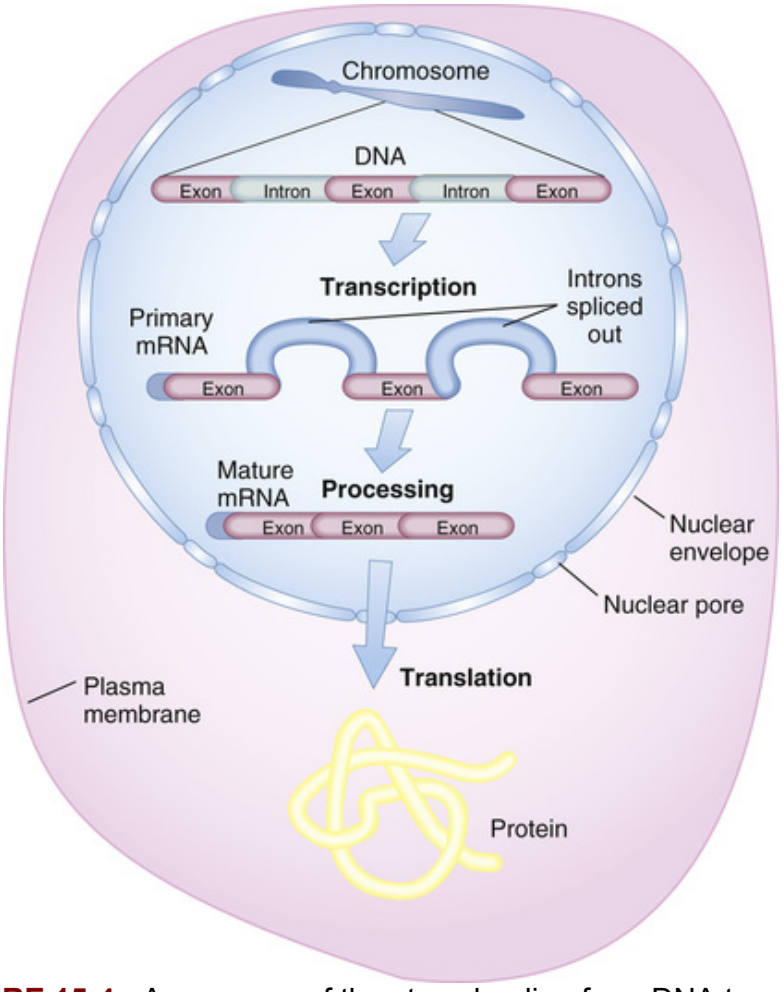

FIGURE 15-4 A summary of the steps leading from DNA to protein creation. Replication and transcription occur in the cell nucleus. The mRNA is then transported to the cytoplasm, where translation of the mRNA into amino acid sequences composing a protein occurs.

Genes are generally stable and are passed from one generation to the next. However, sometimes a change in the gene occurs, referred to as a *variant* or *mutation.* It should be noted that, currently, the field of genetics and genomics typically prefers to describe any difference in a person's nucleotide sequence as compared to a reference sequence as a *variant.* Humans have numerous genetic variants in their DNA, which make us all unique; not all variants manifest in disease. Genetic differences that cause disease are termed *pathogenic variants,* while changes that do not cause disease are called *benign variants.* Outside of this community (and in this chapter), *mutation* is used interchangeably with *pathogenic variant.*

Mutations can occur in the germ line (sperm and eggs) or in the somatic (non-sex) cells after fertilization. Germ-line mutations are those that are passed from one generation to the next and can account for familial syndromes. Approximately 2% of the DNA is composed of sequences that code for specific proteins, and the other 98% is made up of noncoding regions. DNA sequence changes can code for different amino acids that cause structural changes to the protein, and can affect its function.

Primary Categories of Genetic Conditions

Within each human, alterations in genes or in combinations of them can cause genetic disorders. These disorders can be classified into three categories: (1) single-gene disorders; (2) chromosomal disorders; and (3) multifactorial disorders.

Single-Gene Disorders

A disorder caused by a single gene may have a mutation present on only one chromosome of a pair (matched with a normal allele on the homologous chromosome) or on both chromosomes of the pair. These disorders usually exhibit obvious and characteristic inheritance patterns in families and are also referred to as *Mendelian*. Examples of single-gene disorders include cystic fibrosis (CF), Marfan syndrome, and sickle-cell anemia. There are three primary single-gene, or Mendelian, inheritance patterns: (1) autosomal dominant, (2) autosomal recessive, and (3) X-linked. If the mutant gene is located on an autosome, the genetic disorder is called *autosomal.* If the mutant gene is on the X chromosome, the genetic disorder is called *X-linked.* In medical genetics, a family history of clinical information with respect to a hereditary condition is illustrated using a collection of symbols (Figure 15-5) and is called a *pedigree.*

Sickle-cell disease	33
Skin malignancies	25

Autosomal Dominant.

An autosomal dominant trait is one that manifests in the heterozygous state, that is, in a person who has both an abnormal (mutated) and a normal gene. The mutated gene dominates the normal gene. Families with conditions that suggest autosomal dominant inheritance exhibit several characteristics:

1. The affected offspring has one affected parent (with each pregnancy in an affected parent, there is a 50% chance that the characteristic will be passed to the child).
2. Unaffected people do not transmit the trait to their children.
3. Males and females are equally likely to inherit the trait.
4. The trait does not skip generations.

Some examples of autosomal dominant disorders are achondroplasia, Marfan syndrome, neurofibromatosis type 1, and brachydactyly. See Figure 15-6 for an example of a pedigree of a family with an autosomal dominant trait.

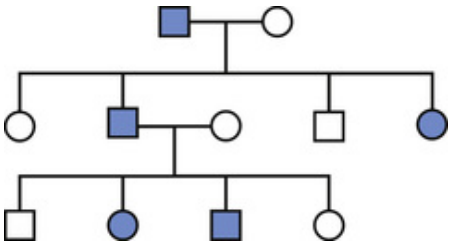

FIGURE 15-6 Pedigree of a family with an autosomal dominant trait.

Punnett squares can be used to determine inheritance possibilities. The Punnett square in Figure 15-7 illustrates the mating of a parent affected with the autosomal dominant trait and an unaffected parent. The probability that the affected parent will pass on the mutated gene to a child is 0.5. Therefore, on average, 50% of the offspring will inherit the trait.

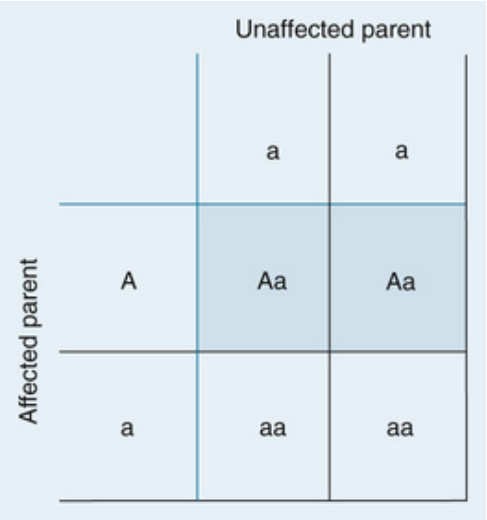

FIGURE 15-7 The Punnett square illustrates the mating of an unaffected individual *(aa)* with an individual who is heterozygous for an autosomal dominant disease gene *(Aa)*. The genotypes of affected offspring are shaded.

Autosomal Recessive.

In the majority of recessive conditions, an affected offspring results from a mating between two unaffected carriers of the mutated gene. The offspring inherits two copies of the mutated gene, one from each parent, which results in the offspring exhibiting the disorder. The parents of these offspring do not exhibit the trait associated with having the mutation because they each carry only one copy of the mutated gene (they are heterozygous carriers). Families with conditions that suggest autosomal recessive inheritance exhibit several characteristics:

1. Most affected individuals have parents that have normal phenotypes (do not exhibit the trait).
2. On average, one in four children is affected.
3. Males and females are equally likely to be affected.
4. Affected people who mate with normal people tend to have phenotypically normal children.

Some examples of autosomal recessive disorders are albinism, CF, and phenylketonuria. See Figure 15-8 for an example of a pedigree of a family with an autosomal recessive trait. The Punnett square illustrating the

mating of two heterozygous parents of an autosomal recessive gene is shown in Figure 15-9.

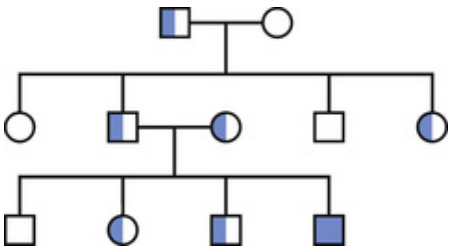

FIGURE 15-8 Pedigree of a family with an autosomal recessive trait.

X-Linked.

An X-linked recessive trait is one determined by a gene carried on the X chromosome, and it usually manifests only in males. In males, there is only one X chromosome (the other is a Y chromosome), whereas females have two X chromosomes. A male with a mutation in a gene on the X chromosome will exhibit the disorder, because he has no corresponding normal gene to mask the mutated gene's effects. Diseases inherited in an

X-linked manner are transmitted by healthy heterozygous female carriers to males, who are thus affected, as well as by affected males to their carrier daughters, with a future risk to male grandchildren. Families with conditions that suggest X-linked recessive inheritance exhibit several characteristics:

1. Unaffected males do not transmit the disorder.
2. Affected males do not transmit the disorder to their sons.
3. All daughters of an affected male are heterozygous carriers and may be unaffected or mildly affected.
4. Heterozygous women transmit the mutant allele to 50% of the sons (who are affected) and to 50% of the daughters (who are heterozygous carriers).

Some examples of X-linked recessive disorders are hemophilia A and Duchenne muscular dystrophy (DMD). See Figure 15-10 for an example of a pedigree of a family with an autosomal recessive trait. The Punnett square in Figure 15-11 illustrates the mating of a female carrier of an X-linked recessive disorder and a normal male.

X-linked dominant inheritance disorders are those in which the dominant gene is carried on the X chromosome and are typically characterized by affected females and lethal in males. X-linked dominant disorders are rarer than X-linked recessive disorders. Some examples include Rett syndrome (*MECP2* gene) and incontinentia pigmenti (*IKBKG* gene).

X-inactivation occurs in all cells in females. In brief, it is a process in which one of the two X chromosomes is randomly inactivated early in development. Skewing of X-inactivation (as well as other mechanisms) can result in the expression of disease in females for recessive conditions. For this reason, the terms *recessive* and *dominant* when referencing X-linked inheritance are less utilized.

Chromosomal Disorders

Abnormalities of chromosomes may be either numerical or structural and may involve one or more autosomes, sex chromosomes, or both together. The most common type of clinically significant chromosomal abnormality involves the number of chromosomes, called *aneuploidy*. In the case of aneuploidy, there are either extra or missing chromosomes. Aneuploidy results from an error during meiotic cell division, creating a sperm or an egg with too many or too few chromosomes, which is passed on to the offspring during conception. Most aneuploid offspring have either trisomy (three chromosomes) or monosomy (only one chromosome) instead of the

normal pair of chromosomes. The most common trisomy that survives birth is trisomy 21 (Down syndrome). In these offspring, there are three copies of chromosome 21. Other examples of aneuploidy are trisomy 13 and trisomy 18. Monosomy for an entire chromosome is almost always lethal, with the exception of monosomy for the X chromosome, as seen in Turner's syndrome.

Abnormalities of chromosome structure result from chromosome breakage and subsequent reconstitution in an abnormal combination. These new configurations can be either balanced or unbalanced. In balanced rearrangements, the chromosome is complete, with no loss or gain of genetic material. These rearrangements are generally harmless except in rare cases in which one of the break points damages an important functional gene. When a chromosome rearrangement is unbalanced, the chromosomal complement contains an incorrect amount of chromosome material, and the clinical effects are usually serious. Chromosomal instability happens during conception and can occur in all cells; it can also occur somatically and possibly lead to cancers (typically caused by single-gene defects) (Charames & Bapat, 2003).

Multifactorial Inheritance

Disorders that are caused by multifactorial inheritance occur as a result of an interaction between one or more genes (polygenic) or between one or more genes and environmental influences. Multifactorial inheritance is thought to be the basis for most common diseases, including cancer, heart disease, and multiple sclerosis. A primary characteristic of this type of inheritance is familial aggregation of diseases. Multifactorial conditions tend to run in families, but the pattern of inheritance is not as predictable as with single-gene disorders. The chance of recurrence of disease traits within families, although greater than the population risk, is less than that for families with single-gene disorders. The degree of risk for a multifactorial disorder occurring in relatives is related to the number of genes they share in common with the affected individual. The closer the degree of relationship, the more genes they have in common. The degree of risk also increases with the severity of the disorder. Although multifactorial conditions run in families, the risk is generally less than the 25% or 50% seen in Mendelian conditions. Identical twins, exactly alike genetically, may not always have the same condition when inheritance is multifactorial. This indicates that there are nongenetic factors that also play a role in the expression of multifactorial traits. For instance, the risk

for coronary heart disease increases with smoking or obesity, and the risk for emphysema in individuals with α_1-antitrypsin deficiency increases greatly with smoking.

Characteristics of multifactorial inheritance include the following:

1. There is a similar risk for first-degree relatives (offspring, siblings, or parents).
2. Identical twins are not 100% concordant, indicating that there are nongenetic factors involved.
3. The greater the number of affected relatives, the higher the recurrence risk.
4. The severity of the disorder and occasionally the sex of the affected individual may modify the risk.

Throughout the book, genetic disorders are highlighted in "Genetics in Clinical Practice" boxes.

Genetics in Clinical Practice

Taking a Family History

A detailed three-generation family history, or *pedigree,* offers great insight into possible genetic conditions within a family. A pedigree is a symbolic representation of family members indicating specific details about each individual. General family history screening should be obtained for each family member, with details for at least three generations. Information (including age, disease status, and vital status) should be collected on the patient, his or her children, and the patient's siblings, parents, aunts, uncles, and grandparents. Standard nomenclature should be used when constructing a pedigree (see Figure 15-5). This initial pedigree can highlight certain areas, such as those pertinent to a specific condition (e.g., cancer), for further questioning. A pedigree targeting the possibility of a hereditary cancer syndrome will gather even more details about the incidence of cancer, the types of cancer, ages at diagnosis, and outcomes. Information about paternal and maternal ethnicity should also be gathered because some genetic mutations are found more commonly in certain ethnic groups.

Genetic Testing

Genetic testing is the analysis of DNA, chromosomes, proteins, or metabolites, or some combination. Testing can be done on blood or other bodily samples and involves looking for a genetic mutation that indicates the presence or absence of a genetic condition or predisposition to (i.e., increased risk for) a genetic condition. Genetic testing can be used in a multitude of ways. A genetic screening test may be useful in determining the potential risk for development of a disease in one's lifetime. Such tests may be done in a variety of settings and at any point during the lifespan, including prenatally, at birth, or throughout childhood and adulthood. Some tests screen for the possibility of a disease and are predictive of expression of disease. Other tests are done to determine whether an individual is a carrier of a mutated gene, which may be passed on to an offspring.

Prenatal Diagnosis and Screening.

The main objective of prenatal diagnosis is to give parents information so they can make informed decisions during pregnancy. The potential

benefits of prenatal testing include the following: (a) decreasing the anxiety of at-risk parents (when test results return as normal); (b) providing risk information to parents before conception so an informed choice can be made regarding future pregnancies; (c) allowing parents to prepare psychologically for the birth of an affected child; and (d) providing risk information to parents when pregnancy termination is an option. Prenatal diagnostic tests can be either invasive (e.g., amniocentesis, chorionic villus sampling) or noninvasive (e.g., maternal serum screening, ultrasonography). The newest noninvasive screen for chromosomal anomalies (such as trisomies 13, 18, and 21) is a blood test, done as early as 10 weeks gestation, that examines the circulating cell-free fetal DNA in the maternal blood and measures the relative abundance of markers on these chromosomes. This screen is called noninvasive prenatal testing (NIPT) and has a detection rate of >98% and a false-positive rate of <2%.

Amniocentesis.

Amniocentesis is traditionally performed 15 to 17 weeks after a pregnant woman's last menstrual period. It can be used to diagnose neural tube defects, chromosome abnormalities, metabolic disorders, and molecular defects. A needle is inserted through the abdominal wall into the amniotic sac while the fetus is being monitored using ultrasound (Figure 15-12). Between 20 and 30 mL of amniotic fluid, which contains living cells (amniocytes) shed by the fetus, is removed. Cytogenetic studies are done after culture of the amniocytes. Common indications for amniocentesis are (a) maternal age older than 35 years; (b) previous child with chromosome abnormality; (c) history of structural chromosome abnormality in one parent; (d) family history of genetic defect that is diagnosable by biochemical or DNA analysis; and (e) risk for neural tube defect. A risk of 0.1 to 1% for miscarriage is associated with this procedure (Akolekar, Beta, Picciarelli, et al., 2015).

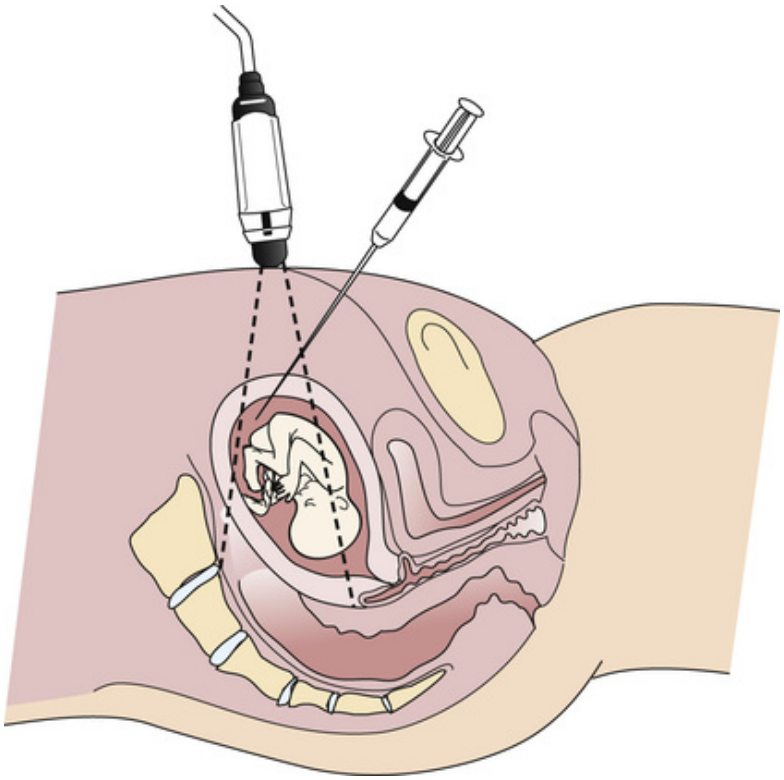

FIGURE 15-12 A schematic illustration of an amniocentesis, in which 20 to 30 mL of amniotic fluid is withdrawn transabdominally (with ultrasound guidance), usually at 15 to 17 weeks' gestation.

Source: Jorde, L., Cary, J., & Bamshad, M. (2010). *Medical genetics* (4th ed., p. 268). St. Louis: Mosby.

Chorionic Villus Sampling.

Chorionic villus sampling (CVS) may be done in the first trimester, usually between 11 and 12 weeks' gestation. It is performed by aspirating fetal trophoblastic tissue (chorionic villi) by either the transcervical or the transabdominal approach for prenatal evaluation of the chromosomal, enzymatic, and DNA status of the fetus (Figure 15-13).

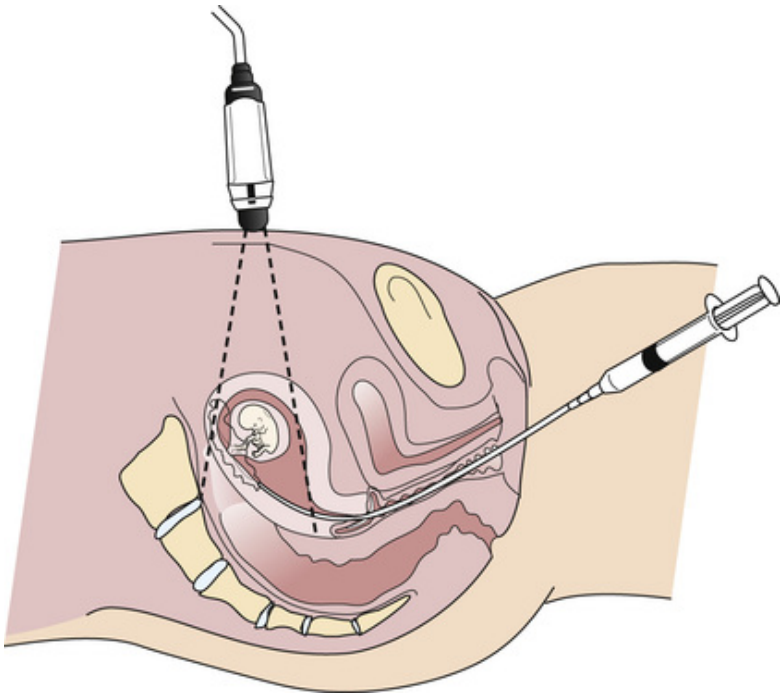

FIGURE 15-13 A schematic illustration of a transcervical chorionic villus sampling procedure. With ultrasound guidance, a catheter is inserted, and several milligrams of villus tissue is aspirated. Source: Jorde, L., Cary, J., & Bamshad, M. (2010). *Medical genetics* (4th ed., p. 269). St. Louis: Mosby.

CVS has the advantage of providing a diagnosis much earlier in a pregnancy than amniocentesis for couples who may consider termination as an option. CVS is associated with a slightly higher risk for miscarriage (0.2 to 1.5%) (Akolekar, Beta, Picciarelli, et al., 2015).

Screening for Carriers of Genetic Disease.

This type of genetic screening is done on healthy individuals (i.e., those unaffected with a genetic condition) to determine whether they carry a mutation that could be passed to offspring and cause genetic diseases. Typically, this test is done for autosomal recessive and X-linked disorders. Individuals may opt for this type of genetic screening if there is a family history of a genetic disease or if they are in an ethnic group that has a greater risk of carrying a certain genetic mutation. Examples of disorders for which testing is available are Tay–Sachs disease, CF, and fragile X syndrome.

Presymptomatic and Predisposition Testing.

Predictive testing includes both presymptomatic and predisposition testing. In presymptomatic testing, an individual has genetic testing to determine whether she or he carries a genetic mutation for a genetic disorder. Typically, individuals electing this testing are members of a family that exhibits a genetic disorder. An example of this would be genetic testing for Huntington's disease, an adult-onset condition characterized by progressive neurological degeneration. The gene responsible for Huntington's disease is 100% penetrant; that is, everyone who inherits this mutation will exhibit the disease and, since there is no cure, will die of the disease. For members of families in which Huntington's disease is present, the decision to undergo predictive testing may be difficult. In Canada, the uptake rate for predictive testing is approximately 18% of the estimated Canadian population at risk for the disease (Creighton, Almqvist, MacGregor, et al., 2003).

Genetic testing is also available to determine an individual's predisposition for developing a genetic condition and is now used in prenatal, pediatric, and adult populations. Many genes that, when mutated, cause an individual to be predisposed to a disease have been identified. However, not all individuals who have the genetic mutation will get the disease. An example of genetic testing that is available is for *BRCA1* and *BRCA2.* Mutations in these genes are responsible for an increased risk for breast cancer (≤80% lifetime risk) and ovarian cancer (≤40% lifetime risk) (Petrucelli, Daly, & Feldman, 2013). Typically, families that carry mutations in these genes have numerous members who have been diagnosed with breast or ovarian cancers (Figure 15-14). Other characteristics that suggest a possible *BRCA1* or *BRCA2* mutation in a family are onset of breast cancer at a young age (<50 years), male breast cancer, and bilateral breast cancer (cancer in both breasts). The advantage of testing for mutations in *BRCA1* and *BRCA2* is that women at high risk for developing breast and ovarian cancers can be identified before the development of cancer. These women can then begin vigilant breast and ovarian cancer screening at an earlier age, or they can elect for preventive options. Included in preventive options are prophylactic surgery (both bilateral mastectomy and bilateral oophorectomy) or chemopreventive drugs (e.g., tamoxifen). Each option offers varying cancer risk reduction, and there are both medical and psychological adverse effects that may result. A Canadian publication reported increasing uptake of preventive options by women with a *BRCA1* or *BRCA2* mutation: 21% of women had a prophylactic mastectomy, 54% of women had a bilateral oophorectomy

(preventive removal of the ovaries), and 6% took tamoxifen (Metcalfe, Ghadirian, Rosen, et al., 2007).

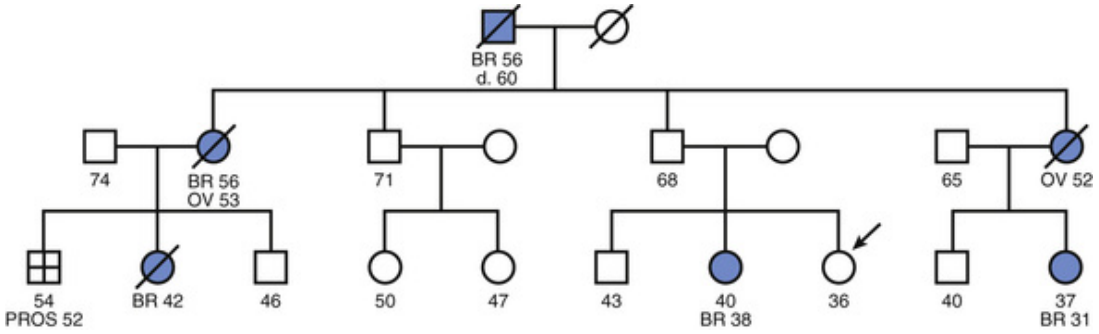

FIGURE 15-14 Pedigree for family with the *BRCA1* mutation. *Numbers without symbols* represent the current ages of family members. *Numbers with symbols* represent the age at which the diagnosis was made. *BR*, breast cancer; *d.*, age of death; *OV*, ovarian cancer; *PROS*, prostate cancer.

Genetic Counselling

Genetic counselling is the process of helping people understand and adapt to the medical, psychological, and familial implications of genetic contributions to disease (National Society of Genetic Counselors [NSGC], n.d.). This process integrates the following:

- Interpretation of family and medical histories to assess the chance of disease occurrence or recurrence
- Education about inheritance, testing, management, prevention, resources, and research
- Counselling to promote informed choices and adaptation to the risk or condition

Andermann and Narod (2002) reported on current practices of genetic counsellors in Ontario who serve a population of over 11 million people. The cost of most genetic counselling was covered by the provincial health plan. There were no private genetic services—either testing or counselling—and there were no patient copayments. The report found that 45% of genetic consultations were for preconception or prenatal diagnosis, 22%

were for breast and ovarian cancer, 5% were for other adult cancers, and 14% were for the evaluation of pediatric conditions.

Although genetics can be integrated into most nurses' practices, some nurses specialize in genetics. “Genetic nurses have specialized education and training in genetics in addition to generic training in healthcare practice with the goal of caring for people's genetic and genomic health” (International Society of Nurses in Genetics, 2010, p. 1). Genetic nurses help people at risk for or affected by diseases with a genetic component to achieve and maintain health. They perform risk assessments, analyze the genetic contribution to disease risk, and discuss the impact of risk on health care management for individuals and families. They also provide genetic education, provide nursing care to patients and families, and conduct research in genetics. The International Society of Nurses in Genetics (ISONG) is an organization of nurses around the world who work in genetics (see the Resources at the end of this chapter.).

Genetic counsellors are health care providers with specialized graduate degrees and experience in the areas of medical genetics and counselling. They provide information and support to families who have members with birth defects or genetic disorders and to families who may be at risk for a variety of inherited conditions. They identify families at risk, investigate the problem that the family has, interpret information about the disorder, analyze inheritance patterns and risks for recurrence, and review available options with the family. Genetic counsellors also provide supportive counselling to families, serve as patient advocates, and refer individuals and families to community or provincial or territorial support services (NSGC, n.d.).

Gene Therapy

Gene therapy is an experimental technique that is used to replace or functionally repair defective or missing genes with normal genes. A normal gene can be inserted into a human chromosome to counteract the effects of a missing or abnormal gene. Although gene therapy is a promising treatment option for a number of diseases (including inherited disorders, some types of cancer, and certain viral infections), the technique remains risky and is still under study to make sure that it will be safe and effective. Gene therapy is currently being tested only for the treatment of diseases that have no cures (National Library of Medicine, 2017).

The first approved gene therapy trials involved children with severe combined immunodeficiency disease caused by adenosine deaminase

deficiency. T lymphocytes from these children were obtained, and the missing gene was inserted into these T cells (Figure 15-15). The new T cells were then reinjected into the children's bloodstreams. The gene signalled the cells to produce the missing enzyme, and these children were capable of developing a functioning immune system.

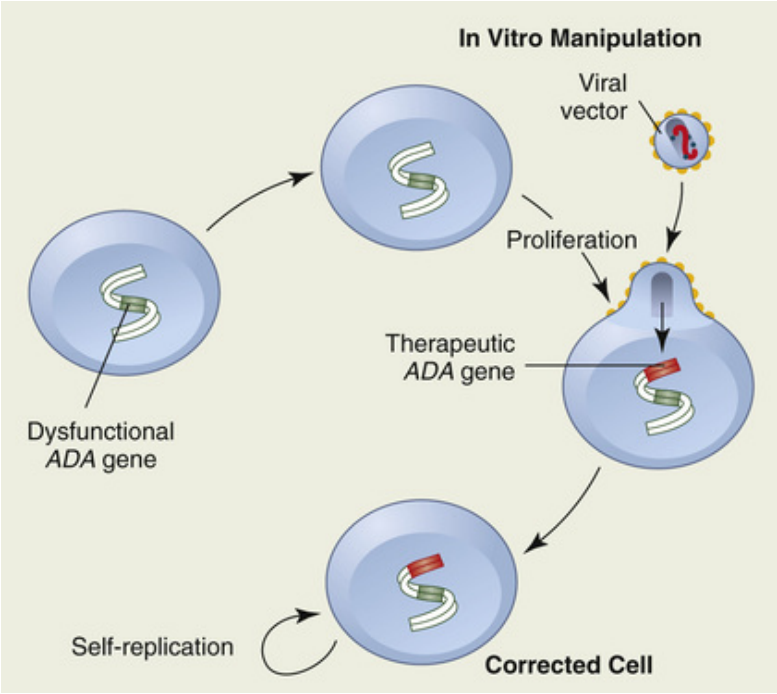

FIGURE 15-15 Gene therapy for adenosine deaminase (ADA) deficiency attempts to correct this immunodeficiency state. The viral vector containing the therapeutic *ADA* gene is inserted into the patient's lymphocytes. These cells can then make the ADA enzyme.

Gene therapy shows promise for treating a wide array of problems that do not respond to conventional methods of intervention. Although gene therapy is not currently used in clinical practice, the treatment strategies closest to being incorporated into mainstream therapies are those that address immunodeficiency disease, hemophilia, and ischemic vascular disease. Before gene therapy can become a practical approach to treating disease, scientists must find improved methods of delivering the genes to directly target the affected cells and must ensure that the new genes can be controlled by the body (National Library of Medicine, 2017).

Methods of Gene Delivery.

One of the major hurdles in gene therapy is finding a way to insert the gene into the body. Genes that are inserted directly into a cell usually do not function. Instead, a carrier, called a *vector*, is used to deliver the gene. The most common vectors are attenuated or modified versions of viruses. The viruses are modified so they cannot cause disease when used in humans (National Library of Medicine, 2017).

Some types of viruses, such as retroviruses, integrate their genetic material (including the new gene) into a chromosome in the human cell. Other viruses, such as adenoviruses, introduce their DNA into the nucleus of the cell, but the DNA is not integrated into a chromosome.

The vector can be injected or given by the intravenous (IV) route directly into a specific tissue in the body, where it is taken up by the individual cells. Alternatively, a sample of the patient's cells can be removed and exposed to the vector in a laboratory setting. The cells containing the vector are returned to the patient. If the treatment is successful, the new gene delivered by the vector will make a functioning protein.

Examples of Gene Therapy for Cancer.

One of the first gene therapy protocols used in treating cancer patients involved the addition of a gene for tumour necrosis factor (TNF). The vector with the gene for TNF was inserted into lymphocytes aimed at sites of malignant melanoma. This approach allows a high dose of TNF to be delivered to the tumour only and avoids systemic adverse effects.

The purpose of the multidrug resistance (MDR) clinical gene therapy trials is to modify the effects of high-dose chemotherapy in bone marrow cells by inserting the *MDR* gene. Bone marrow stem cells are separated and cultured with a virus carrying the genetic material for the *MDR* gene. The virus transfers the *MDR* gene into the patient's stem cells. These stem cells and their offspring become resistant to the toxic effects of chemotherapy by acquiring the ability to pump the chemotherapeutic drugs out of the cells before the drugs are able to kill the cells.

Gene Editing: Using the CRISPR-Cas9 System in Gene Therapy.

One of the major challenges with gene therapy has been the efficient delivery of a corrected copy of a DNA segment to a specific site within the genome and into enough patient cells to correct the inherited gene defect (reviewed in Collins & Thrasher, 2015). Originally identified in bacterial

systems, CRISPR (**c**lustered **r**egularly **i**nterspaced **s**hort **p**alindromic **r**epeats) RNA and a CRISPR-associated (Cas) protein together can use specific RNA sequences (as a guide) to direct the complex to the site of interest, cut DNA, and then attempt to repair it by introducing new DNA. This method has been used in the laboratory to inactivate integrated human immunodeficiency virus (HIV) genomes and to correct genetic defects in disorders such as CF. While the off-target effects are still being evaluated, CRISPR-Cas9 is currently the most promising advance in gene therapy.

Nursing Management Genetics

Nurses must be knowledgeable about the fundamentals of genetics. By understanding the influence that genetics has on health and disease, the nurse can assist the patient and family in making critical decisions related to genetic issues, such as genetic testing. The nurse also should collaborate with the health care team or physician to involve a genetic counsellor. The nurse should be able to give patients and their families accurate information pertaining to genetics, genetic diseases, and probabilities of genetic disorders. Inheritance patterns can be assessed by the nurse and explained to the patient and family through the use of Punnett squares (see Figures 15-7, 15-9, and 15-11) or family pedigrees (see Figures 15-6, 15-8, and 15-10). Maintaining patient confidentiality and respecting the patient's values and beliefs are critical because the information from the counsellor may have major implications for many people who are involved. Examples of applications of genetics in nursing practice include the following (Consensus Panel, 2009):

- Recognizing a newborn infant who is at risk for morbidity and mortality because of genetic metabolism errors
- Identifying an asymptomatic adolescent who is at high risk for hereditary colorectal cancer based on his or her family history
- Identifying a couple who is at risk for having a child with a genetic condition
- Assisting with the selection of a drug or dose of a drug, based on genetic markers, in the treatment of an adult with cancer
- Helping an individual or family with questions related to genetic information or services to find reliable information

Genetic testing may raise many psychological issues. Knowledge of a carrier status of a genetic disorder may influence a person's career plans and decisions about marriage and childbearing. It may also affect significant others when grappling with serious life and health care issues.

Furthermore, there are ethical concerns. At a societal level, who should know the result of a genetic test? How should society or the government protect the privacy of individuals' test results and protect individuals from discrimination? Genetic information should not be misused to stigmatize individuals or particular ethnic groups. Attention must be paid to better understand psychosocial needs of individuals, societal responses, and health care policy related to genetic testing. On a personal level, genetic test results offer individuals insight into conditions that may already exist or that may develop in the future. This type of information may cause internal ethical dilemmas. Prenatal genetic testing, for example, may raise ethics issues for parents. Parents who learn prenatally that their baby has a genetic condition must consider the future of the pregnancy. A fetus identified as having trisomy 21 (Down syndrome) will be born with physical and developmental abnormalities; however, predicting the severity of these abnormalities is difficult. This complicates the situation for parents who have to decide whether or not to terminate the pregnancy. In addition, for some individuals, cultural and religious beliefs often factor into this decision making.

Genetic testing for adult-onset conditions also may raise ethical dilemmas. With testing for adult-onset conditions (e.g., breast cancer), issues related to “duty to warn” may surface. For example, if a woman is told that she has a *BRCA1* mutation, there are significant implications for her blood relatives. Once a *BRCA1* mutation is identified in a family, all blood relatives are eligible to receive genetic testing for the specific mutation. However, if the individual does not share her genetic test results with her family, the family members may be unaware of their chance of having the *BRCA1* mutation and of their significantly increased risk of developing breast and ovarian cancers. The lack of this knowledge may result in a family member's being denied the opportunity to choose a cancer prevention option and developing cancer as a result.

Many of the ethical concerns described in this chapter can also become a legal issue depending on the jurisdiction of the parties involved. As we increase our knowledge of genetic diseases and can better predict what variants mean for the patient (i.e., survival, prognostics, etc.), discrimination based on the genetic findings in healthy individuals has become a major disadvantage. In 2008, the United States government

passed a federal law called the *Genetic Information Nondiscrimination Act* (GINA), which protects individuals from genetic discrimination in health insurance and employment but not in life or disability insurance. Individual states have built on the federal law, such as California's CalGINA law (enacted in 2012), which extends the protection to other areas, such as housing, mortgage lending, education, and public accommodations. Until recently, Canada was the only G8 member without some sort of legislative protection; however, in 2017, the federal government voted in a bill to prevent genetic discrimination (Kirkup, 2017).

Ethical issues must be considered carefully when working with families undergoing genetic testing. These issues are often dealt with in genetic counselling offered by genetic counsellors or genetic nurses. The Committee on Assessing Genetic Risks, Division of Health Sciences Policy, Institute of Medicine, emphasizes autonomy, confidentiality, privacy, and equity as essential to analysis of questions related to genetic testing ("Social, Legal," 1994). Nurses must be aware of these ethical principles when providing care to individuals and families.

Ethical Dilemmas

Genetic Testing

Situation

A 30-year-old woman informs the nurse that she is 3 months pregnant. She has two children with her current husband. This pregnancy was unplanned, and her youngest child has cystic fibrosis (CF). She expresses concern regarding the possibility of having another child with CF. She mentions that she would like to have genetic testing on her fetus. Her husband asks the nurse if they will have another child with CF.

Important Points for Consideration

- With complete and accurate information, the woman and her husband can make a decision on their own without coercion from others.
- With genetic testing, the patient and her family can find out whether or not their child will have CF.

- Genetic counselling is recommended before and after obtaining genetic testing because of the complexity of the information and the emotional issues involved.
- The nurse, knowing that CF is an autosomal recessive condition, can use Punnett squares (see Figures 15-7, 15-9, and 15-11) to show the woman and her husband the probability of having another child with CF.
- Genetic testing in the fetus is most informative if the two pathogenic variants are first identified in the affected child. Without the known familial causative variants, prenatal testing cannot rule out the possibility that testing did not find the underlying cause (but may be outside of the tested regions of the gene). Therefore, a negative test result may not mean the fetus will not be born with CF.

Clinical Decision-Making Questions

1. What information should the nurse give the patient regarding genetic testing in order for her and her husband to make a decision?
2. What options are available for this couple?
3. How should the nurse assist this couple in making a decision about possibly terminating the pregnancy if the results of the genetic testing show that the fetus tested positive for the CF gene?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. What will the Human Genome Project accomplish? *(Select all that apply)*
   a. Help determine risk for genetic-related disease
   b. Allow for earlier detection of genetic predisposition to disease
   c. Improve the diagnosis of disease
   d. Recommend definitive treatments based on a person's genetic makeup
2. What does it mean if a person is heterozygous for a given gene?
   a. The person is a carrier for a genetic disorder.
   b. The person is affected by the genetic disorder.
   c. The person has two identical alleles for the gene.
   d. The person has two different alleles for the gene.
3. A 53-year-old male client presents with a constellation of symptoms that leads the nurse to believe that his disease is of a genetic etiology. His disease manifested when he was a teenager. The client's 29-year-old son is affected with the same disease. The client's 27-year-old daughter is healthy with an unremarkable clinical history. However, her two sons are similarly affected as their uncle. Which of the following is a mode of inheritance that most likely applies to this family?
   a. Autosomal dominant
   b. Autosomal recessive
   c. Genetic diversity
   d. Genetic drift
4. What is a family pedigree?
   a. The family ancestry traced through the father
   b. The family line of descent through the mother
   c. The depiction of an autosomal recessive gene disorder
   d. A family tree drawn in the form of a diagram
5. Which of the following would be a reason for a client or potential parents to undergo genetic testing?
   a. To determine the sex of an unborn child through amniocentesis
   b. To predict the potential for developing diabetes

c. To help couples at risk for genetic disorders to make an informed choice before conception

d. To screen for the possibility of undiagnosed breast cancer

6. Which of the following is the best response for the nurse who is asked by a pregnant woman about the risk associated with invasive prenatal testing?

a. Amniocentesis is associated with a 1 to 5% risk for miscarriage.

b. Chorionic villus sampling (CVS) is associated with a much lower risk for miscarriage than amniocentesis because it is less invasive.

c. Both amniocentesis and CVS are associated with a low risk for miscarriage (<1.5%).

d. CVS is the preferred method of prenatal testing because it can be done as late as 18 weeks gestation.

7. Why might prenatal genetic testing cause ethical, social, or legal dilemmas for parents? *(Select all that apply)*

a. The sex of the child would be known.

b. Decisions about the future of the pregnancy (including termination) would be left to the parents.

c. Health care providers would know about the genetic conditions of the unborn child.

d. Family members might question the couple's decision to undergo genetic testing.

e. Genetic testing results on the fetus could identify nonpaternity situations and have subsequent legal ramifications.

a, b, c; 2. d; 3. a; 4. d; 5. c; 6. c; 7. b, e.

CHAPTER 16

Altered Immune Response and Transplantation

Written by, Sharon L. Lewis

Adapted by, Susan Chernenko

LEARNING OBJECTIVES

1. Describe the functions and components of the immune system.
2. Compare and contrast humoral and cell-mediated immunity regarding lymphocytes involved, types of reactions, and effects on antigens.
3. Characterize the five classes of immunoglobulins.
4. Differentiate among the four types of hypersensitivity reactions in terms of immunological mechanisms and resulting alterations.
5. Identify the clinical manifestations and emergency management of a systemic anaphylactic reaction.
6. Describe the assessment and collaborative care of a patient with chronic allergies.
7. Explain the relationship between the human leukocyte antigen system and certain diseases.
8. Describe the etiological factors, the clinical manifestations, and the treatment modalities of autoimmune diseases.
9. Describe the etiological factors and categories of immunodeficiency disorders.
10. Describe the various kinds of organ transplantation and the types of rejection that may be experienced after transplantation.
11. Identify the types of immuno-suppressive therapy and their adverse effects.
12. Describe alternative strategies that have been explored to address organ donor shortages.

immuno-suppressive therapy, p. 279
monoclonal antibodies, p. 283
organ transplantation, p. 277

This chapter discusses the normal immune response and the altered immune responses of hypersensitivity (including allergies), autoimmunity, and immunodeficiency. Histocompatibility, organ transplantation, and immuno-suppressive therapy are also presented.

Normal Immune Response

Immunity is the body's ability to resist disease. Immune responses serve the following three functions (Mak, Saunders, & Jett, 2014):

1. *Defence:* The body protects against invasions by microorganisms and prevents the development of infection by attacking foreign antigens and pathogens.
2. *Homeostasis:* Damaged cellular substances are digested and removed. Through this mechanism, the body's different cell types remain uniform and unchanged.
3. *Surveillance:* Mutations continually arise in the body but are normally recognized as foreign cells and destroyed.

Antigens

An **antigen** is a substance that elicits an immune response. Most antigens are composed of proteins. However, other substances such as large polysaccharides, lipoproteins, and nucleic acids can act as antigens. All of the body's cells have antigens on their surface that are unique to that person and enable the body to recognize itself. The immune system normally becomes "tolerant" to the body's own molecules and therefore is nonresponsive to "self" antigens.

Types of Immunity

Immunity is classified as innate or acquired.

Innate Immunity.

Innate immunity is present at birth, and its primary role is first-line defence against pathogens. This type of immunity produces a nonspecific response, with neutrophils and monocytes being the white blood cells (WBCs) primarily involved. Innate immunity is not antigen specific, so it can respond within minutes to an invading microorganism without prior exposure to that organism (Mak, Saunders, & Jett, 2014).

Acquired Immunity.

Acquired immunity is the development of immunity, either actively or passively (Table 16-1).

TABLE 16-1

TYPES OF ACQUIRED SPECIFIC IMMUNITY

Active
Natural
Natural contact with antigen through clinical infection (e.g., disease and recovery from chicken pox, measles, and mumps)
Artificial
Immunization with antigen (e.g., immunization with live or killed vaccines)
Passive
Natural
Transplacental and colostrum-mediated transfer from mother to infant (e.g., maternal immunoglobulins in neonate)
Artificial
Injection of serum from immune human (e.g., injection of human γ-globulin)

Active Acquired Immunity.

Active acquired immunity results from the invasion of the body by foreign substances such as microorganisms, which leads to the development of antibodies and sensitized lymphocytes. With each reinvasion of the microorganisms, the body responds more rapidly and vigorously to fight off the invader. Active acquired immunity may result naturally from a disease or artificially through inoculation of a less virulent antigen (e.g., immunization). Because antibodies are synthesized, immunity takes time to develop but is long-lasting.

Passive Acquired Immunity.

Passive acquired immunity implies that the host receives antibodies to an antigen rather than synthesizing them. This may take place naturally through the transfer of immunoglobulins across the placental membrane from mother to fetus or artificially through injection with γ-globulin (serum antibodies). The benefit of this immunity is its immediate effect. Unfortunately, passive immunity is short-lived because the person does not synthesize the antibodies and consequently does not retain memory cells for the antigen.

Lymphoid Organs

The lymphoid system is composed of central (or primary) and peripheral lymphoid organs. The central lymphoid organs are the thymus gland and bone marrow. The peripheral lymphoid organs are the lymph nodes; tonsils; spleen; and gut-, genital-, bronchial-, and skin-associated lymphoid tissues (Figure 16-1).

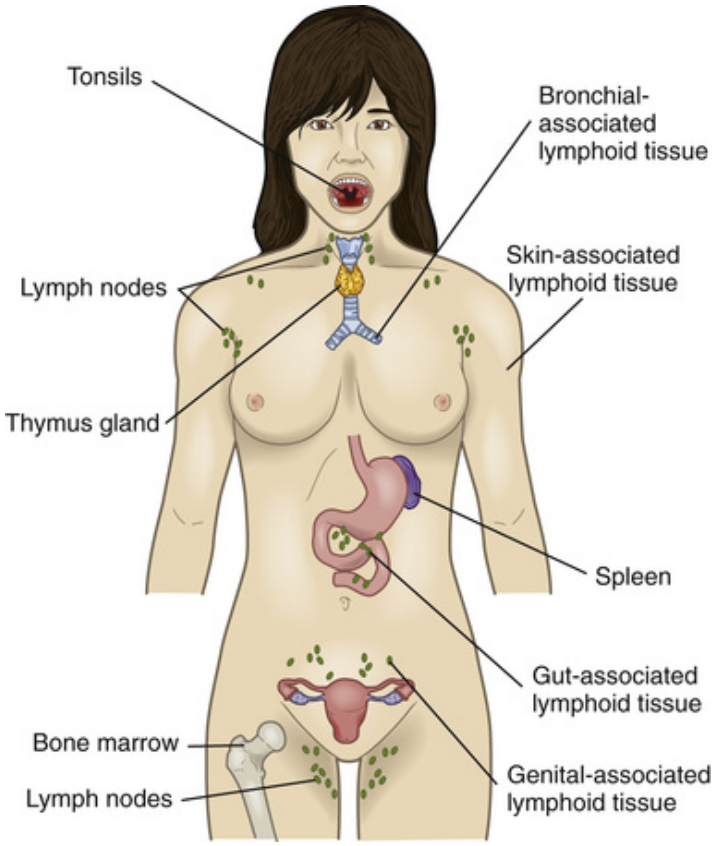

FIGURE 16-1 Organs of the immune system.

Lymphocytes are produced in the bone marrow and eventually migrate to the peripheral organs. The thymus is involved in the differentiation and maturation of T lymphocytes and is therefore essential for a cell-mediated immune response. During childhood, the thymus gland is large; however, it shrinks with age, thus becoming a collection of reticular fibres, lymphocytes, and connective tissue in older adults.

When antigens are introduced into the body, they may be carried by the bloodstream or lymph channels to regional lymph nodes. The antigens interact with B and T lymphocytes and macrophages in the lymph nodes. The two important functions of lymph nodes are (a) filtration of foreign material brought to the site and (b) circulation of lymphocytes.

Lymphoid tissue is found in the submucosa of the respiratory (bronchus-associated), gastro-intestinal (gut-associated), and genito-urinary (genital-associated) tracts. This tissue protects the body surface from external microorganisms. The tonsils are a typical example of lymphoid tissue.

The spleen, a peripheral lymph organ, is important as the primary site for filtering foreign antigens from the blood.

The skin-associated lymph tissue primarily consists of lymphocytes and Langerhans cells (a type of dendritic cell) found in the epidermis of skin. When Langerhans cells are depleted, the skin cannot initiate an immune response. Therefore, a delayed hypersensitivity reaction (as determined by skin testing with injected antigens) does not occur.

Cells Involved in Immune Response

Mononuclear Phagocytes.

The mononuclear phagocyte system includes monocytes in the blood and macrophages throughout the body. Mononuclear phagocytes have a critical role in the immune system. They are responsible for capturing, processing, and presenting the antigen to the lymphocytes. The antigen then stimulates a humoral or cell-mediated immune response. Capturing is accomplished through phagocytosis. The macrophage-bound antigen, which is highly immunogenic, is presented to circulating T or B lymphocytes and thus triggers an immune response (Figure 16-2).

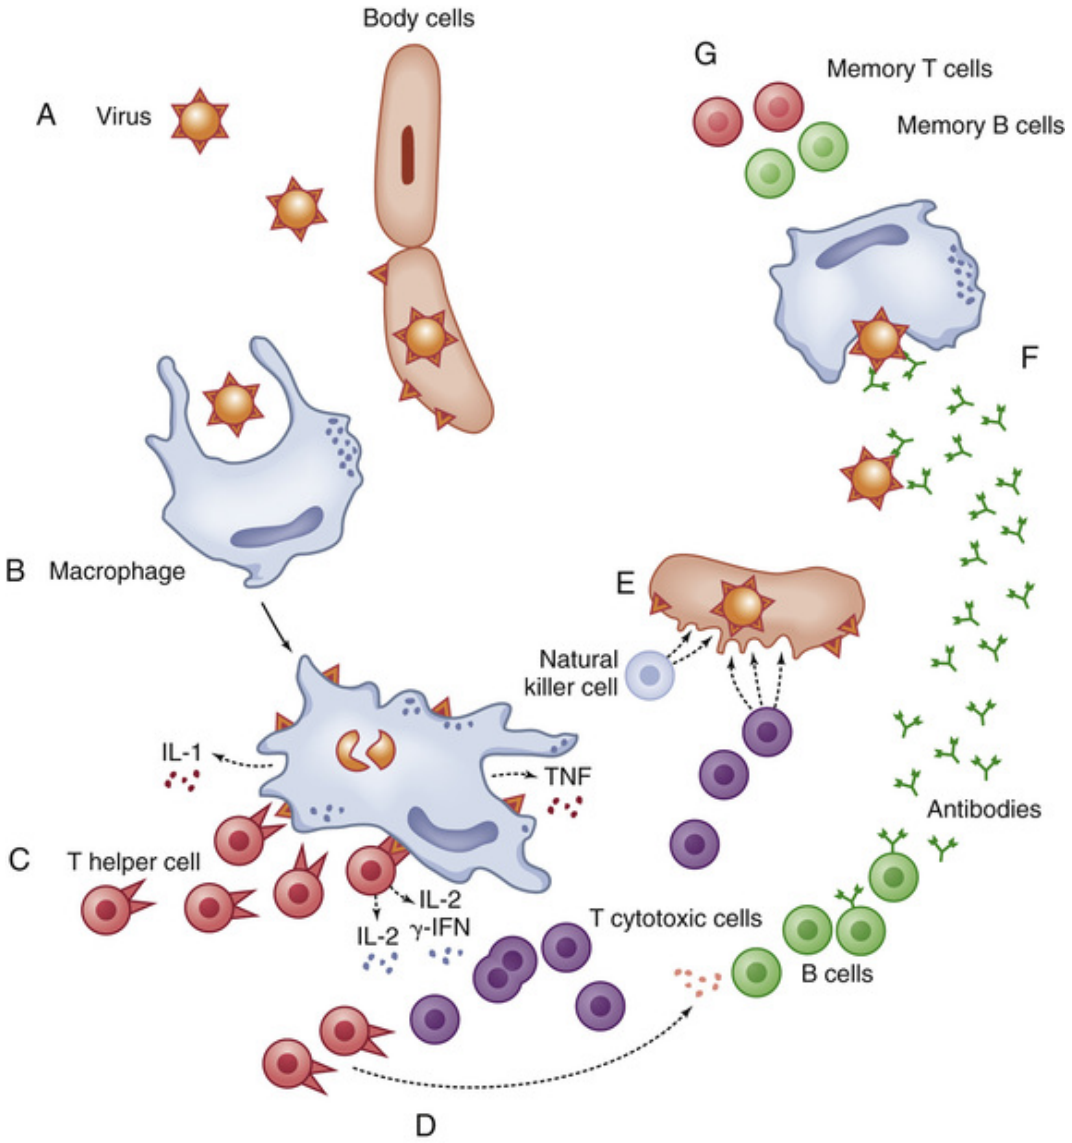

FIGURE 16-2 The immune response to a virus. **A,** A virus invades the body through a break in the skin or another portal of entry. The virus must make its way inside a cell in order to replicate itself. **B,** A macrophage recognizes the antigens on the surface of the virus. The macrophage digests the virus and displays pieces of the virus (antigens) on its surface. **C,** T helper cells recognize the antigen displayed and bind to the macrophage. This binding stimulates the production of cytokines (interleukin-1 [IL-1] and tumour necrosis factor [TNF]) by the macrophage and interleukin-2 (IL-2) and γ-interferon (γ-IFN) by the T helper cells. These cytokines are intercellular messengers that provide communication among the cells. **D,** IL-2 instructs other T helper cells and T cytotoxic cells to proliferate (multiply). T helper cells release cytokines, causing B cells to multiply and produce antibodies. **E,** T cytotoxic cells and natural killer cells destroy infected body cells. **F,** The antibodies bind

to the virus and mark it for macrophage destruction. **G,** Once the virus is gone, activated T and B cells are turned off by suppressor T cells. Memory B and T cells remain behind to respond quickly if the same virus attacks again.

Lymphocytes.

Lymphocytes are produced in the bone marrow (Figure 16-3). They then differentiate into B and T lymphocytes.

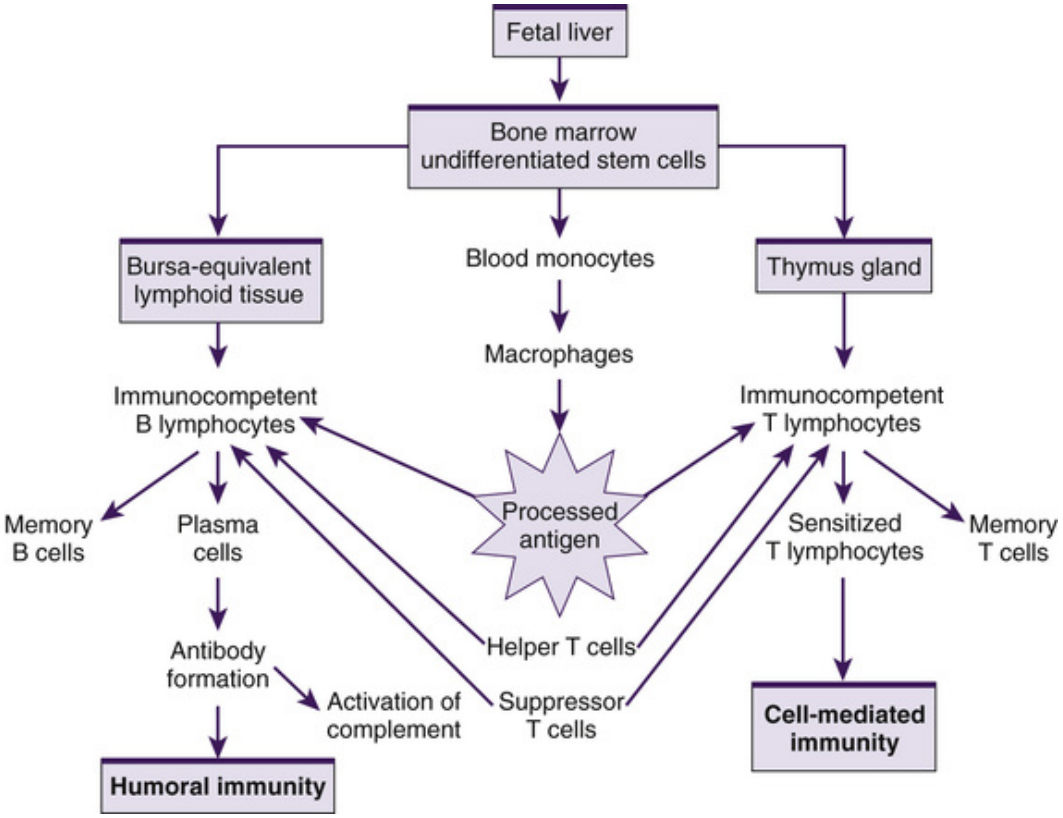

FIGURE 16-3 Relationships and functions of macrophages, B lymphocytes, and T lymphocytes in an immune response.

B Lymphocytes.

Early research on B lymphocytes (bursa-equivalent lymphocytes) in birds showed that they mature under the influence of the bursa of Fabricius; hence the name *B cells.* However, this lymphoid organ does not exist in humans. The bursa-equivalent tissue in humans is the bone marrow. B

cells differentiate into *plasma cells* when activated and produce antibodies (called *immunoglobulins*) (Table 16-2).

TABLE 16-2
CHARACTERISTICS OF IMMUNOGLOBULINS

Class	Relative Serum Concentration (%)	Location	Characteristics
IgG	76	Plasma, interstitial fluid	Is only immunoglobulin that crosses placenta
			Is responsible for secondary immune response
IgA	15	Body secretions, including tears, saliva, breast milk, colostrum	Lines mucous membranes and protects body surfaces
IgM	8	Plasma	Is responsible for primary immune response
			Forms antibodies to ABO blood antigens
IgD	1	Plasma	Is present on lymphocyte surface
			Assists in the differentiation of B lymphocytes
IgE	0.002	Plasma, interstitial fluids	Causes symptoms of allergic reactions
			Fixes to mast cells and basophils
			Assists in defence against parasitic infections

Ig, immunoglobulin.

T Lymphocytes.

Cells that migrate from the bone marrow to the thymus differentiate into T lymphocytes (thymus-dependent cells). The thymus secretes hormones, including thymosin, that stimulate the maturation and differentiation of T lymphocytes. T cells make up 70 to 80% of the circulating lymphocytes and are primarily responsible for immunity to intracellular viruses, tumour cells, and fungi. T cells live from a few months to an individual's lifespan and account for long-term immunity.

T lymphocytes can be categorized into T cytotoxic and T helper cells. Antigenic characteristics of WBCs have now been classified using monoclonal antibodies. These antigens are classified as *clusters of differentiation*, or *CD, antigens.* Many types of WBCs, especially lymphocytes, are referred to by their CD designations. All mature T cells have the CD3 antigen (Kasper, Fauci, Hauser, et al., 2015).

T Cytotoxic Cells.

T cytotoxic (CD8) cells are involved in attacking antigens on the cell membrane of foreign pathogens and releasing cytolytic substances that destroy the pathogen. These cells have antigen specificity and are sensitized by exposure to the antigen (Kasper, Fauci, Hauser, et al., 2015). Much like B lymphocytes, some sensitized T cells do not attack the antigen but remain as memory T cells. As in the humoral immune response, a second exposure to the antigen results in a more intense and rapid cell-mediated immune response.

T Helper Cells.

T helper (CD4) cells are involved in the regulation of cell-mediated immunity and the humoral antibody response. T helper cells differentiate into subsets of cells that produce distinct types of cytokines (discussed in a later section). These subsets are called T_H1 cells and T_H2 cells. T_H1 cells stimulate phagocyte-mediated ingestion and killing of microbes, the key component of cell-mediated immunity. T_H2 cells stimulate eosinophil-mediated immunity, which is effective against parasites and is involved in allergic responses.

Natural Killer Cells.

Natural killer (NK) cells are also involved in cell-mediated immunity. These cells are not T or B cells but are large lymphocytes with numerous granules in the cytoplasm. Prior sensitization is not required for the generation of NK cells. These cells are involved in the recognition and killing of virus-infected cells, tumour cells, and transplanted grafts; however, the mechanism of recognition is not fully understood. NK cells have a significant role in immune surveillance for malignant cell changes.

Dendritic Cells.

Dendritic cells are a system of cells that play a significant role in cell-mediated immune response. They are found in the skin (called *Langerhans cells*), the lining of the nose, the lungs, the stomach, and the intestines, and when in an immature state, they can be found in the blood. Their primary function is to capture antigens at sites of contact with the external environment (e.g., skin, mucous membranes) and then transport this antigen until it encounters a T cell with specificity for the antigen. Dendritic cells have an important function in activating the immune response (William, 2013).

Cytokines

The immune response involves complex interactions of T cells, B cells, monocytes, and neutrophils. These interactions depend on **cytokines** (soluble factors secreted by WBCs and a variety of other cells in the body), which act as messengers between the cell types. Cytokines instruct cells to alter their proliferation, differentiation, secretion, or activity.

Currently more than 100 different cytokines are known, and they can be classified into distinct categories (Mak, Saunders, & Jett, 2014). Some of these cytokines are listed in Table 16-3. In general, the interleukins act as immuno-modulatory factors; colony-stimulating factors act as growth-regulating factors for hematopoietic cells; and interferons are antiviral and immuno-modulatory.

TABLE 16-3
TYPES AND FUNCTIONS OF CYTOKINE

Type	Primary Functions
Interleukins (ILs)	
IL-1	Augments the immune response; mediates the inflammatory response; promotes maturation and clonal expansion of B cells; enhances activity of NK cells; activates T cells; activates macrophages
IL-2	Induces proliferation and differentiation of T cells; plays role in activation of T cells, NK cells, and macrophages; stimulates release of other cytokines (α-IFN, TNF, IL-1, IL-6)
IL-3 (multicolony-stimulating factor)	Hematopoietic growth factor for hematopoietic precursor cells
IL-4	B-cell growth factor: stimulates proliferation and differentiation of B cells; induces proliferation of T cells; stimulates growth of mast cells
IL-5	Promotes B-cell growth and differentiation; promotes growth and differentiation of eosinophils
IL-6	Enhances the inflammatory response; plays role in B-cell stimulation; promotes differentiation of B cells into plasma cells; stimulates antibody secretion; induces fever; has synergistic effects with IL-1 and TNF
IL-7	Promotes growth of T and B cells; increases expression of IL-2 and its receptor
IL-8	Involved in chemotaxis of neutrophils and T cells; stimulates superoxide and granule release
IL-9	Acts as mitogen, supporting proliferation in absence of antigen; enhances T-cell survival; plays role in mast cell activation
IL-10	Inhibits cytokine production by T and NK cells; promotes B-cell proliferation and antibody responses; is potent suppressor of macrophage function
IL-11	Is a multifunctional regulator of hematopoiesis and lymphopoiesis; plays role in osteoclast formation; elevates platelet count; inhibits proinflammatory cytokine production
IL-12	Promotes α-IFN production; plays role in induction of T helper cells; activates NK cells; stimulates proliferation of activated T and NK cells
IL-13	Promotes B-cell growth and differentiation; inhibits proinflammatory cytokine production
IL-14	Stimulates proliferation of activated B cells
IL-15	Mimics IL-2 effects; stimulates proliferation of T cells and NK cells
IL-16	Proinflammatory cytokine; chemoattractant of T cells, eosinophils, and monocytes
IL-17	Promotes release of IL-6, IL-8, G-CSF; enhances expression of adhesion molecules
IL-18	Induces α-IFN, IL-2, and GM-CSF production; plays important role in development of T helper cells; enhances NK activity; inhibits production of IL-10
IL-19	Similar to IL-10
IL-20	Similar to IL-10
IL-21	Similar to IL-2, IL-4, and IL-5
IL-22	Similar to IL-10
IL-23	Similar to IL-12; also promotes memory T-cell proliferation
IL-24	Similar to IL-10
Interferons (IFNs)	
α-IFN	Inhibits viral replication; activates NK cells and macrophages; has antiproliferative effects on tumour cells
β-IFN	Inhibits viral replication; inhibits certain white blood cells; is used in the treatment of multiple sclerosis
γ-IFN	Activates macrophages, neutrophils, and NK cells; promotes B-cell differentiation; inhibits viral replication
Tumour Necrosis Factor (TNF)	
TNF	Activates macrophages and granulocytes; promotes the immune and inflammatory responses; kills tumour cells; is responsible for extensive weight loss associated with chronic inflammation and cancer
Colony-Stimulating Factors (CSFs)	
G-CSF	Stimulates proliferation and differentiation of neutrophils; enhances functional activity of mature PMNs

Type	Primary Functions
GM-CSF	Stimulates proliferation and differentiation of PMNs and monocytes
M-CSF	Promotes the proliferation, differentiation, and activation of monocytes and macrophages

G-CSF, granulocyte colony-stimulating factor; *GM-CSF,* granulocyte-macrophage colony-stimulating factor; *M-CSF,* macrophage colony-stimulating factor; *NK,* natural killer; *PMN,* polymorphonuclear neutrophil.

The net effect of an inflammatory response is determined by a balance between proinflammatory and anti-inflammatory mediators. Sometimes cytokines are classified as proinflammatory or anti-inflammatory. However, it is not that straightforward since many other factors (e.g., target cells, environment) influence the inflammatory response to a given injury or insult.

Cytokines serve a beneficial role in hematopoiesis and immune function but can also have detrimental effects such as those observed in chronic inflammation, autoimmune diseases, and sepsis. Cytokines such as erythropoietin (see Chapters 18, 35, and 49), colony-stimulating factors, interferons (see Chapter 18), and interleukin-2 (see Chapter 18) are used clinically.

Three types of interferons have now been identified (Table 16-3). Interferons help the body's natural defences attack tumours and viruses (Table 16-4). Interferons are not directly antiviral but produce an antiviral effect in cells by reacting with them and inducing the formation of a second protein termed *antiviral protein* (Figure 16-4). This protein mediates the antiviral action of interferons by altering the cell's protein synthesis and prevents the virus from replicating.

TABLE 16-4
CLINICAL USES OF CYTOKINES

Cytokine	Clinical Uses
α-Interferon	
(Intron A)	Hepatitis B and C Kaposi's sarcoma Hairy cell leukemia Lymphomas Melanoma Renal cell carcinoma Multiple myeloma
β-Interferon	
β-Interferon-1b (Betaseron) β-Interferon-1a (Avonex, Rebif)	Multiple sclerosis
Colony-Stimulating Factors: G-CSF, GM-CSF	
Filgrastim (Neupogen)	Neutropenia
Soluble Tumour Necrosis Factor Receptor	
Etanercept (Enbrel)	Rheumatoid arthritis
Interleukin-2	
Aldesleukin (Proleukin)	Renal cell carcinoma Malignant melanoma Lymphoma Acute myelocytic leukemia
Erythropoietin	
Darbepoetin alfa (Aranesp) Epoetin alfa (Eprex)	Anemia
Interleukin-1 Receptor Antagonist	
Anakinra (Kineret)	Rheumatoid arthritis

G-CSF, granulocyte colony-stimulating factor; *GM-CSF,* granulocyte-macrophage colony-stimulating factor.

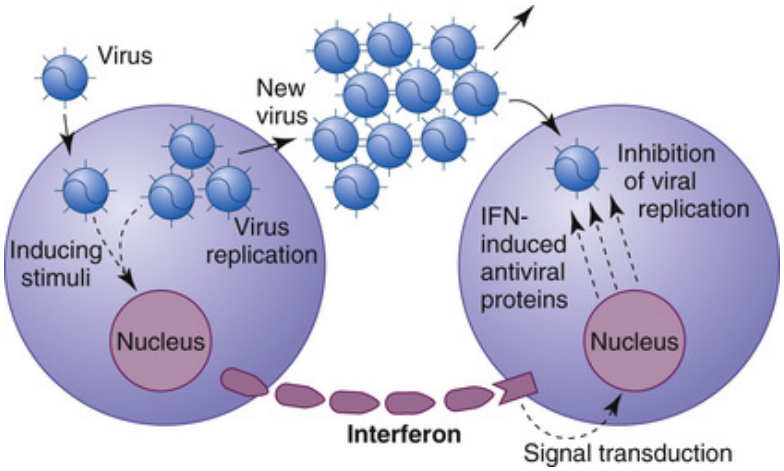

FIGURE 16-4 Mechanism of action of interferons. The virus attacks a cell. The cell begins to synthesize viral DNA and interferons. Interferons serve as intercellular messengers. Interferons induce the production of antiviral proteins. The virus is not able to replicate in the cell.

Comparison of Humoral and Cell-Mediated Immunity

Humans need both humoral and cell-mediated immunity to remain healthy. Each type of immunity has unique properties and different modes of action and reactions against particular antigens. Table 16-5 compares humoral and cell-mediated immunity.

TABLE 16-5

COMPARISON OF HUMORAL IMMUNITY AND CELL-MEDIATED IMMUNITY

Characteristics	Humoral Immunity	Cell-Mediated Immunity
Cells involved	B lymphocytes	T lymphocytes, macrophages
Products	Antibodies	Sensitized T cells, lymphokines
Memory cells	Present	Present
Protection	Bacteria Viruses (extracellular) Respiratory and gastro-intestinal pathogens	Fungi Viruses (intracellular) Chronic infectious agents Tumour cells

Humoral Immunity.

Humoral immunity is antibody-mediated immunity. The term *humoral* comes from the Greek word *humor,* which means "body fluid." Since antibodies are produced by plasma cells (differentiated B cells) and found in plasma, the term *humoral immunity* is used. Production of antibodies is an essential component in a humoral immune response. Each of the five classes of immunoglobulins (Igs)—that is, IgG, IgA, IgM, IgD, and IgE—has specific characteristics (see Table 16-2).

When a pathogen (especially bacteria) enters the body, it may encounter a B lymphocyte specific for antigens located on that bacterial cell wall. In addition, a monocyte or macrophage may phagocytize the bacteria and present its antigens to a B lymphocyte. The B lymphocyte recognizes the antigen because it has receptors on its cell surface specific for that antigen. When the antigen comes in contact with the cell surface receptor, the B cell becomes activated, and most B cells differentiate into plasma cells (see Figure 16-3). The mature plasma cell secretes immunoglobulins. Some stimulated B lymphocytes remain as memory cells.

The primary immune response becomes evident 4 to 8 days after the initial exposure to the antigen (Figure 16-5). IgM is the first type of antibody formed. Because of the large size of the IgM molecule, this immunoglobulin is confined to the intravascular space. As the immune response progresses, IgG is produced and can move from intravascular to extravascular spaces.

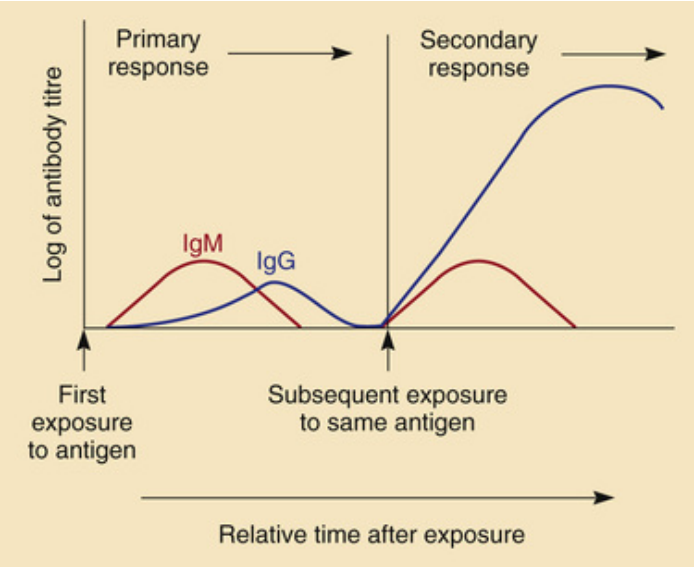

FIGURE 16-5 Primary and secondary immune responses. The introduction of antigen induces a response dominated by two classes of immunoglobulins: immunoglobulin M (IgM) and immunoglobulin G (IgG). IgM predominates in the primary response; some amount of IgG appears later. After the host's immune system is primed, another challenge with the same antigen induces the secondary response, in which some IgM and large amounts of IgG are produced.

When the individual is exposed to the antigen the second time, a secondary antibody response occurs. This response occurs faster (1 to 3 days), is stronger, and lasts for a longer time than a primary response. Memory cells account for the memory of the first exposure to the antigen and the more rapid production of antibodies. IgG is the primary antibody found in a secondary immune response.

IgG crosses the placental membrane and provides the newborn with passive acquired immunity for at least 3 months. Infants may also get some passive immunity from IgA in breast milk and colostrum.

Cell-Mediated Immunity.

Immune responses that are initiated through specific antigen recognition by T cells are termed **cell-mediated immunity**. Several cell types and factors are involved in cell-mediated immunity, including T lymphocytes, macrophages, and NK cells. Cell-mediated immunity is of primary importance in (a) immunity against pathogens that survive inside of cells, including viruses and some bacteria (e.g., *Mycobacterium* species); (b)

immunity against fungal infections; (c) rejection of transplanted tissues; (d) contact hypersensitivity reactions; and (e) tumour immunity.

Age-Related Considerations

Effects of Aging on the Immune System

With advancing age, the effectiveness of the immune system declines (Camous, Pera, Solana, et al., 2012; Table 16-6). The primary clinical evidence for this immuno-senescence is the high incidence of malignancies in older adults. Older people become increasingly susceptible to infections (e.g., influenza, pneumonia) from pathogens they were relatively immunocompetent against earlier in life. Bacterial pneumonia is the leading cause of death from infections in older adults. The antibody response to immunizations (e.g., flu vaccine) in older adults is considerably lower than in younger adults.

TABLE 16-6

AGE-RELATED DIFFERENCES IN ASSESSMENT
Effects of Aging on the Immune System

- ↓ Autoantibodies
- ↓ Cell-mediated immunity
- ↓ Delayed hypersensitivity response
- ↓ Expression of IL-2 receptors
- ↓ IL-1 and IL-2 synthesis
- ↓ Primary and secondary antibody responses
- ↓ Proliferative response of T and B cells
- Thymic involution

IL-1, interleukin-1; *IL-2*, interleukin-2.

The bone marrow is relatively unaffected by increasing age. Immunoglobulin levels decrease with age and therefore lead to a suppressed humoral immune response in older adults. Thymic involution (shrinking) occurs with aging, along with decreased numbers of T cells. These changes in the thymus gland are a primary cause of immunosenescence. Both T and B cells show deficiencies in activation, transit time through the cell cycle, and subsequent differentiation. However, the most significant alterations involve T cells. As thymic output of T cells diminishes, the differentiation of T cells increases. Consequently, memory cells accumulate, rather than new precursor cells responsive to previously unencountered antigens.

The delayed hypersensitivity response, as determined by skin testing with injected antigens, is frequently decreased or absent in older adults. This altered response reflects **anergy** (an immunodeficient condition

characterized by lack of or diminished reaction to an antigen or a group of antigens).

Altered Immune Response

Immuno-competence is the state in which the body's immune system can identify and inactivate or destroy foreign substances. When the immune system is incompetent or under-responsive, severe infections, immunodeficiency diseases, and malignancies may occur. When the immune system overreacts, hypersensitivity disorders such as allergies and autoimmune diseases may occur.

Hypersensitivity Reactions

Sometimes the immune response is overreactive against foreign antigens or reacts against its own tissue, resulting in tissue damage. This is termed a **hypersensitivity reaction**. Autoimmune diseases, a type of hypersensitivity response, occur when the body fails to recognize self-proteins and reacts against self-antigens.

Hypersensitivity reactions may be classified according to the source of the antigen, the time sequence (immediate or delayed), or the basic immunological mechanisms causing the injury. Four types of hypersensitivity reactions exist (Table 16-7). Types I, II, and III are immediate and are examples of humoral immunity. Type IV is a delayed hypersensitivity reaction and is related to cell-mediated immunity.

TABLE 16-7
TYPES OF HYPERSENSITIVITY REACTIONS

Type I: Anaphylactic Reactions	Type II: Cytotoxic Reactions	Type III: Immune-Complex Reactions	Type IV: Delayed Hypersensitivity Reactions
Antigen			
Exogenous pollen, food, drugs, dust	Cell surface of RBCs Basement membrane	Extracellular fungal, viral, bacterial	Intracellular or extracellular
Antibody Involved			
IgE	IgG IgM	IgG IgM	None
Complement Involved			
No	Yes	Yes	No
Mediators of Injury			
Histamine SRS-A	Complement lysis Neutrophils	Neutrophils Complement lysis	Cytokines T cytotoxic cells Monocytes, macrophages Lysosomal enzymes
Examples			
Allergic rhinitis Asthma	Transfusion reaction Goodpasture's syndrome	Serum sickness Systemic lupus erythematosus Rheumatoid arthritis	Contact dermatitis Tumour rejection Transplant rejection
Skin Test			
Wheal and flare	None	Erythema and edema in 3 to 8 hours	Erythema and edema in 24 to 48 hours (e.g., tuberculin test)

*Ig*E, immunoglobulin E; *IgG*, immunoglobulin G; *IgM*, immunoglobulin M; *RBC*, red blood cell; *SRS-A*, slow-reacting substance of anaphylaxis.

Type I: IgE-Mediated Reactions.

Anaphylactic reactions are type I reactions that occur only in susceptible people who are highly sensitized to specific allergens. IgE antibodies, produced in response to the allergen, have a characteristic property of attaching to mast cells and basophils (Figure 16-6; see also Chapter 31, Figure 31-2). Within these cells are granules containing potent chemical mediators (histamine, serotonin, leukotrienes, eosinophil chemotactic factor of anaphylaxis [ECF-A], kinins, and bradykinin). (Chemical mediators of inflammation are discussed in Chapter 14 and Table 14-3. Anaphylaxis is also discussed in Chapters 14 and 31.)

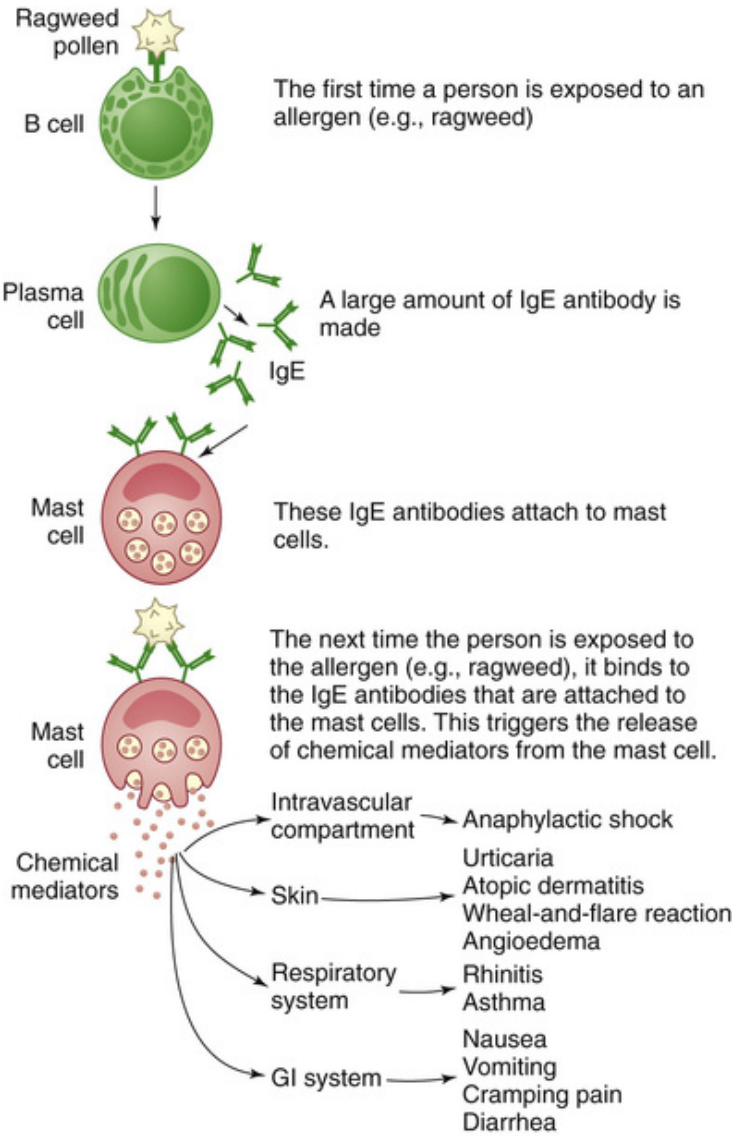

FIGURE 16-6 Steps in a type I allergic reaction. *GI*, gastrointestinal; *IgE*, immunoglobulin E.

On the first exposure to the allergen, IgE antibodies are produced and bind to mast cells and basophils. On any subsequent exposures, the allergen links with the IgE bound to mast cells or basophils and triggers degranulation of the cells and the release of chemical mediators from the granules. These chemical mediators attack target tissues, causing clinical symptoms of allergy (Mak, Saunders, & Jett, 2014). These effects include smooth muscle contraction, increased vascular permeability, vasodilation, hypotension, increased secretion of mucus, and itching. Fortunately, the mediators are short-acting, and their effects are reversible. The mediators and their effects are summarized in Table 16-8.

TABLE 16-8
MEDIATORS OF ALLERGIC RESPONSE

Type and Source	Biological Activity	Clinical Manifestations
Histamine		
Mast cell and basophil granules	Increase vascular permeability; constrict smooth muscle; stimulate irritant receptors	Edema of airways and larynx; bronchial constriction; urticaria, angioedema, pruritus; nausea, vomiting, diarrhea; shock
Leukotrienes		
Metabolites of arachidonic acid by lipoxygenase pathway	Constrict bronchial smooth muscle; increase vascular permeability	Bronchial constriction; enhanced effect of histamine on smooth muscle
Prostaglandins		
Metabolites of arachidonic acid by cyclo-oxygenase pathway	Stimulate vasodilation; constrict smooth muscle	Wheal-and-flare reaction on skin; hypotension; bronchospasm
Platelet-Activating Factor		
Mast cell	Aggregates platelets; stimulates vasodilation	Increase in pulmonary artery pressure; systemic hypotension
Kinins		
Kininogen	Stimulates slow, sustained smooth muscle contraction; increases vascular permeability; stimulates secretion of mucus; stimulates pain receptors	Angioedema with painful swelling; bronchial constriction
Serotonin		
Platelets	Increase vascular permeability; stimulate smooth muscle contraction	Mucosal edema; bronchial constriction
Anaphylatoxins		
C3a, C4a, C5a from complement activation	Stimulate histamine release	Edema of airways and larynx; bronchial constriction; urticaria, angioedema, pruritus; nausea, vomiting, diarrhea; shock

A genetic predisposition to the development of allergic diseases exists. The capacity to become sensitized to an allergen, rather than the specific allergic disorder, appears to be an inherited trait. For example, a father with asthma may have a son who has allergic rhinitis.

The clinical manifestations of an anaphylactic reaction depend on whether the mediators remain local or become systemic or whether they affect particular organs. When the mediators remain localized, a cutaneous response termed the *wheal-and-flare reaction* occurs. This reaction is characterized by a pale wheal (pink, raised, edematous, pruritic areas) containing edematous fluid, surrounded by a red flare from the hyperemia. The reaction occurs in minutes or hours and is usually not dangerous. A classic example of a wheal-and-flare reaction is the mosquito bite. The wheal-and-flare reaction serves a diagnostic purpose as a means of demonstrating allergic reactions to specific allergens during skin tests.

Common allergic reactions include anaphylaxis and atopic reactions.

Anaphylaxis.

Anaphylaxis can occur when mediators are released systemically (e.g., after injection of a drug, after an insect sting). The reaction occurs within minutes and can be life-threatening as a result of bronchial constriction and subsequent airway obstruction and vascular collapse. The target organs affected are depicted in Figure 16-7. Initial symptoms include edema and itching at the site of the exposure to the allergen. Shock can occur rapidly and is manifested by a rapid, weak pulse; hypotension; dilated pupils; dyspnea; and possibly cyanosis. This is compounded by bronchial edema and angioedema. Death occurs if emergency treatment is not initiated. Treatment can range from epinephrine administered subcutaneously for mild symptoms to full circulatory support with oxygen and vasopressor therapy (Waserman, Chad, Francoeur, et al., 2010). Some of the important allergens leading to anaphylactic shock in hypersensitive people are listed in Table 16-9. Medications are the leading cause of anaphylaxis-related deaths (Moore, Kemp, & Kemp, 2015).

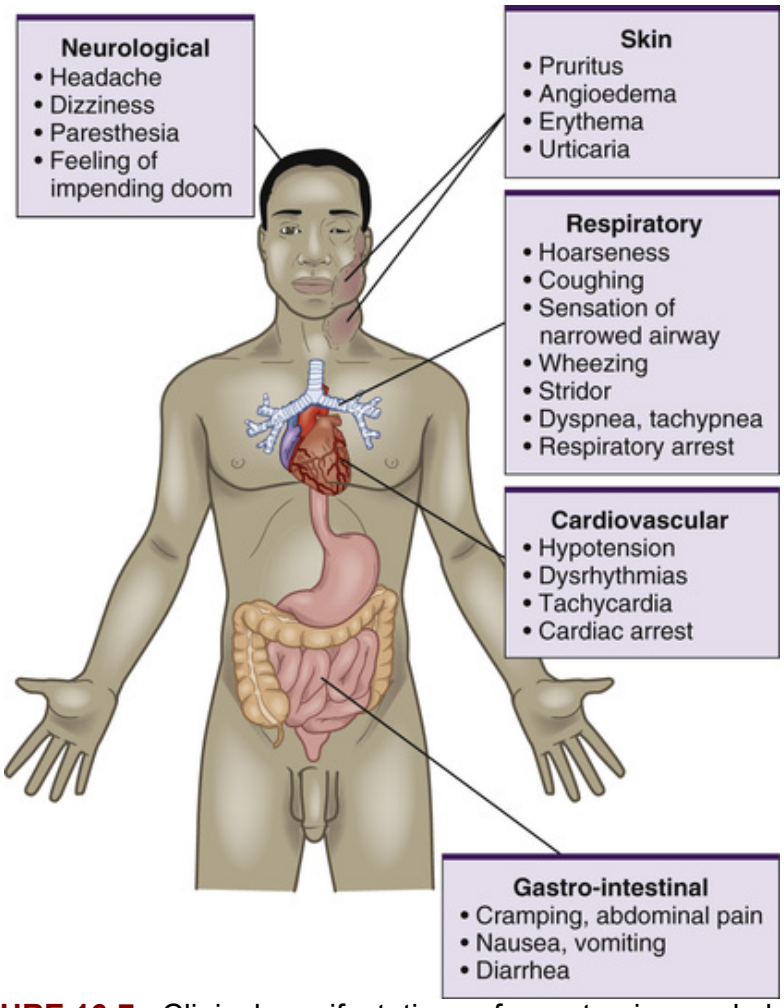

FIGURE 16-7 Clinical manifestations of a systemic anaphylactic reaction.

TABLE 16-9
ALLERGENS THAT CAUSE ANAPHYLACTIC SHOCK

Drugs
• Aspirin • Cephalosporins • Chemotherapeutic drugs • Insulins • Local anaesthetics • Nonsteroidal anti-inflammatory drugs • Penicillins • Sulfonamides • Tetracycline
Insect Venoms
• Hymenoptera*
Foods
• Eggs • Nuts • Shellfish • Chocolate • Milk • Peanuts • Fish • Strawberries
Animal Sera
• Tetanus antitoxin • Diphtheria antitoxin • Rabies antitoxin • Snake venom antitoxin
Treatment Measures
• Blood products (whole blood and components) • Allergenic extracts in hyposensitization therapy • Iodine-contrast media for intravenous pyelography or angiography

*Wasps, hornets, yellow jackets, bumblebees, and ants.

Atopic Reactions.

An estimated 20% of the population are atopic, which means they have an inherited tendency to become sensitive to environmental allergens. The atopic diseases that can result are allergic rhinitis, asthma, atopic dermatitis, urticaria, and angioedema.

Allergic rhinitis, or hay fever, is the most common type I hypersensitivity reaction. It may occur year-round (perennial allergic rhinitis), or it may be seasonal (seasonal allergic rhinitis). Airborne substances such as pollens, dust, or moulds are the primary cause of allergic rhinitis. Perennial allergic rhinitis may be caused by dust, moulds, and animal dander. Seasonal allergic rhinitis is commonly caused by pollens from trees, weeds, or grasses. The target areas affected are the conjunctivas of the eyes and the mucosa of the upper respiratory tract. Symptoms include nasal discharge, sneezing, lacrimation, mucosal

swelling with airway obstruction, and pruritus around the eyes, nose, throat, and mouth. (Treatment of allergic rhinitis is discussed in Chapter 29.)

Many patients with asthma have an allergic component to their disease. These patients frequently have a history of atopic disorders (e.g., infantile eczema, allergic rhinitis, food intolerances). Inflammatory mediators produce bronchial smooth muscle constriction, excessive secretion of viscous mucus, edema of the mucous membranes of the bronchi, and decreased lung compliance. Because of these physiological alterations, affected patients manifest dyspnea, wheezing, coughing, tightness in the chest, and thick sputum. (Pathophysiology and management of asthma are discussed in Chapter 31.)

Atopic dermatitis is a chronic, inherited skin disorder characterized by exacerbations and remissions. It is caused by several environmental allergens that are difficult to identify. Although patients with atopic dermatitis have elevated IgE levels and positive skin tests, the histopathological features do not represent the typical, localized wheal-and-flare type I reactions. The skin lesions are more generalized and involve vasodilation of blood vessels, resulting in interstitial edema with vesicle formation (Figure 16-8). (Dermatitis is discussed in Chapter 26.)

FIGURE 16-8 Eczema of the lower leg. Source: Morison, M. J. (2001). *Nursing management of chronic wounds*. Edinburgh: Mosby.

Urticaria (hives) is a cutaneous reaction against systemic allergens that occurs in atopic people. It is characterized by transient wheals that vary in size and shape and may occur throughout the body. Urticaria develops

rapidly after exposure to an allergen and may last minutes or hours. Histamine causes localized vasodilation (erythema), transudation of fluid (wheal), and flaring. Flaring is caused by dilation of blood vessels on the edge of the wheal. Histamine is responsible for the pruritus associated with the lesions. (Urticaria is discussed further in Chapter 26.)

Angioedema is a localized cutaneous lesion similar to urticaria but involving deeper layers of the skin and submucosa. The principal areas of involvement include the eyelids, lips, tongue, larynx, hands, feet, gastro-intestinal tract, and genitalia. Swelling usually begins in the face and then progresses to the airways and other parts of the body. Dilation and engorgement of the capillaries secondary to release of histamine cause the diffuse swelling. Welts are not apparent as in urticaria. The outer skin appears normal or has a reddish hue. The lesions may burn, sting, or itch and, if in the gastro-intestinal tract, can cause acute abdominal pain. The swelling may occur suddenly or over several hours and usually lasts for 24 hours.

Type II: Cytotoxic and Cytolytic Reactions.

Cytotoxic and cytolytic reactions are type II hypersensitivity reactions involving the direct binding of IgG or IgM antibodies to an antigen on the cell surface. Antigen–antibody complexes activate the complement system, which mediates the reaction. Cellular tissue is destroyed in one of two ways: (a) activation of the complement cascade resulting in cytolysis or (b) enhanced phagocytosis.

Target cells frequently destroyed in type II reactions are erythrocytes, platelets, and leukocytes. The tissue damage usually occurs rapidly. Some of the antigens involved are the ABO blood group, rhesus (Rh) factor, and drugs. Pathophysiological disorders characteristic of type II reactions include ABO incompatibility transfusion reaction, Rh incompatibility transfusion reaction, autoimmune and drug-related hemolytic anemias, leukopenia, thrombocytopenia, erythroblastosis fetalis (hemolytic disease of the newborn), and Goodpasture's syndrome. Tissue damage usually occurs rapidly.

Hemolytic Transfusion Reactions.

A classic type II reaction occurs when a recipient receives ABO-incompatible blood from a donor. Naturally acquired antibodies to antigens of the ABO blood group are in the recipient's serum but are not present on the erythrocyte membranes (see Chapter 32, Table 32-9). For

example, a person with type A blood has anti-B antibodies, a person with type B blood has anti-A antibodies, a person with type AB blood has no antibodies, and a person with type O blood has both anti-A and anti-B antibodies.

If the recipient receives a transfusion with incompatible blood, antibodies immediately coat the foreign erythrocytes, causing agglutination (clumping). The clumping of cells blocks small blood vessels in the body, using and thus depleting existing clotting factors, which leads to bleeding. Within hours, neutrophils and macrophages phagocytize the agglutinated cells. As complement is fixed to the antigen, cell lysis occurs, which in turn causes the release of hemoglobin into the urine and plasma. In addition, a cytotoxic reaction causes vascular spasms in the kidney that further block the renal tubules. Acute kidney injury can result from hemoglobinuria. (Blood transfusions are discussed in Chapter 33.)

Goodpasture's Syndrome.

Goodpasture's syndrome is a rare disorder involving the lungs and the kidneys. An antibody-mediated autoimmune reaction occurs involving the glomerular and alveolar basement membranes. The circulating antibodies combine with tissue antigen to activate the complement system, which causes deposits of IgG to form along the basement membranes of the lungs or the kidneys. This reaction may result in pulmonary hemorrhage and glomerulonephritis. (Goodpasture's syndrome is discussed further in Chapter 48.)

Type III: Immune-Complex Reactions.

Tissue damage in immune-complex reactions, which are type III reactions, occurs secondary to antigen–antibody complexes. Soluble antigens combine with immunoglobulins of the IgG and IgM classes to form complexes that are too small to be effectively removed by the mononuclear phagocyte system. Therefore, the complexes deposit in tissue or small blood vessels. They cause activation of the complement system and release of chemotactic factors that lead to inflammation and destruction of the involved tissue.

Type III reactions may be local or systemic and immediate or delayed. The clinical manifestations depend on the number of complexes and their location in the body. Common sites for deposit are the kidneys, skin, joints, blood vessels, and lungs. Severe type III reactions are associated with autoimmune disorders such as systemic lupus erythematosus (SLE),

acute glomerulonephritis, and rheumatoid arthritis. (SLE and rheumatoid arthritis are discussed further in Chapter 67, and acute glomerulonephritis is discussed further in Chapter 48.)

Type IV: Delayed Hypersensitivity Reactions.

A delayed hypersensitivity reaction—a type IV reaction—is also called a *cell-mediated immune response*. Although cell-mediated immune responses are usually protective mechanisms, tissue damage occurs in delayed hypersensitivity reactions.

The tissue damage in a type IV reaction does not occur in the presence of antibodies or complement. Rather, sensitized T lymphocytes attack antigens or release cytokines, some of which attract macrophages into the area. These macrophages are responsible for most of the tissue destruction. A delayed hypersensitivity reaction takes 24 to 48 hours to occur.

Clinical examples of a delayed hypersensitivity reaction include contact dermatitis (Figure 16-9); hypersensitivity reactions to bacterial, fungal, and viral infections; and transplant rejection. Some drug sensitivity reactions also fit this category.

FIGURE 16-9 Contact dermatitis in reaction to rubber. Source: Morison, M. J. (2001). *Nursing management of chronic wounds*. Edinburgh: Mosby.

Contact Dermatitis.

Allergic contact dermatitis is an example of a delayed hypersensitivity reaction involving the skin. The reaction occurs when the skin is exposed to substances that easily penetrate the skin to combine with epidermal

proteins. The substance then becomes antigenic, and over a period of 7 to 14 days, memory cells for the antigen form. On subsequent exposure to the substance, a sensitized person develops eczematous skin lesions within 48 hours. The most common potentially antigenic substances encountered are metal compounds (e.g., those containing nickel, mercury); rubber compounds; poison ivy, poison oak, and poison sumac; cosmetics; and some dyes.

In acute contact dermatitis, the skin lesions appear erythematous and edematous and are covered with papules, vesicles, and bullae. The involved area is very pruritic but may also burn or sting. When contact dermatitis becomes chronic, the lesions resemble atopic dermatitis because they are thickened, scaly, and lichenified. The main difference between contact dermatitis and atopic dermatitis is that contact dermatitis is localized and restricted to the area exposed to the allergens, whereas atopic dermatitis is usually widespread.

Microbial Hypersensitivity Reactions.

The classic example of a microbial cell-mediated immune reaction is the body's defence against the tubercle bacillus. Tuberculosis (TB) results from invasion of lung tissue by the highly resistant tubercle bacillus. The organism itself does not directly damage the lung tissue. However, antigenic material released from the tubercle bacilli reacts with T lymphocytes, initiating a cell-mediated immune response. The resulting response causes extensive caseous necrosis of the lung.

After the initial cell-mediated immune reaction, memory cells persist; therefore, subsequent contact with the tubercle bacillus or an extract of purified protein from the organism causes a delayed hypersensitivity reaction. This is the basis for the purified protein derivative (PPD) TB skin test, which yields results 48 to 72 hours after the intradermal injection. (TB is discussed in Chapter 30.)

Allergic Disorders

Although an alteration of the immune system may manifest in many ways, allergies or type I hypersensitivity reactions are seen most frequently.

Assessment

For a thorough assessment of a patient with allergies, a comprehensive health history, physical examination, diagnostic workup, and skin testing for allergens must be performed.

Health History.

A comprehensive history that covers family allergies, past and current allergies, and social and environmental factors is essential. The information may be obtained from the patient or the family about atopic reactions in relatives in order to identify at-risk patients. Identifying past and current allergens that may have triggered a reaction is essential for controlling or preventing allergic reactions. In addition to identification of the allergen, information about the clinical manifestations and the course of allergic reaction should be obtained. The patient's use of any over-the-counter (OTC) or prescription medications used to treat the allergies should be documented.

Social factors (patient's lifestyle and stressors), environmental factors, and physical environment should be reviewed in connection with the appearance of allergic symptoms. Questions about pets, trees, plants, air pollutants, floor coverings, and cooling and heating systems in the home or workplace can yield valuable information about potential allergens. In addition, a daily or weekly food diary may be helpful. Of particular importance is a screening for any reaction to medications.

Physical Examination.

A comprehensive head-to-toe physical examination should be given to a patient with allergies, with particular attention focused on the site of the allergic manifestations. A comprehensive assessment that includes subjective and objective data should be obtained from the patient (Table 16-10).

TABLE 16-10

NURSING ASSESSMENT
Allergies

Subjective Data

Important Health Information

Past health history: Recurrent respiratory problems; seasonal exacerbations; unusual reactions to insect bites or stings; past and present allergies; altered home and work environment, presence of pets; family history of allergies
Medications: Unusual reactions to any medications; use of over-the-counter drugs; use of medications for allergies

Symptoms

Food intolerances; vomiting; abdominal cramps, diarrhea; fatigue; hoarseness, cough, dyspnea; itching, burning, stinging of eyes, nose, throat, or skin; chest tightness; malaise

Objective Data

Integumentary

Rashes, including urticaria, wheal-and-flare, papules, vesicles, bullae; dryness, scaliness, scratches, irritation

Eyes, Ears, Nose, and Throat

Eyes: Conjunctivitis; lacrimation; rubbing or excessive blinking; dark circles under the eyes ("allergic shiner")
Ears: Diminished hearing; immobile or scarred tympanic membranes; recurrent ear infections
Nose: Nasal polyps; nasal voice; nose twitching; itchy nose; rhinitis; pale, boggy mucous membranes; sniffling; repeated sneezing; swollen nasal passages; recurrent, unexplained nosebleeds; crease across the bridge of nose ("allergic salute")
Throat: Continual throat clearing; swollen lips or tongue; red throat; palpable neck lymph nodes

Respiratory

Wheezing, stridor; thick sputum

Possible Findings

Eosinophilia of serum, sputum, or nasal and bronchial secretions; ↑ serum IgE levels; positive skin tests; abnormal chest and sinus radiographs

Ig, immunoglobulin.

Diagnostic Studies

Many specialized immunological techniques can be performed to detect abnormalities of lymphocytes, eosinophils, and immunoglobulins. A complete blood cell count (CBC) with WBC differential is done, including an absolute lymphocyte count and eosinophil count. Cellular immunodeficiency is diagnosed if the lymphocyte count is below 1.2×10^9/L. T-cell and B-cell quantification is used to diagnose specific immunodeficiency syndromes. The eosinophil count is elevated with type I hypersensitivity reactions involving IgE. The serum IgE level is also generally elevated in type I hypersensitivity reactions and serves as a diagnostic indicator of atopic diseases.

Sputum and nasal and bronchial secretions may also be tested for the presence of eosinophils. If asthma is suspected, pulmonary function tests (especially forced expiratory volume) are helpful.

Allergy skin testing is the preferred method for determining immediate reactions to allergens, but in some cases blood testing may be ordered. Allergy blood testing is recommended if a person (a) is using a medication that interferes with skin test results (e.g., antihistamines, corticosteroids) and cannot stop taking it for a few days, (b) cannot tolerate the many needle scratches required for skin testing, or (c) has a skin disorder (e.g., severe eczema, dermatitis, psoriasis).

Skin Tests.

Skin testing is used to identify the specific allergens that are causing the allergy symptoms. With the use of empirical allergy medications as the treatment of choice for most people with allergic rhinitis, it has become common practice to omit skin testing for specific allergens in these patients. However, diagnosing an allergy to a specific antigen enables the patient to avoid an allergen and makes the patient a candidate for immunotherapy. Unfortunately, skin testing cannot be done on patients who cannot be removed from medications that suppress the histamine response or on patients with food allergies.

Procedure.

Skin testing may be performed by three different methods: (a) a scratch or prick, (b) an intradermal test, or (c) a patch test. The areas of the body usually used in testing are the arms and the back. Allergen extracts are applied to the skin in rows with a corresponding control site opposite the test site. Saline or another diluent is applied to the control site. In the *scratch test*, the epidermal skin layer is scratched with a pricking device, and the allergen extract is applied at the site. In the intradermal test, the allergen extract is injected intradermally under the skin, similar to a PPD test for TB. In the patch test, an allergen is applied to a patch that is placed on the skin.

Results.

In the scratch and intradermal tests, the reaction typically occurs within 5 to 10 minutes. In the patch test, the patches need to be worn for 48 to 72 hours. If the person is hypersensitive to the allergen, a positive reaction will occur within minutes after insertion in the skin and may last for 8 to

12 hours. A positive reaction is manifested by a local wheal-and-flare response.

The size of the positive reaction is not always correlated with the severity of allergy symptoms. Also, false-positive and false-negative results may occur. Negative results from skin testing do not necessarily mean the person does not have an allergic disorder, and positive results do not necessarily mean that the allergen caused the clinical manifestations. Positive results imply that the person is sensitized to that allergen. Therefore, correlating skin test results with the patient's history is important.

Precautions.

A highly sensitive person is always at risk for developing an anaphylactic reaction to skin tests. Therefore, a patient should never be left alone during the testing period. Sometimes, skin testing is completely contraindicated, and blood allergy testing is used. If a severe reaction does occur with a skin test, the extract is immediately removed, and anti-inflammatory topical cream is applied to the site. For intradermal testing, the arm is used so that a tourniquet can be applied during a severe reaction. A subcutaneous injection of epinephrine may also be necessary.

Collaborative Care

After an allergic disorder is diagnosed, the therapeutic treatment is aimed at reducing exposure to the offending allergen, treating the symptoms, and, if necessary, desensitizing the person through immunotherapy.

Anaphylaxis.

Anaphylactic reactions occur suddenly in hypersensitive patients after exposure to the offending allergen. They may occur after parenteral injection of drugs (especially antibiotics), administration of blood products, and after insect stings. The cardinal principle in management is speed: (a) in recognizing signs and symptoms of an anaphylactic reaction, (b) in establishing and maintaining a patent airway, (c) in preventing spread of the allergen with the use of a tourniquet, (d) in administering drugs, and (e) in performing treatment for shock (Waserman, Chad, Francoeur, et al., 2010). Table 16-11 summarizes the emergency treatment of anaphylactic shock.

TABLE 16-11

EMERGENCY MANAGEMENT
Anaphylactic Shock

Cause
• Injection of, inhalation of, ingestion of, or topical exposure to substance that produces profound allergic response See Table 16-9 for more complete listing.
Assessment Findings
See Figure 16-7.
Interventions
Initial
• Ensure patent airway. • Remove insect stinger if it is present. • Administer epinephrine 1 : 1 000, 0.2 to 0.5 mL subcut for mild symptoms; repeat at 20-minute intervals. • Epinephrine 1 : 10 000, 0.5 mL IV at 5- to 10-minute intervals for severe reaction. • Administer high-flow oxygen via nonrebreather mask. • Place patient in recumbent position, and elevate his or her legs. • Keep patient warm. • Administer diphenhydramine (Benadryl) IM or IV. • Administer histamine H_2 blockers such as cimetidine. • Maintain patient's blood pressure with fluids, volume expanders, vasopressors (e.g., dopamine, norepinephrine bitartrate [Levophed]).
Ongoing Monitoring
• Monitor vital signs, respiratory effort, oxygen saturation, level of consciousness, and cardiac rhythm. • Anticipate intubation in cases of severe respiratory distress. • Anticipate cricothyrotomy or tracheostomy in cases of severe laryngeal edema.

IM, intramuscularly; *IV*, intravenously; *subcut*, subcutaneously.

In severe cases of anaphylaxis, hypovolemic shock may occur because of the loss of intravascular fluid into interstitial spaces secondary to increased capillary permeability (Vacca & McMahon-Bowen, 2013). Peripheral vasoconstriction and stimulation of the sympathetic nervous system occur to compensate for the fluid shift. However, unless shock is treated early, the body will no longer be able to compensate, and irreversible tissue damage will occur, leading to death. (Hypovolemic shock is further discussed in Chapter 69.)

All health care workers must be prepared for the rare but life-threatening anaphylactic reaction, which requires immediate medical and nursing interventions. It remains extremely important to identify all of the patient's allergies and document them in all appropriate areas in the chart (Yunker & Wagner, 2014).

Chronic Allergies.

Most allergic reactions are chronic and are characterized by remissions and exacerbations of symptoms. Treatment focuses on identification and

control of allergens, relief of symptoms through drug therapy, and hyposensitization of a patient to an offending allergen.

Allergen Recognition and Control.

The nurse plays an important role in helping the patient make lifestyle adjustments to minimize exposure to the offending allergens and offers preventive measures that will help control the allergic symptoms. The nurse must reinforce that the patient will never be desensitized or completely symptom free, even with drug therapy and immunotherapy.

Of primary importance is the need to identify the offending allergen, at times performed through skin testing. In the case of food allergies, an elimination diet is sometimes helpful. If an allergic reaction occurs, all food previously eaten should be avoided at first and then gradually reintroduced sequentially until the offending food is identified.

Many allergic reactions, especially asthma and urticaria, may be aggravated by fatigue and emotional stress. The nurse can initiate a stress-management program with the patient that includes relaxation techniques when the patient comes for repeated immunotherapy treatments.

Sometimes, control of allergic symptoms necessitates environmental control, including changing an occupation, moving to a different climate, or giving up a favourite pet. In the case of airborne allergens, sleeping in an air-conditioned room, damp-dusting daily, covering mattresses and pillows with hypoallergenic covers, and wearing a mask outdoors may be helpful.

With an identified drug allergy, the patient should be instructed not only to avoid the drug but also to notify all health care providers of drug intolerance. The patient should wear a medical alert bracelet listing the particular drug allergy and have the offending drug listed on all medical and dental records.

For a patient allergic to insect stings, commercial bee-sting kits containing injectable epinephrine and a tourniquet are available. The nurse should instruct the patient and family on the technique of applying the tourniquet and self-injecting the subcutaneous epinephrine. These patients should wear a medical alert bracelet and carry a bee-sting kit whenever they go outdoors.

Drug Therapy.

The major categories of drugs used for symptomatic relief of chronic allergic disorders include antihistamines, sympathomimetic or

decongestant drugs, corticosteroids, antipruritic drugs, and mast cell–stabilizing drugs. Many of these drugs may be obtained over the counter.

Antihistamines.

Antihistamines are the best drugs for treatment of allergic rhinitis and urticaria; however, they are less effective for severe allergic reactions (see Chapter 29, Table 29-2). They act by competing with histamine for H_1-receptor sites and thus blocking the effect of histamine. Best results are achieved if they are taken as soon as allergy symptoms appear. Antihistamines can be used effectively to treat edema and pruritus but are relatively ineffective in preventing bronchoconstriction. With seasonal rhinitis, antihistamines should be taken during peak pollen seasons. (Antihistamines are discussed further in Chapter 29.)

Sympathomimetic or Decongestant Drugs.

The major sympathomimetic drug is epinephrine (Adrenalin), which is the drug of choice to treat an anaphylactic reaction. Epinephrine is a hormone produced by the adrenal medulla that stimulates α- and β-adrenergic receptors. Stimulation of the α-adrenergic receptors causes vasoconstriction of peripheral blood vessels. Stimulation of β-adrenergic receptors causes relaxation of the bronchial smooth muscles. Epinephrine also acts directly on mast cells to stabilize them against further degranulation. The action of epinephrine lasts only a few minutes. For the treatment of anaphylaxis, the drug must be given parenterally (subcutaneously, intramuscularly, or intravenously).

Several specific, minor sympathomimetic drugs differ from epinephrine because they can be taken orally or nasally and last for several hours. Included in this category are phenylephrine (Neo-Synephrine) and pseudoephedrine (Sudafed). The minor sympathomimetic drugs are used primarily to treat allergic rhinitis.

Corticosteroids.

Nasal corticosteroid sprays are very effective in relieving the symptoms of allergic rhinitis (see Chapter 29, Table 29-2). Occasional patients may experience such severe manifestations of allergies that a brief course of oral corticosteroids is required.

Antipruritic Drugs.

Topically applied antipruritic drugs protect the skin and provide relief from itching. They are most effective when the skin is not broken.

Common OTC drugs include calamine lotion, coal tar solutions, and camphor. Menthol and phenol may be added to lotions to produce an antipruritic effect.

Mast Cell–Stabilizing Drugs.

Nedocromil (Alocril) is a mast cell–stabilizing drug that inhibits the release of histamines, leukotrienes, and other agents from the mast cell after antigen–IgE interaction. It is currently available for topical ophthalmic use only.

Leukotriene Receptor Antagonists.

Leukotriene receptor antagonists (LTRAs) block leukotriene, one of the major mediators of the allergic inflammatory process. They may be used in the treatment of allergic rhinitis and asthma. These medications can be taken orally. (For more information, refer to Chapters 29 and 31.)

Immunotherapy.

Immunotherapy is the recommended treatment for control of allergic symptoms when the allergen cannot be avoided and drug therapy is not effective. Relatively few patients with allergies have symptoms so intolerable that they require allergy immunotherapy. Immunotherapy is absolutely indicated only in individuals with anaphylactic reactions to insect venom. It involves administration of small titres of an allergen extract in increasing strengths until hyposensitivity to the specific allergen is achieved. For best results, the patient should continue to avoid the offending allergen whenever possible because complete desensitization is impossible. Unfortunately, not all allergy-related conditions respond to immunotherapy. Food allergies cannot be safely treated with this therapy, and eczema may worsen with immunotherapy.

Mechanism of Action.

The IgE level is elevated in atopic individuals. When IgE combines with an allergen in a hypersensitive person, a reaction occurs in which histamine is released in various body tissues. Allergens more readily combine with IgG than with other immunoglobulins. Therefore, immunotherapy involves injecting allergen extracts that will stimulate increases in IgG levels. The binding of IgG to allergen-reactive sites interferes with allergen binding to mast cell–bound IgE, preventing mast cell degranulation and thus reducing the number of reactions that cause tissue damage. The goal of

long-term immunotherapy is to maintain high levels of "blocking" IgG. In addition, allergen-specific T suppressor cells develop in individuals receiving immunotherapy.

Method of Administration.

Allergens included in immunotherapy are chosen based on the results of skin testing with a panel of allergens.

Subcutaneous Immunotherapy.

Subcutaneous immunotherapy (SCIT) involves the subcutaneous injection of titrated amounts of allergen extracts biweekly or weekly. The dose is small at first and is increased slowly until a maintenance dosage is reached. In general, it takes 1 to 2 years of immunotherapy to reach the maximal therapeutic effect. Therapy may be continued for about 5 years. After that, discontinuing therapy is considered. In many patients, a decrease in symptoms is sustained after the treatment is discontinued. For patients with severe allergies or sensitivity to insect stings, maintenance therapy is continued indefinitely. Best results are achieved when immunotherapy is administered throughout the year.

Sublingual Immunotherapy.

Sublingual immunotherapy (SLIT) involves allergen extracts taken under the tongue. SLIT has been used in Europe for decades and has recently become available in Canada. Products include a five-grass pollen tablet (Oralair), a single-grass pollen tablet (Grastek), and a ragweed pollen tablet (Ragwitek) (Lee, Nolte, & Benninger, 2015).

SLIT is self-administered (usually daily) by patients at home, although the initial dose is usually given under medical supervision. Some patients experience local application-site reactions (e.g., oral pruritus, throat irritation, tongue swelling), but systemic allergic reactions are markedly fewer than with SCIT. Local reactions subside in many patients within a few days to a week.

An advantage of SLIT is the convenience of an oral therapy that is self-administered and that patients can use at home. The main disadvantage of SLIT is that it requires the patient to be consistently compliant with therapy (Compalati, Braido, & Canonica, 2013).

Nursing Management Immunotherapy

The nurse is often the professional primarily responsible for administering SCIT. Adverse reactions should always be anticipated, especially when a new strength of the dose is used, after a previous reaction occurred, or after a dose is missed. Early signs and symptoms indicative of a systemic reaction include pruritus, urticaria, sneezing, laryngeal edema, and hypotension. Emergency measures for anaphylactic shock should be initiated immediately. A local reaction should be described according to the degree of redness and swelling at the injection site. If the area is greater than the size of a quarter in an adult, the reaction should be reported to the health care provider so that the allergen dosage may be decreased.

Immunotherapy always carries the risk for a severe anaphylactic reaction. Therefore, when injections are given, a health care provider, emergency equipment, and essential medications should be available.

Accurate record keeping is invaluable because it can prevent an adverse reaction to the allergen extract. Before giving the injection, the nurse should check the patient's name against the name on the vial, check the vial strength, the amount of the previous dose, the date of the previous dose, and any reaction information previously identified.

The nurse should always administer the allergen extract in an extremity away from a joint so that a tourniquet can be applied in the event of a severe reaction. The site should be rotated for each injection. Before giving an injection, the nurse must aspirate for blood to ensure the allergen extract is not injected into a blood vessel. An injection directly into the bloodstream can potentiate an anaphylactic reaction. After the injection is given, the patient should be carefully observed for 20 minutes because systemic reactions typically occur immediately. However, the patient should be warned that a delayed reaction can occur as long as 24 hours later.

Latex Allergies

Allergies to latex products have become a problem of increasing proportion, affecting both patients and health care providers. The increase in allergic reactions has coincided with the sharp increase in glove use related to the introduction of universal precautions against infectious diseases in 1987. The more frequent and prolonged the exposure to latex, the greater the likelihood of developing a latex allergy.

In addition to gloves, many other latex-containing products are used in health care, such as blood pressure cuffs, stethoscopes, tourniquets, intravenous (IV) tubing, syringes, electrode pads, oxygen masks, tracheal tubes, colostomy and ileostomy pouches, urinary catheters, anaesthetic masks, and adhesive tape. Latex proteins can become aerosolized through powder on gloves and can result in serious reactions when inhaled by sensitized individuals. It is recommended that all health care facilities use powder-free gloves to avoid respiratory exposure to latex proteins (Canadian Centre for Occupational Health and Safety [CCOHS], 2014).

Types of Latex Allergies.

Two types of latex allergies can occur: type IV allergic contact dermatitis and type I allergic reactions. Type IV contact dermatitis is caused by the chemicals used in the manufacturing process of latex gloves. It is a delayed reaction that occurs within 6 to 48 hours. Typically, the person first has dryness, pruritus, fissuring, and cracking of the skin, followed by redness, swelling, and crusting at 24 to 48 hours. The dermatitis may extend beyond the area of physical contact with the allergen. Chronic exposure can lead to lichenification, scaling, and hyperpigmentation.

A type I allergic reaction is a response to the natural rubber latex proteins and occurs within minutes of contact with the proteins. These types of allergic reactions can manifest as various reactions ranging from skin redness, urticaria, rhinitis, conjunctivitis, or asthma to full-blown anaphylactic shock. Systemic reactions to latex may result from exposure to latex protein via various routes, including the skin, mucous membranes, lungs, or blood.

Latex-Food Syndrome.

Because some proteins in rubber are similar to food proteins, some foods may cause an allergic reaction in people who are allergic to latex. This is called *latex-food syndrome*. The most common of these foods are banana, avocado, chestnut, kiwi, tomato, water chestnut, guava, hazelnut, potato, peach, grape, and apricot. In people with latex allergy, most have a positive allergy test to at least one related food.

Nursing and Collaborative Management Latex Allergies

The identification of patients and health care providers who are sensitive to latex is crucial to preventing adverse reactions. A thorough health history and history of any allergies should be documented, especially for patients with any complaints of latex contact symptoms. Not all latex-sensitive individuals can be identified, even with a carefully documented history. Risk factors include long-term multiple exposures to latex products (e.g., health care providers, individuals who have undergone multiple surgical procedures, rubber-industry workers). Additional risk factors include a patient history of allergic rhinitis, asthma, and allergies to certain foods (listed earlier). The Canadian Centre for Occupational Health and Safety (CCOHS) has published recommendations for preventing allergic reactions to latex in the workplace (2014) (Table 16-12).

TABLE 16-12

RECOMMENDATIONS FOR PREVENTING ALLERGIC REACTIONS TO LATEX IN THE WORKPLACE

1. Powder-free, nonlatex gloves with reduced protein content should be used.
2. Those who wear latex gloves should avoid oil-based hand creams or lotions, which can cause deterioration of latex.
3. Good work and housekeeping practices can help prevent contact with latex-containing dust in the workplace, including contact with eyes and face; hands should be washed after glove removal.
4. Education programs about latex allergies are available in some workplaces.
5. People who suspect an allergy to latex rubber products should consult an allergist to determine if the allergy is to latex (natural) rubber or to chemicals in synthetic rubbers.
6. The symptoms of latex allergy include skin rash; hives; flushing; itching; nasal, eye, or sinus symptoms; asthma; and (rarely) shock.
7. Health care providers (e.g., physicians, nurse practitioners, and dentists) should be notified of any allergy so that they can decide if alternative products should be used in any treatment that normally requires the use of rubber products.

Source: Adapted from Canadian Centre for Occupational Health and Safety. (2014). *Latex allergy*. Retrieved from *https://www.ccohs.ca/oshanswers/diseases/latex.html*; and National Institute for Occupational Safety Health. (n.d.) *NIOSH alert: Preventing allergic reactions to natural rubber latex in the workplace*. Retrieved from *http://www.cdc.gov/niosh/docs/97-135/pdfs/97-135.pdf*.

Latex precaution protocols should be used for patients identified as having either a positive reaction to a latex allergy test or a history of signs and symptoms related to latex exposure. Many health care facilities have

created latex-free product carts that can be used for patients with latex allergies.

Multiple Chemical Sensitivities

Multiple chemical sensitivities (MCS) is a subjective illness marked by recurrent, nonspecific symptoms attributed to low levels of chemical, biological, or physical agents. Common causative substances include smoke, pesticides, plastics, synthetic fabrics, scented products, petroleum products, and paint fumes. Women between the ages of 30 and 50 are more likely to develop the symptoms. MCS is a controversial diagnosis and is not formally recognized as an illness by the Canadian Medical Association or other authorities (Sears, 2007).

These symptoms are usually subjective and are not found during physical examination. The patient experiences wide-ranging symptoms, but evidence of pathological processes or physiological dysfunction is lacking. Symptoms include headache, fatigue, dizziness, nausea, congestion, itching, sneezing, sore throat, chest pain, breathing problems, muscle pain or stiffness, skin rash, diarrhea, bloating, gas, confusion, difficulty concentrating, memory problems, and mood changes.

Diagnosis is usually made based on a patient's health history as there is no established test to diagnose MCS. Treatment includes minimizing or avoiding the chemicals that may trigger the symptoms and creating a chemical-free and odor-free home and workplace.

Psychotherapy is recommended as a primary option. In patients who are unwilling to undergo psychotherapy but willing to accept medications, antidepressants including selective serotonin reuptake inhibitors (SSRIs) (e.g., citalopram [Celexa]) have been used for treatment. Drugs for anxiety and sleep have also been used.

Autoimmunity

Autoimmunity is an immune reaction to self-proteins: the immune system no longer differentiates self from nonself. For unknown reasons, immune cells that are normally unresponsive (tolerant of self-antigens) are activated. In autoimmunity, autoantibodies and autosensitized T cells cause pathophysiological tissue damage (Mak, Saunders, & Jett, 2014).

The cause of autoimmune diseases remains unknown. Age is thought to play a role since the number of circulating autoantibodies increases in people over age 50. However, the principal factors in the development of autoimmunity are (a) the inheritance of susceptibility genes, which may contribute to the failure of self-tolerance, and (b) initiation of autoreactivity by triggers, such as infections, that may activate self-reactive lymphocytes.

Autoimmune diseases tend to occur in clusters, so an individual may have more than one autoimmune disease (e.g., rheumatoid arthritis and Addison's disease), or the same or related autoimmune diseases may be found in other members of the same family. This observation has led to the concept of genetic predisposition to autoimmune disease.

Most of the genetic research in this area correlates certain human leukocyte antigen (HLA) types with an autoimmune condition. (HLAs and disease association are discussed later in this chapter.) Even in a genetically predisposed person, some triggering event is necessary for the initiation of autoreactivity. This event may include infection with an agent such as a virus (Mak, Saunders, & Jett, 2014). Viral infections can alter cells or tissues that make them antigenic. There is some evidence that viruses may be involved in the development of diseases such as type 1 diabetes mellitus. Rheumatic fever and rheumatic heart disease are autoimmune responses triggered by streptococcal infection and mediated by antibodies against group A β-hemolytic streptococci that cross-react with heart muscles, heart valves, and synovial membranes.

Medications can also be precipitating factors in autoimmune diseases. For example, hemolytic anemia can result from methyldopa (Novo-Medopa) administration, and procainamide (Apo-Procainamide) can induce the formation of antinuclear antibodies and cause a lupus-like syndrome.

Gender and hormones also have a role in autoimmune diseases, with more women than men affected. During pregnancy, symptoms of many

autoimmune diseases improve; however, after delivery, the disease frequently worsens.

Autoimmune Diseases

In general, autoimmune diseases are grouped according to organ-specific and systemic diseases. (Table 16-13 lists examples of autoimmune diseases.) SLE is a classic example of a systemic autoimmune disease characterized by damage to multiple organs. It occurs most frequently in women, with onset at 20 to 40 years of age. The cause is unknown, but there appears to be a loss of self-tolerance for the body's own deoxyribonucleic acid (DNA) antigens.

TABLE 16-13
EXAMPLES OF AUTOIMMUNE DISEASES*

Systemic Diseases
• Systemic lupus erythematosus (SLE) • Rheumatoid arthritis • Progressive systemic sclerosis (scleroderma) • Mixed connective tissue disease
Organ-Specific Diseases
Blood
• Autoimmune hemolytic anemia • Immune thrombocytopenic purpura
Central Nervous System
• Multiple sclerosis • Guillain-Barré syndrome
Muscle
• Myasthenia gravis
Heart
• Rheumatic fever
Endocrine System
• Addison's disease • Thyroiditis • Hypothyroidism • Type 1 diabetes mellitus
Gastro-Intestinal System
• Pernicious anemia • Ulcerative colitis
Kidney
• Goodpasture's syndrome • Glomerulonephritis
Liver
• Primary biliary cirrhosis • Autoimmune hepatitis
Eye
• Uveitis

*These diseases are discussed in various chapters throughout the book.

In SLE, tissue injury appears to be the result of the formation of antinuclear antibodies. For an unknown reason (possibly a viral infection), the cell membrane is damaged and DNA is released into the systemic circulation, where it is viewed as nonself material. This DNA is normally sequestered inside the nucleus of cells. On release into circulation, the DNA antigen reacts with an antibody. Some antibodies are involved in immune-complex formation, and others may cause damage directly. Once the complexes are deposited, complement is activated and further damages the tissue, especially the renal glomerulus. (SLE is discussed further in Chapter 67.)

Apheresis

Apheresis has been effectively used to treat autoimmune diseases and other diseases and disorders. **Apheresis** is a procedure in which components of the blood are separated and then one or more of those components is removed. Compound words are often used to describe an apheresis procedure, depending on the blood components being collected. For example, plateletpheresis is the removal of platelets, usually for collection from normal individuals to infuse into patients with low platelet counts (e.g., patients taking chemotherapy who develop thrombocytopenia). *Leukocytapheresis* is a general term indicating the removal of WBCs, a technique used in chronic myelogenous leukemia to remove high numbers of leukemic cells.

Apheresis is also used in hematopoietic stem cell transplantation to collect stem cells from peripheral blood. These stem cells can then be used to repopulate a person's bone marrow after high-dose chemotherapy (see the section “Peripheral Stem Cell Transplantation” in Chapter 18).

Plasmapheresis.

Plasmapheresis is the removal of plasma-containing components that cause or are thought to cause disease. It can also be used to obtain plasma from healthy donors to administer to patients as replacement therapy.

When plasma is removed, it is replaced by substitution fluids such as saline, fresh-frozen plasma, or albumin. Therefore, the term *plasma exchange* more accurately describes this procedure.

Plasmapheresis has been used to treat autoimmune diseases such as SLE, glomerulonephritis, Goodpasture's syndrome, myasthenia gravis, thrombocytopenic purpura, rheumatoid arthritis, and Guillain-Barré syndrome. Many disorders for which plasmapheresis is being used are

characterized by circulating autoantibodies (usually of the IgG class) and antigen–antibody complexes. The rationale for performing therapeutic plasmapheresis in autoimmune disorders is to remove pathological substances present in plasma. Immuno-suppressive therapy has been used to prevent recovery of IgG production, and plasmapheresis has been used to prevent antibody rebound.

In addition to removing antibodies and antigen–antibody complexes, plasmapheresis may remove inflammatory mediators (e.g., complement) that are responsible for tissue damage. In the treatment of SLE, plasmapheresis is usually reserved for patients in an acute attack who are unresponsive to conventional therapy.

Plasmapheresis involves the removal of whole blood through an IV needle and then the circulation of the blood through a cell separator. Inside the separator, the blood is divided into plasma and its cellular components by centrifugation or membrane filtration. Plasma, platelets, WBCs, or erythrocytes can be separated selectively. The undesirable component is removed, and the remainder is returned to the patient. The plasma is generally replaced with normal saline, lactated Ringer's solution, fresh-frozen plasma, plasma protein fractions, or albumin. When blood is manually removed, only 500 mL may be taken at one time. However, with the use of apheresis procedures, more than 4 L of plasma can be removed in 2 to 3 hours.

As with administration of other blood products, nurses must be aware of adverse effects associated with plasmapheresis. The most common complications are hypotension and citrate toxicity. Hypotension is usually the result of vasovagal reaction or transient volume changes. Citrate is used as an anticoagulant and may cause hypocalcemia, which may manifest as headache, paresthesias, and dizziness.

Immunodeficiency Disorders

The condition in which the immune system does not adequately protect the body is **immunodeficiency**. Immunodeficiency disorders involve an impairment of one or more immune mechanisms, which include (a) phagocytosis, (b) humoral response, (c) cell-mediated immune response, (d) complement, and (e) a combined humoral and cell-mediated deficiency. Immunodeficiency disorders are primary if the immune cells are improperly developed or absent and secondary if the deficiency is caused by illnesses or treatment. Primary immunodeficiency disorders are rare and often serious, whereas secondary disorders are more common and less severe.

Primary Immunodeficiency Disorders

The basic categories of primary immunodeficiency disorders are (a) phagocytic defects, (b) B-cell deficiency, (c) T-cell deficiency, and (d) a combined B-cell and T-cell deficiency (Kasper, Fauci, Hauser, et al., 2015; Table 16-14).

TABLE 16-14

PRIMARY IMMUNODEFICIENCY DISORDERS

Disorder	Affected Cells	Genetic Basis
Chronic granulomatous disease	PMNs, monocytes	Sex-linked
Job syndrome	PMNs, monocytes	—
Bruton (X-linked) agammaglobulinemia	B	Sex-linked
Common variable hypogammaglobulinemia	B	—
Selective IgA, IgM, or IgG deficiency	B	Some sex-linked
DiGeorge syndrome (thymic hypoplasia)	T	—
Severe combined immunodeficiency disease	Stem, B, T	Sex-linked or autosomal recessive
Ataxia-telangiectasia	B, T	Autosomal recessive
Wiskott–Aldrich syndrome	B, T	Sex-linked
Graft-versus-host disease	B, T	—

IgA, immunoglobulin A; *IgG*, immunoglobulin G; *IgM*, immunoglobulin M; *PMN*, polymorphonuclear neutrophil.

Secondary Immunodeficiency Disorders

Some important factors that may cause secondary immunodeficiency disorders are listed in Table 16-15. Drug-induced immuno-suppression is

the most common. Immuno-suppressive therapy is prescribed for patients to treat autoimmune disorders and to prevent transplant rejection. In addition, immuno-suppression is a serious adverse effect of drugs used in cancer chemotherapy. Generalized leukopenia often results from chemotherapeutic drugs, leading to a decreased humoral and cell-mediated immune response. Therefore, secondary infections are common in immuno-suppressed patients.

TABLE 16-15
CAUSES OF SECONDARY IMMUNODEFICIENCY

- Age
  - Infants
  - Older adults
- Anaesthesia
- Burns
- Cachexia
- Chemotherapeutic drugs
- Cirrhosis
- Corticosteroids
- Dietary deficiency
- Drug-induced immunodeficiency
- Malnutrition
- Predisposing factors
  - Acquired immune deficiency syndrome (AIDS)
  - Alcoholic cirrhosis
  - Chronic renal disease
  - Diabetes mellitus
  - Malignancies
  - Systemic lupus erythematosus
- Radiation
- Stress
- Surgery
- Trauma

Malnutrition alters cell-mediated immune responses. When protein is deficient over a prolonged period, the thymus gland atrophies, and lymphoid tissue decreases. In addition, an increased susceptibility to infections always exists with malnourishment.

Hodgkin's lymphoma also greatly impairs the cell-mediated immune response, and patients may die from severe viral or fungal infections. (Hodgkin's lymphoma is discussed in Chapter 18.) Viruses, especially rubella, may cause immunodeficiency by direct cytotoxic damage to lymphoid cells. Systemic infections can place such a demand on the immune system that resistance to a secondary or subsequent infection becomes impaired.

Radiation can destroy lymphocytes either directly or through depletion of stem cells. As the radiation dose is increased, more bone marrow

atrophies, leading to severe pancytopenia and suppression of immune function. Splenectomy in children is especially dangerous and may lead to septicemia simply from respiratory tract infections.

The immune response involves interrelationships among the nervous, endocrine, and immune systems and can be altered by stress (see Chapter 8).

Human Leukocyte Antigen System

The antigens responsible for rejection of genetically unlike tissues are called the *major histocompatibility antigens.* These antigens are products of histocompatibility genes. In humans, they are called the **human leukocyte antigen (HLA) system**. The genes for the HLA antigens are linked and occur together on the sixth chromosome. HLAs are present on all nucleated cells and platelets. The HLA system plays an important part in the body's immune response to foreign substances and, therefore, is used in matching organs and tissues for transplantation.

An important characteristic of HLA genes is that they are highly polymorphic (variable). Each HLA locus can have many different possible alleles, and thus many combinations exist. Each person has two alleles for each locus, one inherited from each parent. Both alleles of a locus are expressed independently (i.e., they are codominant). The proteins encoded by certain genes are known as *antigens.*

The entire set of A, B, C, and D/DR genes (the HLA genes) is located on one chromosome and is termed a *haplotype.* The complete set is inherited as a unit. One haplotype is inherited from each parent (Figure 16-10). This means that a person has HLA genes that are one-half identical to those of each parent. The HLA genes of one person have a 25% chance of being identical to the HLA genes of a sibling.

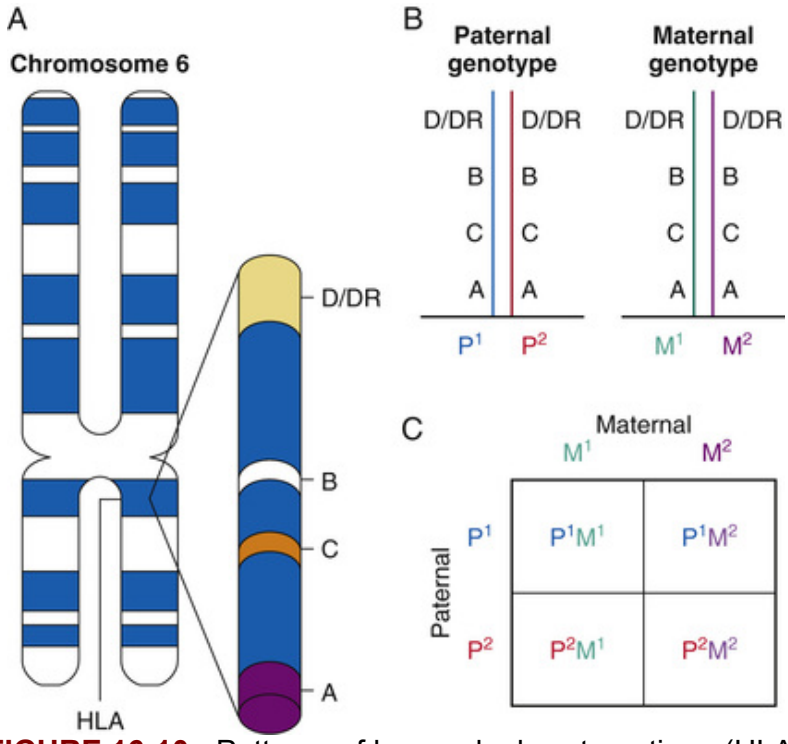

FIGURE 16-10 Patterns of human leukocyte antigen (HLA) inheritance. **A,** HLA genes are located on chromosome 6. **B,** The two haplotypes of the father are labelled P^1 and P^2, and the haplotypes of the mother are labelled M^1 and M^2. Each child inherits two haplotypes, one from each parent. **C,** Therefore, only four combinations—P^1M^1, P^1M^2, P^2M^1, P^2M^2—are possible, and the offspring have a 25% chance of having identical HLA haplotypes.

In organ transplantation, A, B, and DR are primarily used for compatibility matching. The specific allele at each locus is identified by a number. For example, a person could have an HLA of A2, A6, B7, B27, DR4, and DR7. Currently more than 8 000 HLA alleles have been identified for the various HLA genes.

Human Leukocyte Antigen and Disease Associations.

The early interest in HLA was stimulated by its potential role in matching donors and recipients of organ transplants. Since that time, interest in the association between HLA and disease has grown.

A number of diseases show significant associations with specific HLA alleles. People who have these alleles are much more likely to develop the associated disease than those who do not have the allele. However, the possession of a particular HLA allele does not mean that the person will

necessarily develop the associated disease—only that the relative risk is greater than in the general population.

Most of the HLA-associated diseases are classified as autoimmune disorders. Examples of associations between HLA types and diseases include (a) the presence of HLA-B27 with ankylosing spondylitis, (b) the presence of HLA-DR2 and HLA-DR3 with SLE, (c) the presence of HLA-DR3 and HLA-DR4 with diabetes mellitus, and (d) the presence of HLA-DR2 with narcolepsy.

It is now known that at least part of the genetic basis of HLA-associated diseases lies in the HLA region, but the actual mechanisms involved in these associations are still unknown. However, most individuals who inherit an HLA type associated with a disease never actually develop the disease. While the discovery of HLA associations with certain diseases is a major breakthrough in understanding the genetic basis of these diseases, this information is, at present, of little practical clinical importance. Nevertheless, there is promise for the development of clinical applications in the future. For example, in families with certain autoimmune diseases, it may be possible to identify the members who are at greatest risk for developing the same or a related autoimmune disease. These people would need close medical supervision, implementation of preventive measures (if possible), and early diagnosis and treatment to prevent chronic complications.

Organ Transplantation

During the 1960s, organ and tissue transplantation was considered an experimental procedure reserved for patients with critical end-stage medical disease. However, as a result of advances in medical technology, including histocompatibility testing, surgical procedures, and improved immuno-suppressive regimens, organ transplantation has resulted in improved survival rates and quality of life. **Organ transplantation** is the transfer of a whole or partial organ from one individual to another for the purpose of replacing the recipient's damaged or failing organ with a working one from the donor. Commonly transplanted organs and tissues include the heart, lungs, liver, kidneys, pancreas, corneas, skin, bone marrow, heart valves, bone, and connective tissues (Figure 16-11). Corneas are transplanted to prevent or correct blindness, and skin grafts are used to assist in managing burns. Bone marrow or stem cells are transplanted to help patients with leukemias and other hematological malignancies.

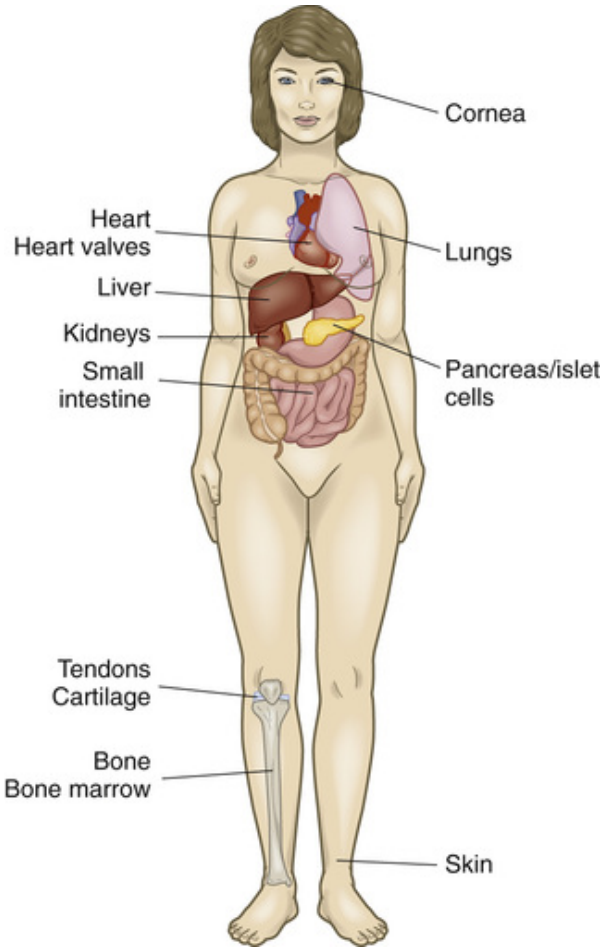

FIGURE 16-11 Tissues and organs that can be transplanted.

Organs can be successfully transplanted together; for example, a patient may receive both a pancreas transplant for pancreatic insufficiency and a kidney transplant for renal failure.

Some organs may be transplanted in segments rather than in their entirety. Liver and lung lobes may be transplanted, or an intestine may be used in segments, thus allowing one person's organ donation to benefit multiple recipients. This technique not only enables living donors to donate part of an organ while maintaining their functioning organ but also addresses the high rate of mortality among patients on the waiting list that results from poor organ donation rates.

Organ donations can be taken from two sources: deceased (cadaveric) and living donors. Patients are matched to available donors through ABO blood and HLA typing, medical urgency, body size, and, for some organs, length of time on the waiting list. Currently, most donated organs originate from deceased donors. The majority of living donors are relatives of the recipient, although a number are also unrelated living donors.

In order to become an organ or tissue donor, an individual either signs an organ and tissue donor card or registers his or her consent through the provincial registry. However, despite registering as an organ or tissue donor, the individual is encouraged to discuss the decision with loved ones because doctors will not proceed with donation without the consent of family members. (Organ donation is discussed further in Chapter 71.)

Nurses caring for a patient in the intensive care unit or emergency department who has a diagnosis of brain death should discuss with the health care team the option of organ donation for the patient's family. The local organ procurement organization should then be contacted to speak with the family.

Tissue Typing

The recipient usually receives a transplant from an ABO blood group–compatible donor (see Chapter 32, Table 32-10). The donor and recipient do not need to share the same Rh factor.

HLA Typing.

HLA typing is done on potential donors and recipients. Currently only the A, B, and DR antigens are thought to be clinically significant for transplantation. Because each locus has two alleles that encode for antigens, a total of six antigens are identified. In transplantation, an attempt is made to match as many antigens as possible between the HLA-A, HLA-B, and HLA-DR loci. Antigen matches of five and six antigens and certain four-antigen matches have been found to have better clinical outcomes (i.e., the patient is less likely to reject the transplanted organ), especially in kidney and bone marrow transplants.

The degree of HLA matching required or deemed suitable for successful solid organ transplantation depends on the type of organ. Certain organ and tissue transplants require a closer histocompatibility match than other organs. For example, a cornea transplant can be accepted by nearly any individual because corneas are avascular, and therefore no antibodies reach the cornea to cause rejection. In kidney and bone marrow transplantation, HLA matching is very important, since these transplants are at high risk for graft rejection. On the other hand, for liver transplants, HLA mismatches have little impact on graft survival. Heart and lung transplants fall somewhere in between, but minimizing HLA mismatches significantly improves survival. In addition, for liver, lung, and heart

transplants, fewer donors are available; therefore, it can be more difficult to obtain good HLA matches.

Transporting, storing, and then implanting donated organs take time and the "best" match may live many miles from the "ideal" recipient. The need to have the "best" matches has to be balanced against the time it takes to retrieve, transport, and transplant a donated organ.

Panel of Reactive Antibodies.

A panel of reactive antibodies (PRA) indicates the recipient's sensitivity to various HLAs before receiving a transplant. To detect preformed antibodies to HLA, the recipient's serum is mixed with a randomly selected panel of donor lymphocytes to determine reactivity. The potential recipient may have been exposed to HLA antigens by means of previous blood transfusions, pregnancy, or a previous organ transplant.

PRA allows for the determination of whether a recipient is of high or low reactivity to potential donors. The results for the PRA are calculated in percentages. A high PRA indicates that the person has a large number of cytotoxic antibodies and is highly sensitized, which means there is a reduced chance of finding a crossmatch-negative donor. In patients awaiting transplantation, a PRA panel is usually done on a routine basis. In highly sensitized patients (high PRA), plasmapheresis and IV immunoglobulin (IVIG) can be used to reduce the number of circulating antibodies.

Crossmatch.

A crossmatch is done to determine the existence of antibodies against the potential donor. A crossmatch uses serum from the recipient mixed with donor lymphocytes to test for any preformed anti-HLA antibodies to the potential donor organ. The crossmatch can be used as a screening test when possible living donors are being considered or once a cadaver donor is selected.

A negative crossmatch indicates that no preformed antibodies are present and it is safe to proceed with transplantation. A positive crossmatch indicates that the recipient has cytotoxic antibodies to the donor and is an absolute contraindication in living donor transplants such as in kidney transplants. Live donor transplants may be done for patients with a positive crossmatch if no other live donors (with a negative crossmatch) exist. In this situation, plasmapheresis or IVIG can be performed to remove antibodies.

It is not always possible to complete a crossmatch prior to transplantation. If a retrospective crossmatch has to be done, the results will have implications for immuno-suppression protocols after the transplantation.

Transplant Rejection

Rejection is one of the major contributing factors for organ loss after solid organ transplantation. Organ rejection can occur if the HLA profile of the donor organ does not identically match that of the recipient. Rejection can be prevented through close matching of ABO and HLA profiles of the donor and recipient. Unfortunately, because many differing HLA profiles have been found in humans, a perfect match is impossible, with the exception of tissue matching of identical twins. Three forms of rejection can develop: hyperacute, acute, or chronic. Prevention, early diagnosis, and treatment of rejection are essential for long-term graft function.

Hyperacute Rejection.

Hyperacute rejection (also called *antibody-mediated* or *humoral rejection*) occurs minutes to hours after transplantation. Hyperacute rejection may result from antibody development through a number of mechanisms, some of which are not clearly understood. Recipients who have received prior blood transfusions may have antibodies to major histocompatibility complex antigens from the transfused blood that may match those in the graft (donated organ), which results in hyperacute rejection. Furthermore, multiple prior pregnancies may have exposed a woman to paternal antigens of the fetus, resulting in the development of antibodies. In the absence of these factors, antibody-mediated rejection may occur nonetheless, and the cause often remains unknown.

Acute Rejection.

Acute rejection most commonly occurs days to months after transplantation. This type of rejection is mediated by the recipient's T cytotoxic lymphocytes, which attack the foreign organ (Figure 16-12). In addition to cell-mediated rejection, another type of acute rejection occurs when the recipient develops antibodies to the transplanted organ (humoral rejection). Many transplant recipients experience at least one rejection episode after transplantation. These episodes are usually reversible with alteration in or additional immuno-suppressive therapy

that may include increased corticosteroid doses or polyclonal or monoclonal antibody treatment. Unfortunately, increased doses of immuno-suppressants increase the risk for infection. To combat acute rejection, all patients with transplants require lifelong use of immuno-suppressants, putting them at a high risk for infection, especially in the first few months after transplantation, when the immuno-suppressant doses are highest.

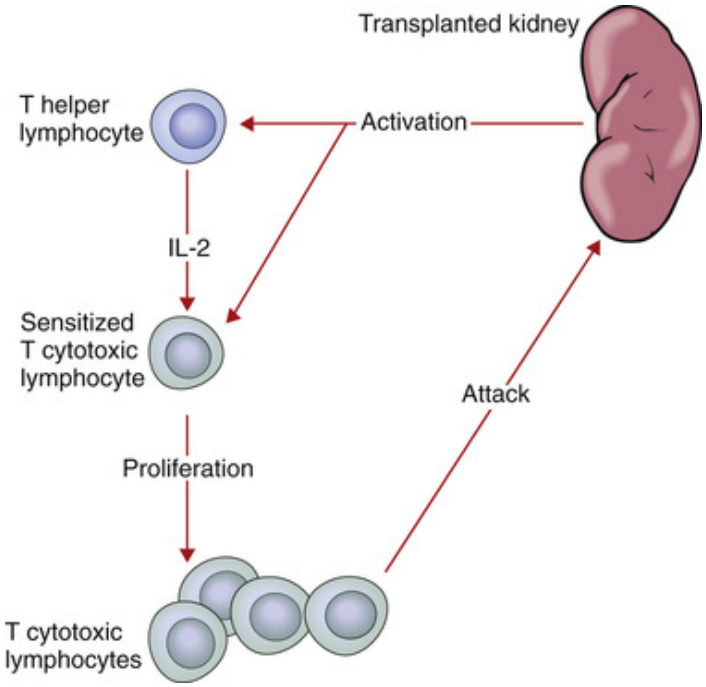

FIGURE 16-12 Mechanism of action of T cytotoxic lymphocyte activation and attack of transplanted tissue. The transplanted organ (e.g., kidney) is recognized as foreign, and the immune system is activated. T helper cells are activated to produce interleukin-2 (IL-2), and T cytotoxic lymphocytes are sensitized. After the T cytotoxic cells proliferate, they attack the transplanted organ.

Chronic Rejection.

Chronic rejection is a process that occurs over months to years and is considered irreversible. The transplanted organ is infiltrated with large numbers of T and B cells, which is characteristic of an ongoing, low-grade, immune-mediated injury. Chronic rejection results in fibrosis and scarring. In heart transplants, it manifests as accelerated coronary artery disease. In lung transplants, it manifests as bronchiolitis obliterans, which is

inflammation and fibrosis of the small airways. In liver transplants, it is characterized by loss of bile ducts. In kidney transplants, it manifests as fibrosis and glomerulopathy.

No definitive therapy is yet available for chronic rejection. Switching immuno-suppressive therapy has yielded some improvement for patients; however, treatment has largely been supportive. Ultimately, the prognosis for patients with chronic rejection remains poor, and if possible, such patients should be offered the option of retransplantation.

Immuno-Suppressive Therapy

The goal of **immuno-suppressive therapy** is to adequately suppress the immune response to prevent rejection of the transplanted organ and yet maintain sufficient immunity to prevent overwhelming infection. Immuno-suppressive therapy is also used to treat autoimmune diseases.

Many of the medications used to achieve immuno-suppression have adverse effects. The most common medications, routes of administration, mechanisms of action, and adverse effects are listed in Table 16-16. In a combination of medications that work in different phases of the immune response, lower doses of each drug produce effective immuno-suppression and minimize adverse effects. The major immuno-suppressive agents are (a) calcineurin inhibitors, which include cyclosporin (Sandimmune, Neoral) and tacrolimus (Prograf); (b) corticosteroids (prednisone, methylprednisolone [Solu-Medrol] by IV route); (c) mycophenolate mofetil (CellCept); and (d) sirolimus (Rapamune). Azathioprine (Imuran) and cyclophosphamide (Procytox) are also used but less frequently, because of the effectiveness of the newer generation of immuno-suppressants. Antithymocyte globulin, antilymphocyte globulin, and muromonab-CD3 (OKT 3) are medications administered intravenously for short periods to prevent early rejection (induction therapy) or to reverse acute rejection.

TABLE 16-16

DRUG THERAPY
Immuno-Suppressive Therapy

Agent	Route	Mechanism of Action	Adverse Effects
Corticosteroids: prednisone, methylprednisolone (Solu-Medrol)	PO, IV	Suppress inflammatory response; inhibit cytokine production and T-cell activation	Peptic ulcers, hypertension, GI bleeding, osteoporosis, aseptic necrosis, Na^+ and H_2O retention, acne, muscle weakness, easy bruising, delayed healing, hyperglycemia, ↑ appetite, mood alterations, leukopenia, cataracts, dyslipidemia, ↓ resistance to infection
Tacrolimus (Prograf)	PO, IV	Inhibits calcineurin; prevents production and release of IL-2, IL-4, and α-interferon; inhibits production of T cytotoxic lymphocytes	Nephrotoxicity, neurotoxicity, seizures, tremors, nausea and vomiting, hyperglycemia, hypertension, alopecia, lymphoma, ↓ resistance to infection
Cyclosporine (Sandimmune, Neoral*)	PO, IV	Inhibits calcineurin; prevents production and release of IL-2, IL-4, and α-interferon; inhibits production of T cytotoxic lymphocytes	Nephrotoxicity, neurotoxicity, headaches, seizures, tremors, hyperglycemia, hypertension, nausea and vomiting, dyslipidemia, gingival hyperplasia, hirsutism, hepatotoxicity, lymphoma, ↓ resistance to infection
Mycophenolate mofetil (CellCept)	PO, IV	Antimetabolite that inhibits purine synthesis; suppresses proliferation of T and B cells	Diarrhea, nausea and vomiting, leukopenia, thrombocytopenia, ↓ resistance to infection, ↑ incidence of malignancies
Sirolimus (Rapamune)	PO	Suppresses lymphocyte proliferation; inhibits B cells from synthesizing antibodies	Diarrhea, dyslipidemia, hypercholesterolemia, arthralgias, delayed wound healing, thrombocytopenia, ↓ resistance to infection, ↑ incidence of malignancies
Muromonab-CD3 (OKT 3)	IV push	Monoclonal antibody that binds to CD3 receptors on lymphocytes, causing cell lysis; inhibits function of cytotoxic T cells	Fever, chills, tachycardia, pulmonary edema, muscle and joint pain, diarrhea, hypertension or hypotension, aseptic meningitis, ↓ resistance to infection, ↑ incidence of malignancies
Basiliximab (Simulect)	IV	Monoclonal antibody that acts as IL-2 receptor antagonist by inhibiting the binding of IL-2; inhibits T-cell activation and proliferation	Generally no adverse effects
Polyclonal antibody serums: ATG, ALG (Thymoglobulin, ATGAM)	IV	Polyclonal antibodies directed against lymphocytes; particularly deplete T cells	Serum sickness (fever, chills, muscle and joint pain), tachycardia, back pain, shortness of breath, hypotension, anaphylaxis, leukopenia, thrombocytopenia, rash, ↓ resistance to infection, ↑ incidence of malignancies

*Neoral is a microemulsion with better absorption than Sandimmune.

ALG, antilymphocyte globulin; *ATG,* antithymocyte globulin; *GI,* gastro-intestinal; *IL-2,* interleukin-2; *IL-4,* interleukin-4; *IV,* intravenous (route); *PO,* by mouth.

Immuno-suppressive protocols are highly variable among transplant centres, with different combinations of medications being used. Most patients are initially on triple therapy, which includes a calcineurin

inhibitor, a corticosteroid, and either mycophenolate mofetil (CellCept) or azathioprine (Imuran). The doses of immuno-suppressant drugs are reduced over time after the transplant, with some organ groups able to wean off corticosteroids entirely.

Calcineurin Inhibitors

This group of drugs, including tacrolimus (Prograf) and cyclosporin (Sandimmune, Neoral), is the foundation of most immuno-suppression regimens. These drugs prevent a cell-mediated attack against the transplanted organ (Figure 16-13). They do not cause bone marrow suppression or alterations of the normal inflammatory response. They are generally used in some combination with corticosteroids, mycophenolate mofetil (CellCept), and sirolimus (Rapamune). Tacrolimus (Prograf) is the most widely used calcineurin inhibitor with cyclosporin used less frequently.

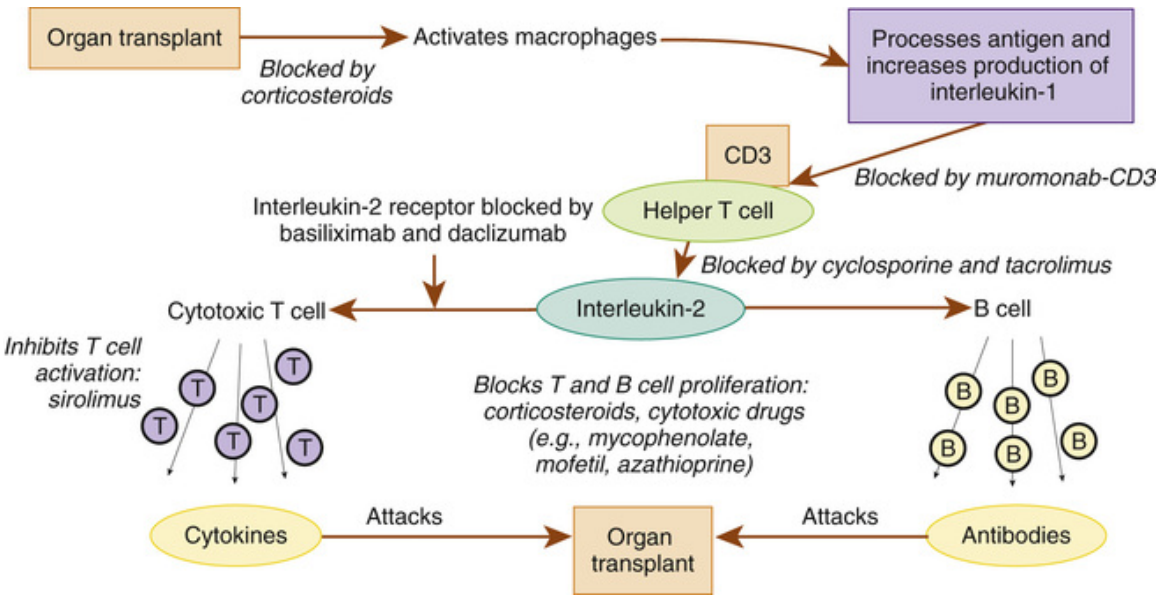

FIGURE 16-13 Sites of action for immuno-suppressive agents.

Source: Adapted from McKenry, L., Tessier, E., & Hogan, M. (2006). *Mosby's pharmacology in nursing* (22nd ed., p. 1161). St. Louis: Mosby.

Adverse effects of calcineurin inhibitors are dose related and include nephrotoxicity; therefore, drug levels are closely monitored.

Drug Alert

Tacrolimus (Prograf) and Cyclosporin (Sandimmune, Neoral)

- A substance in grapefruit and grapefruit juice prevents metabolism of these drugs. Consuming grapefruit or grapefruit juice while using these drugs could increase their toxicity.

Mycophenolate Mofetil (CellCept)

Mycophenolate mofetil (CellCept) inhibits purine synthesis with suppressive effects on both T and B lymphocytes. The major limitation of this drug is its gastro-intestinal toxicities, including nausea, vomiting, and diarrhea. In many cases, the adverse effects can be diminished by reduction in the dose or administration of smaller doses more frequently. Myfortic is an enteric-coated form of mycophenolate mofetil that has a similar adverse effect profile.

Drug Alert

Mycophenolate Mofetil (CellCept)

- When given IV, it must be reconstituted in D_5W and no other solution.
- Do not give as IV bolus. Give over 2 or more hours.

Sirolimus (Rapamune)

Sirolimus (Rapamune) is an immuno-suppressive drug that suppresses T-cell activation and proliferation. At relatively low doses, it has a synergistic effect with cyclosporin (Sandimmune, Neoral), tacrolimus (Prograf), and corticosteroids.

Monoclonal Antibodies

Monoclonal antibodies are used for preventing and treating acute rejection episodes. Muromonab-CD3 (OKT 3) was the first monoclonal antibody to be used in clinical transplantation. It is a mouse monoclonal antibody that

binds with the CD3 antigen found on the surface of human thymocytes and mature T cells. It interferes with the function of the T lymphocyte, the pivotal cells involved with graft rejection. It is administered via IV bolus. All T cells are affected, rather than just the subset active in graft rejection. Within minutes of the initial infusion of muromonab-CD3 (OKT 3), the number of circulating T cells decreases significantly.

A flulike syndrome occurs during the first few days of treatment, as a result of cytokine release. Adverse effects include fever, rigors, headache, myalgias, and various gastro-intestinal disturbances. To reduce the expected adverse effects of muromonab-CD3 (OKT 3), patients should receive acetaminophen (Tylenol), diphenhydramine (Benadryl), and intravenous corticosteroids before the dose is administered.

Newer generation monoclonal antibodies basiliximab (Simulect) (Ponticelli, 2014) and daclizumab (Zenapax) are a hybrid of mouse and human antibodies. They have fewer adverse effects than muromonab-CD3 (OKT 3) because large parts of the molecule have been replaced with human IgG. They target the IL-2 receptor and impair lymphocyte proliferation. Another monoclonal antibody is alemtuzumab (MabCampath), which targets the CD52 antigen found on T and B cells and the monocytes and macrophages. It can cause prolonged T-cell depletion.

Polyclonal Antibodies

Antilymphocyte globulin and antithymocyte globulin are used as induction therapy or to treat acute rejection. The purpose of induction therapy is to provide significant immuno-suppression to an individual immediately after transplantation to prevent early rejection. These agents are prepared by immunizing horses or rabbits with human lymphoid material (thymocytes, lymph nodes, or spleen cells) and then harvesting and purifying the resultant antibody.

Allergic reactions to the foreign proteins from the host animal, manifested by fever, arthralgias, and tachycardia, are common but usually not severe enough to preclude use. These adverse effects can be attenuated by administering the preparation slowly, over 4 to 6 hours, and administering premedication such as acetaminophen (Tylenol), diphenhydramine (Benadryl), and methylprednisolone (Solu-Medrol). The main toxic effects of polyclonal antibodies are lymphopenia and thrombocytopenia, caused by antibody contaminants that are not completely removed during preparation of the antibodies.

Graft-Versus-Host Disease

Graft-versus-host (GVH) disease occurs when an immuno-incompetent (immunodeficient) patient receives a transfusion or transplant with immuno-competent cells. A GVH response is most commonly seen in hematopoietic stem cell transplants. In most transplantation situations, the biggest concern is the patient's (host's) rejection of the organ or transplant. However, in GVH disease, the graft (donated tissue) rejects the host (recipient) tissue (Flowers & Martin, 2015).

The GVH response may begin 7 to 30 days after transplantation. Once the reaction is started, little can be done to modify its course. The exact mechanism involved in this reaction is not completely understood. However, it involves donor T cells' attacking and destroying vulnerable host (recipient) cells.

The target organs for the GVH phenomenon are the skin, the gastro-intestinal tract, and the liver. The skin disease may be a maculopapular rash, which may be pruritic or painful. It initially involves the palms and the soles of the feet but can progress to a generalized erythema with bullous formation and desquamation (shedding of the outer layer of skin). The liver disease may manifest as mild jaundice with elevated levels of liver enzymes and progress to hepatic coma. The GI manifestations may include mild to severe diarrhea, severe abdominal pain, gastro-intestinal bleeding, and malabsorption.

The biggest problem with GVH disease is differing types of infection at different time periods. Bacterial and fungal infections predominate immediately after transplantation, when granulocytopenia is occurring. Later, the development of interstitial pneumonitis is the predominant problem.

Once GVH disease is established, there is no adequate treatment. Although corticosteroids are often used, the susceptibility to infection then increases. The use of immuno-suppressive agents (e.g., methotrexate, cyclosporin [Sandimmune, Neoral]) has been most effective as a preventive rather than as a treatment measure. Irradiated blood products before administration is another measure to prevent T-cell replication.

Alternative Strategies

In the past decade, there has been a rapid rise in solid organ transplantation worldwide because of the increased incidence of organ failure and greater improvements in post-transplantation outcomes. However, cadaveric organ donation rates have not met demand; thus waiting lists are long, and increasing numbers of patients die waiting for a suitable organ (Gómez, Pérez, & Manyalich, 2014). The number of patients waiting for an organ transplant in Canada in 2013 was 4 361, but only 2 367 organs were transplanted. Approximately 246 people die annually waiting for an organ transplant in Canada (Canadian Institute for Health Information, 2015). Various strategies worldwide have been implemented to offset the critical organ shortage, some with modest success, others remaining under scientific investigation and ethical debate (see the "Ethical Dilemmas" box).

Ethical Dilemmas

Transplantation

Situation

A 24-year-old female patient is admitted to hospital with evidence of acute organ rejection. The patient informs the nurse in confidence that she does not take her antirejection medications regularly because she is very busy with work and school. The patient also states that she usually feels so well that she does not think she needs to take them every day. She asks the nurse not to inform the health care team that she has been missing some of her antirejection medications.

Important Points for Consideration

- Building a trusting relationship with patients is key in the health care environment; however, the larger implications for the patient's health supersede the issue of confidentiality. There are some limits to confidentiality, including potential or real harm to self or others.
- The nurse is a member of the treatment team.

- Organ rejection can cause reduced organ function and potential loss of the graft and subsequent death for the patient. With complete information, the patient can understand the importance of adherence to the medication regimen.

Critical Thinking Questions

1. How should the nurse respond to this patient's request for confidentiality? Should the nurse inform the treatment team? If so, should he or she tell the patient?
2. What information should the nurse give the patient regarding the importance of taking her antirejection medications?
3. How could the nurse work with the patient who has a busy schedule and forgets to take her medications?

Transplantation of Organs From Deceased Donor

One of the most rapid increases in organ recovery rates has been from deceased people who are declared dead on the basis of cardiopulmonary criteria (irreversible cessation of circulatory and respiratory function) rather than neurological criteria of "brain death" (irreversible loss of all functions of the entire brain, including the brain stem) (Hernandez-Alejandro, Wall, Jevnikar, et al., 2011). Such patients typically are on a ventilator because of devastating and irreversible brain injury (not complete brain death) from trauma or intracranial bleeding. Furthermore, in some of these patients, complete cessation of the heartbeat with subsequent cardiac resuscitation was followed by irreversible brain injury as the result of a long period of anoxia (lack of oxygen). Further treatment has been deemed futile, and end-of-life care management implemented. Often, family members express interest in organ donation. The potential donor must meet cardiac death criteria at onset of asystole or absence of a heartbeat. In order to avoid conflict of interest, those involved in end-of-life care or declaration of death of the potential donor are not involved in the care of the transplant recipient. Organs most commonly recovered for donation include the kidneys, the liver, the pancreas, and the lungs (Hernandez-Alejandro, Wall, Jevnikar, et al., 2011). In 2012 in Canada, 166 organs were recovered after deceased cardiac death and successfully transplanted into recipients (Canadian Institute for Health Information, 2015).

Xenotransplantation

Xenotransplantation is the replacement of a patient's diseased and malfunctioning organ with an organ harvested from another species. Animals considered as a possible source of organs for human use include primates (because of their genetic similarities to humans) and pigs (because of their large availability). Organs from primates have been largely dismissed because of logistical difficulties. The pig is believed to be the most appropriate candidate because of comparable organ size, large litters, and rapid gestation. Difficulties in successful organ transplantation from one species to another, as in from pig to human, include multiple biological barriers. First, the significant degree of antigen disparity means that there is more for the human immune system to recognize and reject. Second, the possibility of diseases "jumping" the species barrier and infecting humans, such as porcine endogenous retroviruses, is one of the main reasons people remain sceptical and concerned regarding xenotransplantation. This possibility has decreased enthusiasm for xenotransplantation as an alternative to allogeneic organ transplantation (Health Canada, 2010). However, despite strong scepticism, much scientific research and advancement in this area continues.

Ex Vivo Transplantation

A novel strategy to help overcome donor lung shortages has been through the development of normothermic ex vivo lung perfusion (EVLP) (Figure 16-14). The injured donor lungs are reassessed and conditioned through the EVLP system by mimicking the lung's natural physiological environment and by providing oxygen and other substrates necessary for active metabolism. Through the use of EVLP, therapeutic interventions can be performed in the donor lungs that reduce the degree or negative influence of pulmonary edema, pulmonary emboli, gastric aspiration, pneumonia, and lung inflammation (Reeb & Cypel, 2016).

FIGURE 16-14 The Toronto EVLP System. **A,** Surgeons working on the ex vivo lung. **B,** Thoracic Surgeons at Toronto General Hospital, Dr. Marcelo Cypel and Dr. Shaf Keshavjee Director of the Toronto Lung Transplant Program, perform a bronchoscopy on the ex vivo lung for clinical evaluation. Published with the permission of Dr. Shaf Keshavjee, Director, Toronto Lung Transplant Program, University Health Network.

Stem Cell Transplantation

Stem cells are the subject of much discussion. It is believed that the use of stem cells may allow for the regeneration of lost tissue and restoration of function in many chronic diseases such as Parkinson's disease, Alzheimer's disease, heart disease, diabetes mellitus, and spinal cord injuries.

Stem cells are cells in the body that have the ability to differentiate into other cells. Stem cells can be divided into two types: embryonic and adult. Embryonic stem cells have the ability to become any one of the hundreds

of types of cells in the human body. They are derived from human embryo cells that are 4 to 5 days old. These stem cells are pluripotent and can differentiate into any cell type that they are stimulated to become. Because of their versatility, embryonic stem cells are preferred for use in medical research. Donor eggs, like stem cells, can be used with existing adult tissue to produce new tissue. In a process known as *nuclear transfer* or *therapeutic cloning,* the nucleus is removed from the egg and replaced with the nucleus of the desired tissue. Then, as the egg divides, a 200-cell blastocyst of the desired tissue is created. Adult stem cells are undifferentiated cells that are found in small numbers in most adult tissues; they have been discovered in the skin, the gastro-intestinal tract, and bone marrow. They are also found in newborns and can be extracted from umbilical cord blood. The primary roles of adult stem cells in the body are to maintain and repair tissues in which they are found. They are usually thought of as multipotent cells, giving rise to a closely related family of cells within the tissue. For example, hematopoietic stem cells form all the various cells in blood, whereas skin stem cells produce new skin cells. Scientists hope that adult stem cells can be coaxed into providing tissue for unrelated organs.

Stem cells found within the bone marrow are the body's site of hematopoiesis. The cells are prolific by design and are already being donated in the treatment of certain diseases, such as leukemia. Cells similar to the stem cells found in bone marrow can be found in the umbilical cord and blood from the placenta. These cells are used in situations similar to those of bone marrow. Studies are being conducted to find future uses that will allow the cells to become other tissues in the body (National Institutes of Health, 2015). With increasing waiting lists for organ transplantation, embryonic stem cell research may be the key to solving the problem of organ shortages through organ regeneration. However, conflicts exist regarding creating embryonic stem cells for therapeutic purposes such as organ development, with much debate over the definition of human life at the earliest stages versus a potentially life-saving therapy. Much discussion continues in this area internationally.

New Technologies in Immunology

Hybridoma Technology: Monoclonal Antibodies

Monoclonal antibodies are homogeneous populations of identical antibody molecules produced by specialized tissue cell culture lines. They are manufactured through cell fusion techniques and standard in vitro tissue culture systems (Figure 16-15). The two essential biological components are immunized mice or rats and myeloma tumour cell lines, which are of lymphoid origin. Single antibody-forming cells (lymphocytes) from rodents previously immunized with antigen are fused with myeloma cells to create hybrid cells with properties of both parent cell types. Like the myeloma parent cell, the hybrids have an unlimited capacity to reproduce. The hybrids produce the single type of antibody molecule that they inherited from the normal, antibody-forming parent cell. Hybrid cells derived in this way can produce unlimited quantities of specific antibodies. With appropriate selection techniques, producing monoclonal antibodies to virtually any antigen is possible. Because the monoclonal antibodies are a completely homogeneous population, their use incurs fewer problems than does that of conventional polyclonal antisera.

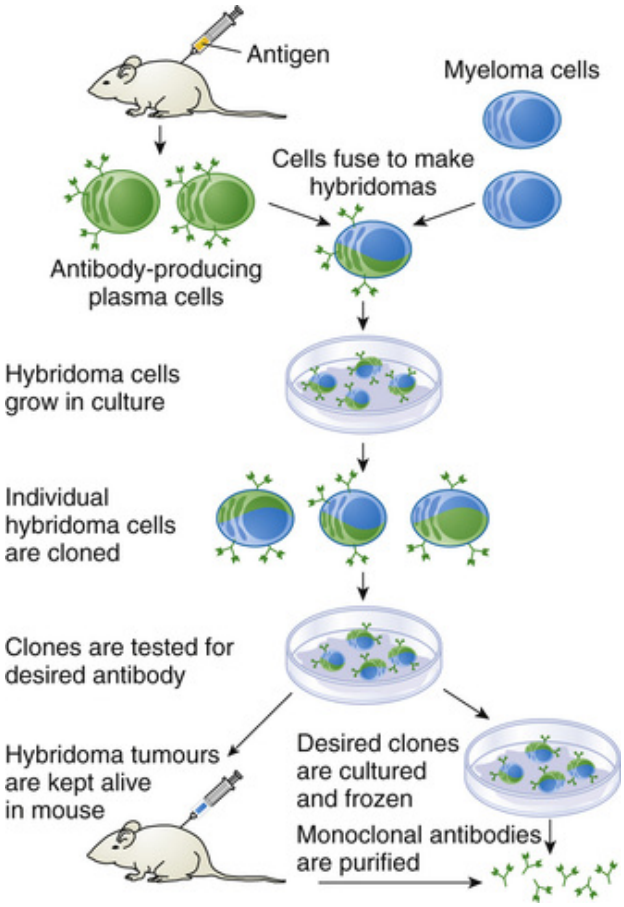

FIGURE 16-15 Monoclonal antibodies are identical antibodies made by clones of a single antibody-producing cell. The target antigen is injected into a mouse. Plasma cells are harvested from the spleen of the mouse and fused with myeloma cells. The fused cells, or hybridomas, are then cloned. A clone can secrete monoclonal antibodies over a long period.

Monoclonal antibodies are used widely in many areas of medicine and biological science. Thousands of monoclonal antibodies have been made against many different types of antigens. Monoclonal antibodies have begun to replace conventional antibodies in blood banking and are used in the identification of organisms in bacteriology laboratories. Monoclonal antibodies have also been extensively used in radioimmunoassays to measure serum levels of various substances (e.g., parathyroid hormone). They have been useful in quantifying types of WBCs and subtypes of lymphocytes and in the diagnosis of leukemia. More recently, monoclonal antibodies have been used in the treatment of malignancies (see Chapter 18). They have been used to treat transplant rejection episodes, to purge bone marrow of tumour cells in bone marrow transplants, and to remove

mature T cells that cause GVH disease in bone marrow transplant recipients.

A major limitation of monoclonal antibody use for humans is that they are mouse antibodies and therefore can elicit an antibody response by the host against the foreign agent. Human hybridomas have been produced through the use of human myelomas. These hybrids synthesize human monoclonal antibodies and are therefore advantageous for in vivo use in diagnosis and therapy.

Case Study

Anaphylactic Reaction

Source: Creative Family/Shutterstock.com.

Patient Profile

Kiara Riley, a 21-year-old university student, is brought to the emergency department by ambulance from her school lunch room after a sudden change in level of consciousness and difficulty with speech.

Subjective Data

Conscious on admission but confused, disoriented, very restless, and anxious.

Objective Data

Physical Assessment

- Vital signs on admission: BP 82/58, pulse 124/minute, respirations 8/minute, temp 39.3°C, O_2 saturation 84% on 100% oxygen

- Skin: mild facial edema, urticaria, itchy eyes
- Respiratory: tightness of throat, shortness of breath, runny nose
- Gastro-intestinal tract: nausea, mild abdominal pain

A few of her friends arrive at the emergency department, and it is discovered that she had eaten some cookies that were thought to have peanuts in them right before the event occurred. Family could not be contacted to determine if Ms. Riley had a previous documented allergy to nuts/peanuts. Her friends were unaware of such an allergy in her history but do not remember seeing her eating nuts of any kind in the past.

Discussion Questions

1. What kind of reaction is the patient experiencing?
2. ***Priority decision:*** Based on the assessment data provided, what are the priority nursing diagnoses?
3. ***Priority decision:*** What are the priority nursing interventions for Ms. Riley?
4. What first-line medication would likely be administered, and how is it going to work to assist the patient?
5. Based on the assessment data provided and the diagnoses, what future nursing care should be provided for this patient?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. What is the function of monocytes in immunity?
   a. They stimulate the production of T and B lymphocytes.
   b. They produce antibodies on exposure to foreign substances.
   c. They bind antigens and stimulate natural killer cell activation.
   d. They capture antigens by phagocytosis and present them to lymphocytes.
2. Which of the following is a function of cell-mediated immunity?
   a. Formation of antibodies
   b. Activation of the complement system
   c. Surveillance for malignant cell changes
   d. Opsonization of antigens to allow phagocytosis by neutrophils
3. Which immunoglobulin from maternal transmission protects newborns in the first 3 to 6 months of life from bacterial infections?
   a. IgG
   b. IgA
   c. IgM
   d. IgE
4. Which primary immunological disorder typically occurs in a type I hypersensitivity reaction?
   a. Binding of IgG to an antigen on a cell surface
   b. Deposit of antigen–antibody complexes in small vessels
   c. Release of lymphokines to interact with specific antigens
   d. Release of chemical mediators from IgE-bound mast cells and basophils
5. Which response may alert the nurse that a possible anaphylactic shock reaction may be occurring immediately after a client has received an intramuscular penicillin injection?
   a. Edema and itching at the injection site
   b. Sneezing and itching of the nose and eyes
   c. A wheal-and-flare reaction at the injection site

d. Chest tightness and production of thick sputum

6. Which is the most appropriate response when a person requests a friend who is a nurse to administer his allergy shot?
   a. It is illegal for nurses to administer injections outside of a medical setting.
   b. He or she is qualified to do it if the friend has epinephrine in an injectable syringe provided with his extract.
   c. Avoiding the allergens is a more effective way of controlling allergies, and allergy shots are not usually effective.
   d. Immunotherapy should be administered only in a setting where emergency equipment and drugs are available.
7. Association between HLA antigens and diseases is most commonly found in what disease conditions?
   a. Malignancies
   b. Infectious diseases
   c. Neurological diseases
   d. Autoimmune disorders
8. A client is undergoing plasmapheresis for treatment of SLE. What effect does plasmapheresis have?
   a. Removes T lymphocytes in the client's blood that are producing antinuclear antibodies
   b. Removes normal particles in the client's blood that are being damaged by autoantibodies
   c. Exchanges the client's plasma that contains antinuclear antibodies with a substitute fluid
   d. Replaces viral-damaged cellular components of the client's blood with replacement whole blood
9. What is the most common cause of secondary immunodeficiencies?
   a. Drugs
   b. Stress
   c. Malnutrition
   d. Human immunodeficiency virus
10. Which of the following accurately describes rejection after transplantation?

a. Hyperacute rejection can be treated with mycophenolate mofetil.
b. Acute rejection can be treated with sirolimus or tacrolimus.
c. Chronic rejection can be treated with tacrolimus or cyclosporin.
d. Hyperacute rejection can usually be avoided if crossmatching is done before transplantation.

11. Which of the following does the nurse understand regarding acute rejection of a transplanted lung? (*Select all that apply*)
a. A new transplant should be considered immediately.
b. Acute rejection can be treated with high-dose corticosteroids.
c. Acute rejection always leads to chronic rejection.
d. Acute rejection is treated with muromonab-CD3.
e. Acute rejection is common after a transplant and is treated with augmentation of immuno-suppression.

12. Which of the following statements best describes cardiac death in a deceased donor?
a. Severe brain damage; coma has progressed to a state of wakefulness without detectable awareness
b. Irreversible loss of all functions of the entire brain, including the brain stem
c. Devastating and irreversible brain injuries (not complete brain death) from trauma or intracranial bleeding; complete cessation of the heartbeat may have occurred, and after subsequent cardiac resuscitation, irreversible brain injury results from a long period of lack of oxygen
d. Inability to be awakened; fails to respond normally to pain or light, does not have sleep–wake cycles, and does not take voluntary actions

1. d; 2. c; 3. a; 4. d; 5. a; 6. d; 7. d; 8. c; 9. a; 10. d; 11. b, e; 12. c.

CHAPTER 17

Infection and Human Immunodeficiency Virus Infection

Written by, Jeffrey Kwong

Adapted by, Jane McCall

LEARNING OBJECTIVES

1. Discuss the effect of emerging and re-emerging infections on health care.
2. Review infection prevention and control strategies.
3. List the modes and variables involved in the transmission of the human immunodeficiency virus (HIV).
4. Describe the pathophysiological processes of HIV infection.
5. Outline HIV disease progression against the spectrum of untreated HIV infection.
6. List the diagnostic criteria for acquired immune deficiency syndrome (AIDS).
7. Explain the methods of testing for HIV infection.
8. Discuss the collaborative management of HIV infection.
9. Discuss the long-term consequences of HIV infection and treatment of HIV infection.
10. Explain the characteristics of opportunistic diseases associated with AIDS.

11. Describe the nursing management of HIV-infected patients and those at risk for HIV infection.
12. Compare and contrast the methods of HIV prevention that eliminate risk and those that decrease risk.

KEY TERMS

acquired immunodeficiency syndrome (AIDS), p. 293
acute retroviral syndrome, p. 297
bacteria, p. 287
emerging infectious disease, p. 289
fungi, p. 288
human immunodeficiency virus (HIV), p. 295
opportunistic diseases, p. 297
oral hairy leukoplakia, p. 297
protozoa, p. 288
retroviruses, p. 295
reverse transcriptase, p. 296
viral load, p. 294
viremia, p. 296
viruses, p. 288
window period, p. 295

Infections

An infection is an invasion of the body by a *pathogen* (any microorganism that causes disease) and the resulting signs and symptoms that develop in response to the invasion. Infections can be divided into two categories: localized and systemic. A localized infection is limited to a small area. Systemic infections are widespread throughout the body and are often spread via the blood.

Causes of Infections

A number of microorganisms can cause infections. The most common are bacteria, viruses, fungi, and protozoa. **Bacteria** are one-celled microorganisms that are found virtually everywhere on earth and are involved in fermentation, putrefaction, infectious diseases, and nitrogen fixation. They were first observed by Anton Van Leeuwenhoek, who named them "animalcules." A number of bacteria are considered to be normal flora. Under normal circumstances, they live harmoniously in or on the human body without causing disease. These normal flora act protectively and prevent the overgrowth of other microorganisms. *Escherichia coli* organisms, for example, are bacteria that are normal flora in the large intestine (Huether & McCance, 2012).

Bacteria cause disease in two ways. They can enter the body and grow inside human cells (e.g., tuberculosis [TB]), or they can secrete toxins that damage cells. Bacteria are divided into categories on the basis of the shape of their cells. Cocci, including streptococci and staphylococci, are round cells. Bacilli are rod-shaped and include tetanus and TB. Bacilli that are curved rods include *Vibrio* bacteria, one of which causes cholera. Table 17-1 lists common pathogenic bacteria and the diseases that they cause (Huether & McCance, 2012).

TABLE 17-1
COMMON DISEASE-CAUSING BACTERIA

Type	Diseases Caused
Clostridium organisms	
• *C. botulinum*	Food poisoning with progressive muscle paralysis
• *C. tetani*	Tetanus (lockjaw)
Corynebacterium diphtheriae	Diphtheria
Escherichia coli	Urinary tract infections, peritonitis
Haemophilus organisms	
• *H. influenzae*	Nasopharyngitis, meningitis, pneumonia
• *H. pertussis*	Pertussis (whooping cough)
Helicobacter pylori	Peptic ulcers, gastritis
Klebsiella and *Enterobacter* organisms	Urinary tract infections, peritonitis, pneumonia
Legionella pneumophila	Pneumonia (legionnaires disease)
Mycobacterium organisms	
• *M. leprae*	Hansen's disease (leprosy)
• *M. tuberculosis*	Tuberculosis
Neisseria organisms	
• *N. gonorrhoeae*	Gonorrhea, pelvic inflammatory disease
• *N. meningitidis*	Meningococcemia, meningitis
Proteus organisms	Urinary tract infections, peritonitis
Pseudomonas aeruginosa	Urinary tract infections, meningitis
Salmonella organisms	
• *S. typhi*	Typhoid fever
• Other *Salmonella* organisms	Food poisoning, gastro-enteritis
Shigella organisms	Shigellosis, diarrhea with abdominal pain and fever (dysentery)
Staphylococcus aureus	Skin infections, pneumonia, urinary tract infections, acute osteomyelitis, toxic shock syndrome
Streptococcus organisms	
• *S. faecalis*	Genito-urinary infection, infection of surgical wounds
• *S. pneumoniae*	Pneumococcal pneumonia
• *S. pyogenes* (group A β-hemolytic streptococci)	Pharyngitis, scarlet fever, rheumatic fever, acute glomerulonephritis, erysipelas, pneumonia
• *S. pyogenes* (group B β-hemolytic streptococci)	Urinary tract infections
• *S. viridans*	Bacterial endocarditis
Treponema pallidum	Syphilis

Viruses can also cause infections. The word *virus* comes from the Latin term *virus,* meaning "poison." Unlike bacteria, viruses are not cells. They consist of either RNA or DNA and a protein envelope. Viruses can reproduce only in the cells of a living organism and are therefore obligate parasites. Examples of diseases caused by viruses are presented in Table 17-2 (Huether & McCance, 2012).

TABLE 17-2
COMMON DISEASE-CAUSING VIRUSES

Type	Diseases Caused
Adenoviruses	Upper respiratory tract infection, pneumonia
Arbovirus	Syndrome of fever, malaise, headache, myalgia; aseptic meningitis; encephalitis
Coronavirus	Upper respiratory tract infection
Coxsackieviruses A and B	Upper respiratory tract infection, gastro-enteritis, acute myocarditis, aseptic meningitis
Echoviruses	Upper respiratory tract infection, gastro-enteritis, aseptic meningitis
Hepatitis A, B, C, D, E	Viral hepatitis
Human herpesviruses	
• Cytomegalovirus (CMV)	Gastro-enteritis; pneumonia and retinal damage in immuno-suppressed individuals; infectious mononucleosis–like syndrome
• Epstein-Barr virus	Mononucleosis, Burkitt's lymphoma (possibly)
• Herpes simplex, type 1	Herpes labialis (“fever blisters”), genital herpes infection
• Herpes simplex, type 2	Genital herpes infection
• Varicella-zoster	Chickenpox; shingles
HIV	HIV infection, AIDS
Influenza A and B	Upper respiratory tract infection
Mumps	Parotitis, orchitis in postpubertal males
Papovavirus	Warts
Parainfluenza types 1–4	Upper respiratory tract infection
Parvovirus	Gastro-enteritis
Poliovirus	Poliomyelitis
Poxviruses	Smallpox
Reoviruses 1, 2, 3	Upper respiratory tract infection
Respiratory syncytial virus	Gastro-enteritis, respiratory tract infection
Rhabdovirus	Rabies
Rhinovirus	Upper respiratory tract infection, pneumonia
Rotaviruses	Gastro-enteritis
Rubella	German measles
Rubeola	Measles
West Nile virus	Flulike symptoms, meningitis, encephalitis

AIDS, acquired immune deficiency syndrome; *HIV*, human immunodeficiency virus.

Fungi are organisms similar to plants, but they lack chlorophyll. Mycosis is any disease caused by a fungus. Pathogenic fungi cause infections that are usually localized to a small area, but in an immuno-compromised person, they can become disseminated.

Athlete's foot and ringworm are two common mycotic infections. Some fungi are normal flora in various places in the body, but when overgrowth occurs, disease can result. Overgrowth of *Candida albicans,* for example, causes oral candidiasis (thrush), esophageal candidiasis, intestinal symptoms, and vaginitis, depending on the affected site (Huether & McCance, 2012). Other fungi and their respective mycotic infections are listed in Table 17-3. Fungal infections of the lungs are presented in Chapter 30 (see Table 30-9) and fungal infections of the skin in Chapter 26 (see Table 26-8).

TABLE 17-3
COMMON DISEASE-CAUSING FUNGI

Organism	Diseases Caused	Organs Affected
Aspergillus fumigatus	Aspergillosis	Lungs*
	Otomycosis	Ears
Blastomyces dermatitidis	Blastomycosis	Lungs, various organs
Candida albicans	Candidiasis	Intestines
	Vaginitis	Vagina
	Thrush	Skin,† mouth
Coccidioides immitis	Coccidioidomycosis	Lungs*
Pneumocystis jiroveci	Pneumocystis pneumonia	Lungs*
Sporothrix schenckii	Sporotrichosis	Skin, lymph vessels
Trichophyton species	Tinea pedis	Skin†
Microsporum species	Tinea capitis	Skin
Epidermophyton species	Tinea corporis	Skin†

*See Table 30-9 (Fungal Infections of the Lung).

†See Table 26-8 (Common Fungal Infections of the Skin and Mucous Membranes).

Protozoa are single-cell, animal-like microorganisms. Protozoa can be divided into four categories: amoebas, ciliates, flagellates, and sporozoa. Protozoa normally live in soil and bodies of water. When they are introduced into the human body, infection can result. Amoebic dysentery and giardiasis are caused by protozoan parasites. Malaria is caused by a sporozoa called *Plasmodium malariae* (Huether & McCance, 2012).

Emerging Infections

An **emerging infectious disease** is an infectious disease whose incidence has recently increased or threatens to increase in the

immediate future. Examples of emerging infections are described in Table 17-4. Emerging infectious diseases can originate from unknown sources, contact with animals, changes in known diseases, natural disasters, or even biological warfare. For example, the coronavirus that causes severe acute respiratory syndrome (SARS) and the West Nile virus come from animal sources, whereas other pathogens, such as *Staphylococcus aureus,* have emerged because a previously treatable organism developed resistance to antibiotics. Climate change has resulted in an increase of disease-carrying mosquitoes, as well as increases in rodent numbers and in hantavirus. Earthquakes, such as the large one in Haiti in 2010, are associated with the spread of waterborne diseases such as cholera. The battle against infectious disease is an age-old problem. However, modern technologies have changed how disease spreads. Global travel, population density, encroachment into new environments, and the misuse of antibiotics have all increased the risk for widespread new or untreatable infectious diseases (Public Health Agency of Canada [PHAC], 2015b).

TABLE 17-4
EXAMPLES OF EMERGING INFECTIONS

Microorganism	Related Disease
Bacteria	
Borrelia burgdorferi	Lyme disease
Campylobacter jejuni	Diarrhea
Escherichia coli O157:H7	Hemorrhagic colitis, hemolytic uremic syndrome
Helicobacter pylori	Peptic ulcer disease
Legionella pneumophila	Legionnaires disease
*Vibrio cholera*e 0139	New strain associated with epidemic cholera
Viruses	
Ebola virus	Ebola hemorrhagic fever
Hantavirus	Hantavirus pulmonary syndrome (found in North and South America) Hemorrhagic fever with renal syndrome (found mainly in Europe and Asia)
H1N1 virus	H1N1 (swine) flu
Hepatitis A virus	Enterically transmitted hepatitis
Hepatitis C virus	Parenterally transmitted hepatitis
Hepatitis E virus	Enterically transmitted hepatitis
HIV	HIV infection and AIDS
HHV-6	Roseola
HHV-8	Associated with Kaposi's sarcoma and Castleman's disease in immuno-suppressed patients, patients with AIDS
West Nile virus	West Nile fever
Avian influenza A (H5N1) virus	Avian flu
Zika virus	Zika fever, microcephaly
Parasites	
Cryptosporidium parvum	Acute and chronic diarrhea

AIDS, acquired immunodeficiency syndrome; *HHV*, human herpesvirus; *HIV*, human immunodeficiency virus.

It is interesting that, not too long ago, many people believed that science had conquered infectious disease. Unfortunately, infections remain the leading cause of death worldwide. More than 30 newly recognized infectious diseases have emerged since the 1980s, including human immunodeficiency virus (HIV) infection, Lyme disease, hepatitis C, SARS, avian flu, and Ebola virus disease. In addition, some diseases once thought to be under control, including TB and drug-resistant strains of other bacteria, have re-emerged (PHAC, 2015b).

Results of studies in zoonosis (the science of transmission of diseases from animals to humans) indicate that many known

infectious diseases come from animals and insects (vectors). The SARS outbreak in China in 2003, for instance, was linked to the civet cat, a small carnivorous mammal found throughout much of Asia and Africa. (SARS is discussed in Chapters 70 and 72.) Animal-borne infections are difficult to predict and prevent.

West Nile virus is transmitted by a virus carried by mosquitoes. Mosquitoes acquire the virus as they draw blood from infected birds (PHAC, 2014). The virus does not cause illness in the mosquito but can be transferred to animals and humans as the mosquito continues to feed. Bird deaths are an indicator of the spread of the West Nile virus and can serve as an early warning sign of an outbreak that can spread quickly if action is not taken in a timely manner (PHAC, 2014). (West Nile virus is discussed in Chapter 59.) Another serious disease transmitted by animals is Lyme disease, which is caused by the bite of a black-legged tick. Lyme disease is most common in the northeastern and north central United States, as well as on the west coast, including British Columbia. Lyme disease has, however, also been reported in Ontario. (See Chapter 67 for further discussion on Lyme disease.)

Sometimes, an organism alters its normal path of transmission. In the past, influenza A viruses were typically spread from birds to pigs to humans. More recently, in cases such as the avian flu outbreak, the virus has been spread directly from chickens to humans. This was first demonstrated in Hong Kong in 1997 and also in the Netherlands in 2003. Infected people generally suffer from conjunctivitis or mild influenza-like symptoms. However, 200 deaths related to avian flu have occurred worldwide (PHAC, 2015a). Upon discovery of an outbreak, all chickens in the area are typically slaughtered to remove the source of the infection.

The disease caused by Ebola virus is an emerging entity that has presented an ongoing challenge to public health since it was first observed in 1976. Ebola virus causes a severe hemorrhagic fever and is usually lethal. Therapeutic and preventive measures are extremely limited. The natural reservoir and path of transmission of the virus are unknown, which makes it impossible to effectively combat the disease (Government of Canada, 2016a). In 2014, there was a large outbreak of Ebola in West Africa that was unusually difficult to

control. This outbreak was also the first time Ebola was seen outside of Africa, with cases reported in the United States and Europe (World Health Organization [WHO], 2016).

A relatively new and emerging entity is the outbreak caused by Zika virus. Originally identified in Africa and Asia in the 1950s and historically occurring in low numbers, it has occurred in a large outbreak in South and Central America, with some cases reported in the United States and Canada. Zika virus generally causes a relatively mild infection, manifested by muscle and joint pain, headache, rash, and conjunctivitis. It is spread primarily by mosquitoes, but there is some evidence of sexual transmission. Zika does not pose a risk to most people; however, women who are infected with the virus during pregnancy are more likely to have a baby with microcephaly (Government of Canada, 2016b).

Re-Emerging Infections

Vaccines and proper medications have led to the near eradication of some infections. However, infective agents can always re-emerge if conditions are right. Table 17-5 illustrates some diseases that have re-emerged in recent decades.

TABLE 17-5
EXAMPLES OF RE-EMERGING INFECTIONS

Microorganism	Infection	Description
Bacteria		
Corynebacterium diphtheriae	Diphtheria	Localized infection of mucous membranes or skin
Bordetella pertussis	Pertussis	Acute, highly contagious respiratory disease that is characterized by loud whooping inspiration; also known as *whooping cough*
Mycobacterium tuberculosis	Tuberculosis	Chronic infection transmitted by inhalation of infected droplets (see Chapter 30)
Viruses		
Dengue viruses (flaviviruses)	Dengue fever	Acute infection transmitted by mosquitoes and occurring mainly in tropical and subtropical regions
Parasite		
Giardia	Giardiasis	Diarrheal illness that usually originates in fecal-contaminated water; also known as travellers' diarrhea

For example, the incidence of TB began to decrease steadily in the mid-1950s. However, by 2013, the declining trend stabilized and

incidence levelled out to 4.7 cases per 100,000 people in Canada (PHAC, 2015b). One factor that has influenced the continued incidence of TB in Canada is the increase in people with HIV, whose depressed immune systems allow pathogens such as TB bacilli to cause disease. There has been an increase in drug-resistant TB, although, in Canada, the rates remain relatively low (PHAC, 2015b). International travel creates a new dilemma for the local eradication of diseases. Measles, for instance, is no longer considered endemic in Canada, but it remains a leading cause of morbidity in developing countries. Some measles cases in Canada have been found in people who have travelled to these measles-endemic countries and in people in religious nonimmunizing communities (PHAC, 2015b).

Resistant Organisms

Antibiotic-resistant organisms, also called *multidrug-resistant organisms* or *superbugs,* are bacteria whose growth and reproduction are unaffected by particular antibiotics. Microorganisms can become resistant to classic antibiotics (e.g., penicillin), as well as to newer antibiotic and antiviral agents.

Methicillin-resistant *S. aureus* (MRSA), vancomycin-resistant enterococci, health care–associated *Clostridium difficile*, and carbapenem-resistant enterobacteriaceae are four of the most troublesome resistant bacteria in North America (PHAC, 2014). Table 17-6 lists the most common antibiotic-resistant bacteria.

TABLE 17-6

COMMON ANTIBIOTIC-RESISTANT ORGANISMS AND TREATMENT

Bacteria	Resistant To	Preferred Treatment
Clostridium difficile	Associated with the overuse of certain antibiotics, including fluoroquinolones, cephalosporins, and clindamycin	Metronidazole (Flagyl) Vancomycin (Vancocin) Fidaxomicin (Dificid) Stool transplantation
Staphylococcus aureus	Methicillin*	Vancomycin (Vancocin)
Enterococcus faecalis	Vancomycin (Vancocin), streptomycin, gentamicin	Penicillin G or ampicillin
Enterococcus faecium	Vancomycin, streptomycin, gentamicin	Penicillin G or ampicillin
Carbapenem-resistant enterobacteriaceae	Carbapenem class of antibiotics	Fosfomycin (Monurol) Tigecycline (Tygacil)

*No longer used clinically.

Bacteria are highly adaptable organisms that have evolved genetic and biochemical means of resisting antimicrobial actions. Genetic mechanisms include mutation and acquisition of new DNA. Biochemically, bacteria resist antibiotics by producing enzymes that destroy or inactivate the drugs. Drug target sites are then altered so that the antibiotic cannot bind to or enter the bacteria. If the drug cannot enter the cell, it cannot kill the bacteria (WHO, 2015a). MRSA can be acquired in a hospital setting and in the community. In health care workers exposed to MRSA, their bodies can become colonized, and they can spread the infection to other health care workers and to patients. The organism can remain viable for days on environmental surfaces and clothing. It is important to understand that many people are colonized with antibiotic-resistant organisms, but they are not infected. However, certain patients are at particular risk of becoming infected including those who are immuno-suppressed (e.g., receiving chemotherapy), have invasive devices (e.g., indwelling catheters), or have breaks in the skin barrier (e.g., surgical wounds). Vancomycin-resistant enterococci are hardier than MRSA

and can remain viable on environmental surfaces for weeks. Alcohol preparations are the most effective antimicrobial agents, followed by chlorhexidine gluconate (PHAC, 2012a). The PHAC (2012b) recommended that infection control for antibiotic-resistant organisms consist of routine practices or standard precautions (see Tables 17-8 and 17-9 later in this chapter), which should be used for all patient care.

Drug resistance is a particularly difficult problem in dealing with infectious diseases. Health care providers can contribute to the development of drug-resistant organisms by (a) administering antibiotics for viral infections, (b) succumbing to pressures from patients to prescribe unnecessary antibiotic therapy, (c) using inadequate drug regimens to treat infections, or (d) using broad-spectrum or combination agents for infections that should be treated with first-line medications. Patients who miss doses or do not take antibiotics for the full duration of the prescribed therapy also contribute to the development of resistance. In addition, limited resources or access to medications makes it difficult for some patients to get adequate treatment for infections. Patients and their families should be taught that the proper use of antibiotics (Table 17-7) is crucial to treatment success and prevention of drug-resistant pathogens.

TABLE 17-7

PATIENT & CAREGIVER TEACHING GUIDE
Decreasing Risk for Antibiotic-Resistant Infection

1. **Do Not Take Antibiotics to Prevent Illness.** Doing this increases the risk for developing resistant infection.
    - Exceptions include taking antibiotics before certain surgical procedures and taking antibiotics before dental work if the patient has a heart valve disorder.
2. **Wash Hands Frequently.** Handwashing is the most important way to prevent an infection.
3. **Follow Directions.** Not taking antibiotic as prescribed or skipping doses can encourage the development of antibiotic-resistant bacteria.
4. **Finish the Antibiotic.** Patients must not stop taking antibiotic when they feel better. If they stop taking the antibiotic early, the hardiest bacteria survive and multiply. Eventually a patient could develop an infection resistant to many antibiotics. Patients should never have leftover antibiotics.
5. **Do Not Request an Antibiotic for Flu or Colds.** If the health care provider says that an antibiotic is not needed, chances are that this is true. Antibiotics are effective against bacterial infections but not viruses, which cause colds and flus.
6. **Do Not Take Leftover Antibiotics.** People often save unfinished antibiotics for later use or borrow leftover drugs from family or friends. This is dangerous because (a) the leftover antibiotic may not be appropriate for the patient, (b) the illness may not be a bacterial infection, (c) old antibiotics can lose their effectiveness, and in some cases, ingesting them can even be fatal, and (d) there will not be enough doses in a leftover bottle to allow for a full treatment.

Health Care–Associated Infections

Health care–associated infections (HAIs; formerly called *nosocomial infections*) are infections that are acquired as a result of exposure to a microorganism in any setting in which health care is delivered (e.g., acute or long-term care facility, ambulatory clinic, home) and are related to receiving health care. More than 8 000 people die in Canadian hospitals each year as a result of infections acquired during their hospitalization (PHAC, 2013). More than 200 000 Canadians acquire a health care–associated infection each year (PHAC, 2013). Surgical patients are at greater risk. In addition, some bacteria that are not normally pathological can cause infections in patients who are immuno-compromised as a result of illness or treatment of illness. HAIs can be caused by any organism, but certain bacteria—including *E. coli, S. aureus, Enterobacter aerogenes, C. difficile,* and various types of streptococci—are the more common culprits. At least 30% of HAIs can be prevented by following infection prevention strategies (PHAC, 2012b). HAIs are often transmitted from patient to patient through direct contact by health

care providers. Hand hygiene (handwashing or use of alcohol-based hand rub) between patient visits and procedures and the appropriate use of personal protective equipment (PPE) such as gloves remain the first lines of defence in preventing the spread of HAIs. It is important to remember that *C. difficile* is not killed by alcohol-based hand rub. Handwashing with soap and water must be followed in this instance. Isolated infections can be caused when bacteria that are normally present in one area of the body are introduced into another area. Therefore, nurses must take care to change gloves and use hand hygiene when changing tasks, even when working with one patient (PHAC, 2012a).

Age-Related Considerations

Infection in Older Adults

The rate of HAIs is significantly higher among older adults than among younger patients (PHAC, 2013). Individuals in long-term care facilities are at special risk for HAI. Age-related changes (e.g., impaired immune function, comorbid conditions such as diabetes, physical disabilities) can contribute to higher infection rates. HAIs common in older adults include pneumonia, urinary tract infections, skin infections, and TB. Urinary tract infections are more common in older adults who reside in long-term care facilities than in those who live at home. They are often found in patients who have indwelling catheters. Infections in older adults often have atypical manifestations, such as cognitive and behavioural changes, before the emergence of fever, pain, or alterations in laboratory values. Disease should typically be suspected if a patient demonstrates changes in the ability to perform daily activities or in cognitive function. In addition, underlying diseases, increased frequency of drug reactions, and institutionalization can all complicate the management of the older adult with infection.

Safety Alert

Nurses should not rely on the presence of fever to indicate infection in older adults because many have lower core body temperatures and decreased immune responses.

Infection Prevention and Control

Infection Precautions

If a patient develops an infection that is considered a risk to others, infection precautions may be needed. The purpose of these precautions is to prevent the transmission of organisms from patients to health care providers, from health care providers to

patients, and from one patient to another. The Centers for Disease Control and Prevention (CDC) issue isolation precaution guidelines that are used in many health care institutions in Canada and around the world. Health Canada has issued similar recommendations (PHAC, 2012b).

Both sets of guidelines contain two levels of precautions (Table 17-8): *routine practices,* or *standard precautions,* which are designed for the care of all patients in hospitals and health care facilities regardless of their diagnosis or presumed infection status, and *additional precautions,* or *transmission-based precautions,* which are used for patients known to be or suspected of being infected with epidemiologically important pathogens that can be transmitted by airborne or droplet transmission or by contact with dry skin or contaminated surfaces.

TABLE 17-8

SUMMARY OF ROUTINE PRACTICES AND ADDITIONAL PRECAUTIONS FOR PREVENTING THE TRANSMISSION OF INFECTION IN HEALTH CARE

Routine Practices or Standard Precautions	Additional or Transmission-Based Precautions		
	Airborne*	Droplet*	Contact
When to Use			
All patients	Used in addition to routine practices or standard precautions for patients known to be or suspected of being infected with microorganisms transmitted by airborne droplet (e.g., measles, varicella, tuberculosis). Requires negative-pressure room.	Used in addition to routine practices or standard precautions for patients known to be or suspected of being infected with microorganisms transmitted by droplets (e.g., *Haemophilus influenzae, Neisseria meningitidis, Streptococcus pneumoniae, Mycoplasma pneumoniae,* febrile respiratory illness).	Used in addition to routine practices or standard precautions for specified patients known to be or suspected of being infected with epidemiologically important microorganisms that can be transmitted by direct contact with patient or environmental surfaces (e.g., enteric pathogens, multidrug-resistant bacteria, *Clostridium difficile,* herpes simplex).
Hand Hygiene			
Hand hygiene (the removal or killing of microorganisms on the hands) is done either by handwashing or by use of alcohol-based hand rubs. Using alcohol-based hand rubs is more effective than washing hands (even with antibacterial soap) when hands are not visibly soiled. Hand hygiene should be performed (a) before initial patient contact or contact with the patient's environment, (b) before aseptic procedures, (c) after body fluid exposure risk, and (d) after contact with a patient or the patient's environment.	Same as routine practices or standard precautions.	Same as routine practices or standard precautions.	Same as routine practices or standard precautions.
Gloves			

Routine Practices or Standard Precautions	Additional or Transmission-Based Precautions		
	Airborne*	Droplet*	Contact
Nurses wear nonsterile gloves when touching blood, body fluids, secretions, excretions, and contaminated items; they put on clean gloves just before touching mucous membranes and nonintact skin; they remove gloves promptly after use, before touching noncontaminated items, environmental surfaces, or going to another patient.	Same as routine practices or standard precautions.	Same as routine practices or standard precautions.	In addition to glove use as described in routine practices or standard precautions, nurses wear gloves when entering the patient's room and whenever providing direct patient care or having hand contact with potentially contaminated surfaces or items in patient's environment.
Mask, Eye Protection, Face Shield			
Nurses wear mask and eye protection or face shield to protect mucous membranes of eyes, nose, and mouth during procedures and patient care activities likely to generate splashes or sprays of blood, body fluids, secretions, and excretions. These should be worn within 1 m of coughing patient.	In addition to routine practices or standard precautions, nurses wear respiratory protection when entering room of patient known to have or suspected of having tuberculosis. *Note:* Nurses should check the facility's policy for use of respirator.	In addition to routine practices or standard precautions, a mask should be worn.	Same as routine practices or standard precautions.
Gown			
Nurses wear clean, nonsterile gown to protect skin and prevent soiling of clothing during procedures and patient care activities likely to generate splashes or sprays of blood, body fluids, secretions, or excretions or likely to cause soiling of clothing. Gown is removed promptly when tasks are completed; hands are washed.	Same as routine practices or standard precautions.	Same as routine practices or standard precautions.	Clean, nonsterile gown is worn if substantial contact is anticipated with patient, surfaces, or items in environment and if patient is incontinent or has diarrhea, an ileostomy, a colostomy, or uncontained wound drainage. Gown is removed carefully when tasks are completed; hands are washed.
Linen			
Handle, transport, and process used linen in manner that prevents skin and mucous membrane exposure, contamination of clothing, and environmental soiling.	Same as routine practices or standard precautions.	Same as routine practices or standard precautions.	Same as routine practices or standard precautions.

Routine Practices or Standard Precautions	Additional or Transmission-Based Precautions		
	Airborne*	Droplet*	Contact
Patient Transport	Movement and transport of patient from room should be limited to instances of essential purposes only; if transport or movement is necessary, patient dispersal of droplet nuclei is minimized by placement of surgical mask on patient, if possible.	Movement and transport of patient from room should be limited to instances of essential purposes only; if transport or movement is necessary, patient dispersal of droplet nuclei is minimized by placement of surgical mask on patient, if possible.	Movement and transport of patient from room should be limited to instances of essential purposes only; if transport is necessary, precautions are maintained to minimize contamination of environmental surfaces or equipment.

*In the case of certain infections (e.g., chicken pox and disseminated zoster), a combination of airborne and contact transmission precautions may be required. For certain other infections (e.g., influenza and invasive group A streptococci), a combination of droplet and contact precautions is required.

The system of routine practices or standard precautions applies to (a) blood; (b) all body fluids, secretions, and excretions regardless of whether they contain visible blood; (c) nonintact skin; and (d) mucous membranes. Routine practices or standard precautions are designed to reduce the risk of transmission of microorganisms from both recognized and unrecognized sources of infection in hospitals. Routine practices or standard precautions should be applied to all patients regardless of diagnosis or infection status.

Additional or transmission-based precautions are designed for patients suspected of or documented as being infected with highly transmissible or epidemiologically important pathogens for which additional precautions beyond routine practices or standard precautions are needed to interrupt transmission in hospitals. The three types of additional or transmission-based precautions are *airborne precautions, droplet precautions,* and *contact precautions.* They may be used in combination for diseases that have multiple routes of

transmission. When used either by themselves or in combination, these precautions are used in addition to routine practices or standard precautions.

Preventing Occupational Infections in Health Care Workers

In 2002, Health Canada issued updated standards for preventing and controlling occupational infections in health care workers. These standards mandated that any employer whose employees are potentially exposed to blood from needles and other sharps must implement sharps safety devices wherever feasible. Many provinces have implemented mandatory use of safety-engineered needles and needle-free infusion devices. In addition, employees at risk need to be provided with appropriate PPE. Health care workers must minimize or eliminate exposure to infectious material. When that is not possible, appropriate PPE must be selected. These include gloves, clothing, and facial protection (Table 17-9). Appropriate PPE will vary, depending on the situation (PHAC, 2012b).

TABLE 17-9

HEALTH CANADA RECOMMENDATIONS FOR THE USE OF PERSONAL PROTECTIVE EQUIPMENT FOR HEALTH CARE WORKERS

Equipment	Indications for Use
Medical gloves	Should be worn for all procedures that might involve direct skin or mucous membrane contact with blood or fluids capable of transmitting bloodborne pathogens. May also be indicated for other activities (e.g., procedures involving other infectious agents, toxins, or contaminated equipment).
Masks and protective eyewear (e.g., goggles, safety glasses) or face shields	Should be worn to protect mucous membranes, nonintact skin, and conjunctiva during procedures that are likely to generate splashes of blood or fluids capable of transmitting bloodborne pathogens.
Gowns or aprons	Should be worn during procedures that are likely to generate splashes of blood or fluids capable of transmitting bloodborne pathogens. Assessment of the specific risk will determine the type of gown required (e.g., fluid-resistant).

Source: Public Health Agency of Canada (2012). *Routine practices and additional precautions for preventing the transmission of infection in health care settings.* Ottawa: Author. Retrieved from *www.publications.gc.ca/collections/collection_2013/aspc-phac/HP40-83-2013-eng.pdf*.

In the event that a health care worker is exposed to blood or body fluids, as a result of either a needle stick or a mucous membrane splash, the worker should seek immediate medical attention to assess the level of risk for acquiring a bloodborne virus from the incident. If the risk is deemed serious enough to put the worker at risk for acquiring HIV, postexposure prophylaxis is initiated. There is no postexposure prophylaxis for hepatitis C virus. Statistics have been compiled since the early 1990s about the rates of HIV seroconversion in health care workers as a result of an accidental exposure, and in fact, the rates are extremely low; however, cases have been documented, and so it is important for nurses to use routine practices or standard precautions with every patient with whom they come into contact (PHAC, 2012b).

Human Immunodeficiency Virus Infection

The HIV epidemic in Canada and the United States began in the early 1980s. HIV had been circulating in sub-Saharan Africa since the early 1920s (Pepin, 2011), but it was not until 1981 that public health officials documented the presence of a new disease that would become known as the **acquired immunodeficiency syndrome (AIDS).** Interestingly, people had been dying of AIDS in North America for several decades before it was identified. This first documented case in Canada was in 1959. By 1985, the causative agent, HIV, had been identified, and AIDS was determined to be the end stage of chronic HIV infection. In addition, an antibody test was developed and routes of transmission were determined. Drug therapy to treat the infection became available in 1987 with the release of zidovudine (ZDV, azidothymidine [AZT], Retrovir) and has since expanded. Since 1994, several important advances have been made, including the development of laboratory tests to assess the number of HIV particles in the blood **(viral load),** the production of new drugs, combination drug therapy, the ability to test for antiretroviral drug resistance, treatment to decrease the risk of transmission from mother to baby (AIDSinfo, 2016a), and the use of treatment as prevention (Montaner, 2011). In developed countries around the world, these advances have led to decreases in the number of HIV-related deaths, improved quality of life, and decreases in the number of cases of congenital HIV infection. Unfortunately, these advances are not effective or available for all those who need them. Although great progress has been made, the HIV epidemic is not over. There are signs that it is levelling off, with fewer new infections each year, but it continues to take its toll, inasmuch as approximately 7000 people are newly infected every day (United Nations AIDS [UNAIDS], 2015a). Nursing care for patients with HIV infection continues to be a critical need that must change as new findings and treatment advances emerge.

Significance of the Problem

Almost 2.4 million people were living with HIV infection in North America and Western Europe at the end of 2014, with an estimated 85 000 new infections and 26 000 HIV-related deaths that year (UNAIDS, 2015b). Of those living with the infection, 260 000 (25%) were adolescent and adult women, and 11 000 were children younger than age 15. At the end of 2014, Health Canada estimated that approximately 75 500 people in Canada were living with HIV infection (including those living with AIDS) and that approximately 21% were not aware that they were infected (PHAC, 2015d). Although the numbers are increasing, the number of new cases per year is declining. In addition, treatment has provided major advances in the ability to keep HIV-infected people healthy for longer periods, and the death rate has fallen dramatically. Globally, HIV infection has been devastating. Since the beginning of the pandemic, more than 60 million people have been infected, and more than 30 million of those have died (UNAIDS, 2015b). At the end of 2014, an estimated 36.9 million people—including 2.2 million children younger than age 15—were living with HIV infection. During that year, 2.0 million people were newly infected with HIV, and more than 1.8 million died of HIV-related causes (PHAC, 2015b).

The burden of HIV is not evenly distributed. Since the beginning of the epidemic, sub-Saharan Africa has been the most devastated, but Asia, Russia, India, Central America, and South America also have rampant epidemics. In developing countries, the major mode of transmission is through heterosexual sex, and women and children bear a large part of the burden of illness. Industrialized countries have fared better but have not been able to eliminate the infection or provide appropriate care to all HIV-infected individuals. For the most part, HIV infection remains a disease of marginalized individuals: those who are disenfranchised by virtue of sex, race, sexual orientation, poverty, drug use, or lack of access to health care.

Transmission of Human Immunodeficiency Virus

HIV is a fragile virus. It can be transmitted only under specific conditions that allow contact with infected body fluids, including blood, semen, vaginal secretions, and breast milk. HIV is transmitted through sexual intercourse with an infected partner, exposure to HIV-infected blood or blood products, as a result of either contaminated transfusion or needle sharing, and perinatally at the time of delivery or through breastfeeding (CDC, 2015a).

HIV-infected individuals can transmit HIV to others within a few days after becoming infected. After that, the ability to transmit HIV is lifelong. Transmission of HIV is subject to the same requirements as other microorganisms: a large enough amount of the virus must enter the body of a susceptible host. Duration and frequency of contact, volume of fluid, virulence and concentration of the organism, and host immune status all affect whether infection actually occurs after an exposure. The viral load in the blood, the semen, the vaginal secretions, or the breast milk of the "donor" is an important variable. In HIV infection, large amounts of virus can be found in the blood during the first 2 to 6 months after infection and again during the late stages of the disease (Figure 17-1). Unprotected sexual or blood exposure to an infected individual is more risky during these periods, although HIV can be transmitted during all phases of the disease (CDC, 2015a).

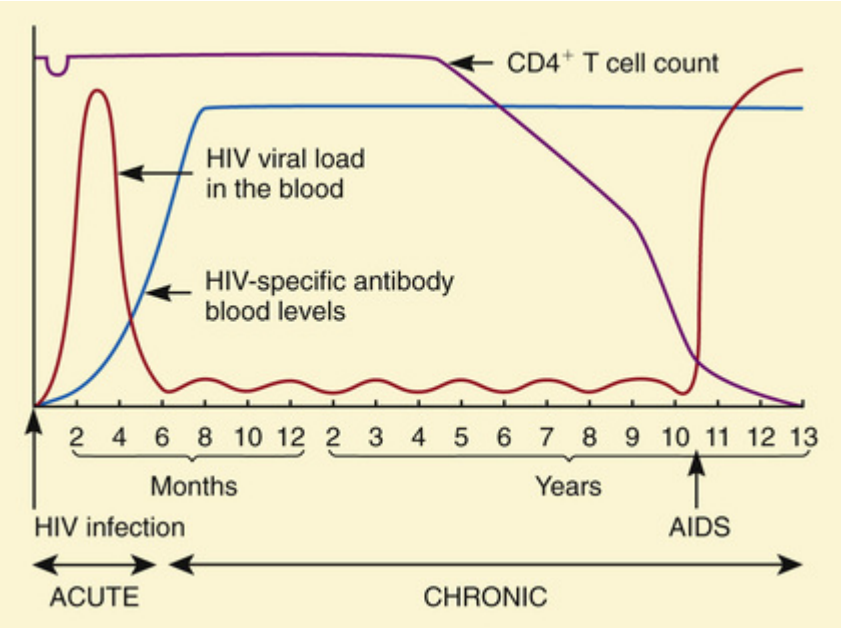

FIGURE 17-1 Viral load in the blood and $CD4^+$ T cell counts across the spectrum of untreated human immunodeficiency virus (HIV) infection. *AIDS*, acquired immune deficiency syndrome.

HIV is not spread casually. The virus cannot be transmitted through hugging, dry kissing, shaking hands, sharing eating utensils, using toilet seats, or attending school or working with an HIV-infected person. It is not transmitted through tears, saliva, urine, emesis, sputum, feces, or sweat. Repeated studies have failed to demonstrate transmission of the virus by respiratory droplets, enteric routes, or casual encounters in any setting. Health care workers have a very low risk of acquiring HIV at work, even after a needle-stick injury (Kuhar, Henderson, Struble, et al., 2013). Should a health care worker become exposed, she or he should follow the hospital policy for reporting needle-stick incidents.

Sexual Transmission

The most common mode of HIV transmission is unprotected sexual contact with an HIV-infected partner. Sexual activity involves contact with semen, vaginal secretions, blood, or a combination of these, all of which have lymphocytes that may contain HIV. During any form of sexual intercourse (anal, vaginal, or oral), the risk of

infection is greater for the partner who receives the semen, although infection can also be transmitted to the inserting partner. This occurs because the receiver has prolonged contact with infected fluids, and it helps explain why it is easier to infect women than men during heterosexual intercourse. Sexual activities that cause trauma to local tissues can increase the risk of transmission. In addition, genital lesions from other sexually transmitted infections (e.g., herpes, syphilis) significantly increase the likelihood of HIV transmission.

Contact With Blood and Blood Products

HIV is transmitted by exposure to contaminated blood through the accidental or intended sharing of injection equipment. Sharing equipment to inject illegal drugs is a major means of transmission in many large metropolitan areas and is becoming more common in smaller cities and rural areas. Once used, equipment used to inject any drug, whether prescribed or not, is contaminated, potentially with HIV, other bloodborne organisms, or both, and sharing that equipment can result in disease transmission.

In Canada, an estimated 1150 individuals were infected with HIV through blood transfusions between 1978 and 1985. In 1985, the practices of routine screening of blood donors to identify at-risk individuals and testing donated blood for the presence of HIV were implemented, which improved the safety of the blood supply. HIV infection as a result of blood transfusions is now rare. In 2001, a new, highly sensitive nucleic acid amplification test (NAAT) was implemented by the Canadian Blood Services to detect HIV genetic material in blood of potential donors. The NAAT has a much shorter **window period**—the time between exposure to HIV infection and when the test yields an accurate result—than does antibody testing and is now the standard test for donated blood in Canada.

Puncture wounds are the most common means of work-related transmission. The risk of infection after a needle-stick exposure to HIV-infected blood is 0.3% to 0.4% (or 3–4 in 1000). The risk is higher if the exposure involves blood from a patient with a high viral load, from a deep puncture wound, from a needle with a hollow bore and visible blood, from a device used for venous or arterial access, or

from a patient who dies within 60 days. Splash exposures of blood on skin with an open lesion present some risk, but it is much lower than from a puncture wound (HIV.gov, 2015; Kuhar, Henderson, Struble, et al., 2013; PHAC, 2016).

Perinatal Transmission

Perinatal transmission from an HIV-infected mother to her infant can occur during pregnancy, delivery, or breastfeeding (CDC, 2015b; PHAC, 2010). On average, 25% of infants born to women with untreated HIV infection are born with HIV. Fortunately, the risk of transmission can be reduced to less than 1% in settings where pregnant women are routinely tested for HIV infection and, if found to be infected, treated with antiretroviral therapy (ART) (Burdge et al., 2003).

Pathophysiology

Human immunodeficiency virus (HIV) is an RNA virus. RNA viruses are called **retroviruses** because they replicate in a "backward" manner (transcribing their RNA and DNA after entering a cell). Like all viruses, HIV cannot replicate unless it is inside a living cell. HIV can enter a cell when the glycoprotein 120 (gp120) "knobs" (Figure 17-2) on the viral envelope bind to specific CD4 receptor sites and CCR5 and CXCR4 co-receptor sites on the cell's surface (Figure 17-3). Once bound, viral genetic material enters the cell. In the cell, viral RNA is transcribed into a double strand of viral DNA with the assistance of **reverse transcriptase,** an enzyme made by HIV and other retroviruses. At this point, viral DNA can enter the cell's nucleus and, using an enzyme called integrase, splice itself into the genome, becoming a permanent part of the cell's genetic structure. There are two consequences of this action: (a) because all genetic material is replicated during cellular division, all daughter cells from the infected cell will also be infected; and (b) because the genome now contains viral DNA, the cell's genetic codes can direct the cell to make HIV. Production of HIV within the cell is a complicated process that results in long strands of HIV RNA.

These are cut into appropriate lengths with the assistance of the enzyme protease during the budding sequence (AIDSinfo, 2016b).

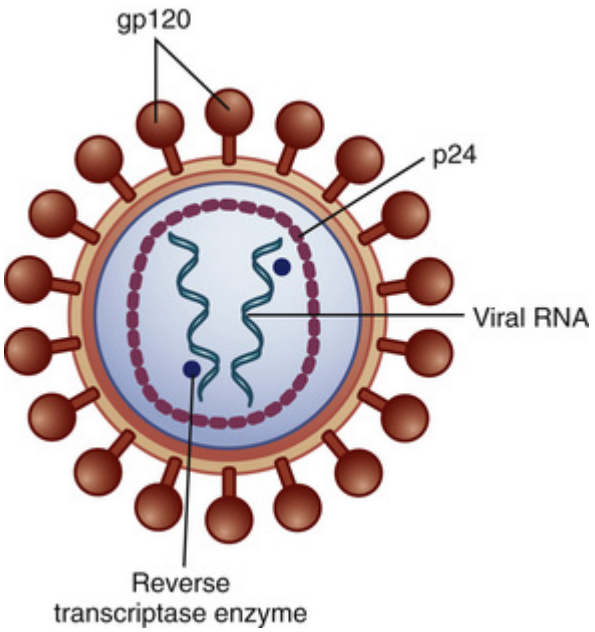

FIGURE 17-2 The human immunodeficiency virus (HIV) is surrounded by an envelope made up of proteins (including glycoprotein 120 [gp120]) and contains a core of viral RNA and proteins (including p24).

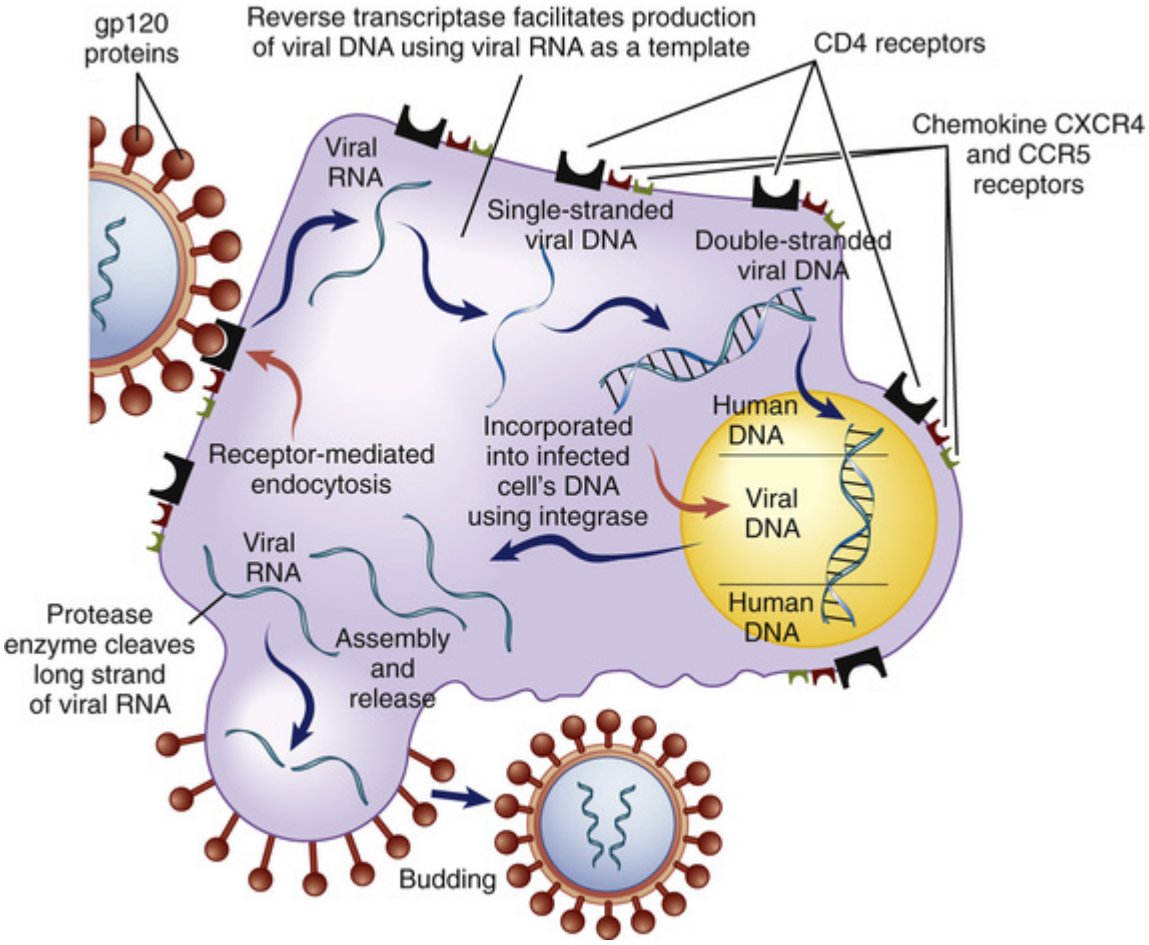

FIGURE 17-3 The human immunodeficiency virus (HIV) has glycoprotein 120 (gp120) that attaches to CD4 and chemokine CXCR4 and CCR5 receptors on the surface of $CD4^+$ T cells. Viral RNA then enters the cell, produces viral DNA in the presence of reverse transcriptase, and incorporates itself into the cellular genome in the presence of integrase, causing permanent cellular infection and the production of new virions. New viral RNA develops initially in long strands that are cut in the presence of protease and leave the cell through a budding process that ultimately contributes to cellular destruction.

Initial infection with HIV results in **viremia** (large amounts of virus in the blood). This is followed within a few weeks by a prolonged period during which HIV levels in the blood remain low even without treatment (see Figure 17-1). During this time, which may last for 10 to 12 years, there are few clinical symptoms. It was initially thought that this phase represented a latency period during

which very little viral activity occurred. It is now known that HIV replication occurs at rapid and constant rates in the blood and lymph tissues from early in the infection. A steady-state viral load can be maintained in the body of infected individuals for many years. To do this, 108 to 109 new viruses are produced each day. A major consequence of rapid replication is that errors can occur in the copying process, causing mutations that can contribute to resistance to ART and limit treatment options.

In a normal immune response, foreign antigens interact with B cells and T cells. In the initial stages of HIV infection, these cells respond and function normally. B cells make HIV-specific antibodies that are effective in reducing viral loads in the blood, and activated T cells mount a cellular immune response to viruses trapped in the lymph nodes (AIDSinfo, 2016b).

HIV infects human cells whose surfaces have CD4 receptors. These cells include lymphocytes, monocytes and macrophages, astrocytes, and oligodendrocytes. Immune dysfunction in HIV disease is caused predominantly by damage to and destruction of $CD4^+$ T cells (also known as T helper cells or $CD4^+$ T lymphocytes). These cells are targeted because they have more CD4 receptors on their surfaces than do other CD4 receptor–bearing cells. This is unfortunate because $CD4^+$ T cells play a key role in the ability of the immune system to recognize and defend against pathogens.

Adults without immune dysfunction normally have 800 to 1200 $CD4^+$ T cells per microlitre of blood. The normal life span of a $CD4^+$ T cell is about 100 days, but HIV-infected $CD4^+$ T cells die after an average of only 2 days. The compromise of the immune system is also caused by the chronic state of immune activation that is a result of HIV infection. This activation leads to elevated levels of inflammatory markers and destruction of T helper cells (Wasserman, Segal-Maurer, Wehbeh, et al., 2011).

Viral activity destroys about 1 billion $CD4^+$ T cells every day. Fortunately, the bone marrow and the thymus are able to produce enough $CD4^+$ T cells to replace the destroyed cells for many years. Eventually, however, the ability of HIV to destroy $CD4^+$ T cells exceeds the body's ability to replace the cells. The result is a decline in the $CD4^+$ T-cell count and a decrease in immune capability. In

general, the immune system remains healthy with more than 500 $CD4^+$ T cells per microlitre. Immune problems start to occur when the count drops below this number. Severe problems develop with fewer than 200 $CD4^+$ T cells per microlitre and a CD4 fraction of less than 15%. Eventually in HIV infection, so many $CD4^+$ T cells are destroyed that not enough remain to regulate immune responses (see Figure 17-1). The major concern related to immune suppression is the development of **opportunistic diseases** (infections and cancers that occur in immuno-suppressed patients that can lead to disability, disease, and death).

Clinical Manifestations and Complications

The typical course of untreated HIV infection follows the pattern shown in Figure 17-4. However, it is important to remember that HIV is highly individualized. The information depicted in Figure 17-4 represents data from large groups of people and should not be used to predict an individual's lifespan after HIV infection.

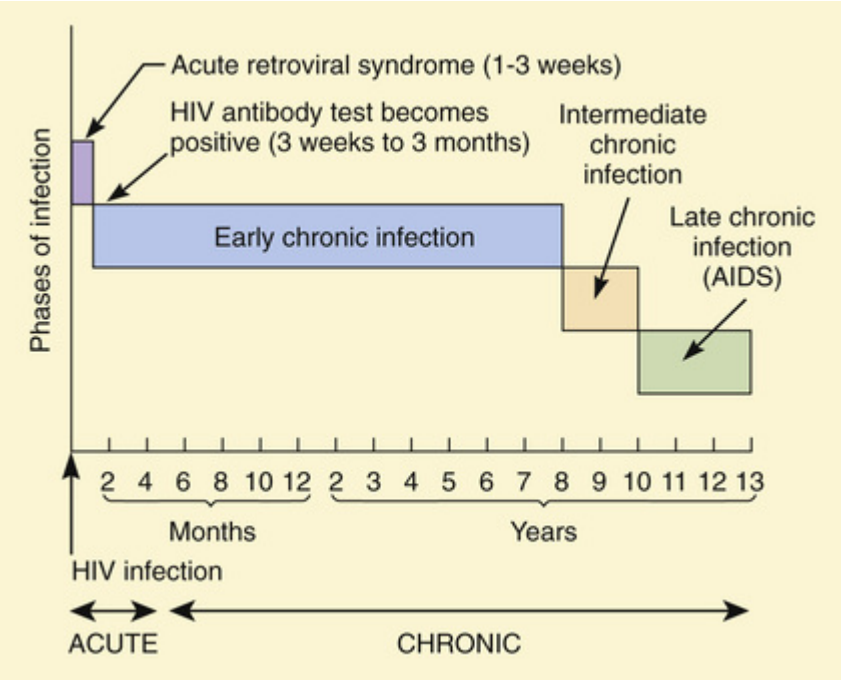

FIGURE 17-4 Timeline for the spectrum of untreated human immunodeficiency virus (HIV) infection. The timeline represents the course of the illness from the time of infection to the clinical manifestations of disease. *AIDS*, acquired immune deficiency syndrome.

Acute Infection

Development of HIV-specific antibodies *(seroconversion)* is frequently accompanied by a flulike syndrome of fever, swollen lymph glands, sore throat, headache, malaise, nausea, muscle and joint pain, diarrhea, or a diffuse rash, or a combination of these. These symptoms, called **acute retroviral syndrome**, generally occur 1 to 3 weeks after the initial infection and last for 1 to 2 weeks, although some of the symptoms may continue for several months. During this time, a high level of HIV in the blood is noted, and $CD4^+$ T-cell counts fall temporarily but quickly return to baseline (see Figure 17-1). In most infected people, acute retroviral symptoms are moderate and may be mistaken for a cold or flu. In some infected people, neurological complications, such as aseptic meningitis, peripheral neuropathy, facial palsy, or Guillain-Barré syndrome, have developed (Smith, Rutstein, Powers, et al., 2013).

Chronic Infection

Early Chronic Infection.

The median interval between untreated HIV infection and a diagnosis of AIDS is about 10 years. During this time, $CD4^+$ T-lymphocyte counts remain above 500 cells per microlitre (normal) or slightly decreased, and the viral load in the blood remains low. This phase has been referred to as *asymptomatic disease,* but fatigue, headache, low-grade fever, night sweats, persistent generalized lymphadenopathy, and other symptoms often occur.

Because most of the symptoms during early infection are vague and nonspecific for HIV, people with HIV infection may not be aware that they are infected. According to the PHAC (2015d), approximately 21% of individuals infected with HIV are estimated to be unaware of their status. During this time, infected people continue activities that may include high-risk sexual and drug-using behaviours, which creates a public health problem because infected people can transmit HIV to others even if they have no symptoms. Personal health is also affected because people who do not know they are infected have no motivation to seek treatment or to make changes in health habits that could beneficially alter the quality and quantity of their lives.

Intermediate Chronic Infection.

When the $CD4^+$ T-cell count drops below 500 cells per microlitre (as low as 200 cells per microlitre), the viral load rises, and HIV infection advances to a more active stage. Symptoms and signs that occurred in earlier phases tend to become worse, manifesting as persistent fever, frequent drenching night sweats, chronic diarrhea, recurrent headaches, and fatigue severe enough to interrupt normal routines. Other problems that may occur at this time include localized infections, lymphadenopathy, and nervous system manifestations.

The most common infection associated with this phase of HIV disease is oropharyngeal candidiasis, or thrush (Figure 17-5). *Candida* organisms rarely cause problems in healthy adults, but such problems do occur in most HIV-infected people at some time. Other infections that can occur at this time include shingles (caused by the

varicella-zoster virus), persistent vaginal candidal infections, outbreaks of oral or genital herpes, bacterial infections, and Kaposi's sarcoma (Figure 17-6). **Oral hairy leukoplakia,** an Epstein-Barr virus infection that causes painless, white, raised lesions on the lateral aspect of the tongue, can also occur (Figure 17-7). Oral lesions may provide the earliest indication of HIV infection.

FIGURE 17-5 Oral thrush involving the hard and soft palate surfaces. Source: Emond, R., Welsby, P., & Rowland, H. (2003). *Colour atlas of infectious diseases* (4th ed.). Edinburgh: Mosby.

FIGURE 17-6 **Kaposi's sarcoma: malignant vascular lesion on the torso. The lesions can appear anywhere on the skin surface and on internal organs. Lesions vary in size from pinpoint to very large (several centimetres) and may appear in a variety of shades. Source: Courtesy of Jeffrey Kwong.**

FIGURE 17-7 Oral hairy leukoplakia on the lateral aspect of the tongue. Source: Set of slides published in 1992 by Jon Fuller, MD, and Howard Libman, MD, at Boston University School of Medicine, Boston.

Late Chronic Infection or Acquired Immune Deficiency Syndrome.

A diagnosis of AIDS cannot be made until the HIV-infected patient meets the criteria established by the WHO (2007).

These criteria (Table 17-10) are more likely to occur when the immune system becomes severely compromised. As the viral load increases, the absolute number and percentage of T cells decrease and the risk of developing opportunistic diseases increases.

TABLE 17-10
DIAGNOSTIC CRITERIA FOR AIDS

AIDS is diagnosed when an individual with HIV infection develops at least one of these conditions:

- Atypical disseminated leishmaniasis
- Central nervous system toxoplasmosis
- Chronic cryptosporidiosis
- Chronic herpes simplex virus infection
- Chronic isosporiasis
- Cytomegalovirus disease (other than liver, spleen, or lymph nodes)
- Disseminated mycosis (coccidiomycosis or histoplasmosis)
- Disseminated nontuberculous mycobacterial infection
- Esophageal candidiasis
- Extrapulmonary cryptococcosis (including meningitis)
- Extrapulmonary tuberculosis
- HIV encephalopathy
- HIV wasting syndrome (*wasting* is defined as a loss of 10% or more of ideal body mass)
- Invasive cervical carcinoma
- Kaposi's sarcoma
- Lymphoma (cerebral or B-cell non-Hodgkin's)
- *Pneumocystis* pneumonia
- Progressive multifocal leukoencephalopathy
- Recurrent bacterial pneumonia
- Recurrent nontyphoid *Salmonella* bacteremia
- Symptomatic HIV-associated cardiomyopathy
- Symptomatic HIV-associated nephropathy

AIDS, acquired immune deficiency syndrome; *HIV*, human immunodeficiency virus.

Source: World Health Organization. (2007). *WHO case definitions of HIV for surveillance and revised clinical staging and immunological classification of HIV-related disease in adults and children.* Geneva: Author. Retrieved from *http://www.who.int/hiv/pub/guidelines/HIVstaging150307.pdf*.

Opportunistic diseases, often reactivations of a prior infection, generally do not occur in the presence of a functioning immune system. Numerous infections, a variety of malignancies, wasting, and dementia can result from HIV-related immune impairment (Table 17-11). Organisms that do not usually cause disease in people with functioning immune systems can cause severe, debilitating, disseminated, and life-threatening infections during this stage.

Several opportunistic diseases are likely to occur at the same time, further compounding the difficulties of diagnosis and treatment. Advances in HIV treatment have led to significant decreases in opportunistic diseases because successful treatment helps maintain the immune system's function.

TABLE 17-11

DRUG THERAPY
Manifestations and Treatment of Common Opportunistic Diseases Associated With HIV Infection

Organism and Disease	Clinical Manifestations	Prophylaxis* and Treatment†
Candida albicans	Thrush, esophagitis, vaginitis; whitish yellow patches in mouth, esophagus, GI tract, vagina	Treatment: fluconazole (Diflucan), clotrimazole, nystatin, itraconazole (Sporanox); if infection is resistant to fluconazole: amphotericin B (Fungizone) Secondary prophylaxis (only if subsequent episodes are frequent or severe recurrences): fluconazole (Diflucan), itraconazole (Sporanox)
Castleman's disease (caused by HHV-8)	Generalized malaise, night sweats, rigors, fever, anorexia, weight loss Eventually lymphadenopathy, hepatosplenomegaly, ascites, edema, pulmonary and pericardial effusions	Treatment: antivirals such as IV ganciclovir (Cytovene) or oral valganciclovir (Valcyte) Chemotherapy, either single drug or combined: the CHOP protocol is most recommended
Cervical cancer	Cancerous lesions in the cervix Vaginal bleeding, pain during intercourse	Surgical excision of the cancerous lesion Chemotherapy Radiotherapy
Coccidioides immitis	Pneumonia: fever, weight loss, cough	Treatment: amphotericin B (Fungizone), fluconazole (Diflucan), itraconazole (Sporanox) Secondary prophylaxis (to prevent recurrence of documented disease): fluconazole (Diflucan), amphotericin B (Fungizone), itraconazole (Sporanox)
CNS lymphoma	Cognitive dysfunction, motor impairment, aphasia, seizures, personality changes, headache	Treatment: radiation, chemotherapy
Cryptococcus neoformans	Meningitis, cognitive impairment, motor dysfunction, fever, seizures, headache	Treatment: amphotericin B (Fungizone), fluconazole (Diflucan), itraconazole (Sporanox) Secondary prophylaxis (to prevent recurrence of documented disease): fluconazole (Diflucan), amphotericin B (Fungizone), itraconazole (Sporanox) Therapeutic lumbar punctures to reduce intracranial pressure
Cryptosporidium muris	Gastro-enteritis, watery diarrhea, abdominal pain, weight loss	Treatment: antidiarrheals, nitazoxanide (Alinia), paromomycin (Humatin)

Organism and Disease	Clinical Manifestations	Prophylaxis* and Treatment†
CMV	Retinitis: retinal lesions, blurred vision, loss of vision Esophagitis, stomatitis: difficulty swallowing; colitis, gastritis: bloody diarrhea, pain, weight loss Pneumonitis: respiratory symptoms Neurological disease: CNS manifestations	Treatment: ganciclovir (Cytovene), foscarnet (Foscavir), cidofovir (Vistide), valganciclovir (Valcyte) Secondary prophylaxis (to prevent recurrence of documented disease): ganciclovir (Cytovene), foscarnet (Foscavir), cidofovir (Vistide), valganciclovir (Valcyte)
Hepatitis B virus (HBV)	Jaundice, fatigue, abdominal pain, loss of appetite, nausea, vomiting, joint pain; 30% of affected patients may have no signs or symptoms	Primary prevention: HBV vaccine series; screening and vaccination of people with no evidence of previous HBV infection; encouragement of patients to reveal injection drug use, whether they are sexually active men who have sex with men, sexual partners or household contacts of HBV-infected individuals, and those with HCV; HAV vaccine series should be given to prevent additive effects and advanced liver damage; screening and vaccination of people without evidence of previous HAV infection Treatment: adefovir dipivoxil (Hepsera), α-interferon, lamivudine (3TC), entecavir (Baraclude)
hepatitis C virus (HCV)	Jaundice, fatigue, abdominal pain, loss of appetite, nausea, vomiting, dark urine; 80% may have no signs or symptoms	Prophylaxis: none for HCV; HAV and HBV vaccines series should be given to prevent additive effects and advanced liver damage; screening and vaccination of people without evidence of previous HAV or HBV infection Treatment: α-interferon, ribavirin (Virazole), boceprevir (Victrelis)
Herpes simplex virus (HSV)	Type 1 (HSV1): orolabial and mucocutaneous vesicular and ulcerative lesions; keratitis: visual disturbances; encephalitis: CNS manifestations Type 2 (HSV2): genital and perianal vesicular and ulcerative lesions	Treatment: acyclovir (Zovirax), famciclovir (Famvir), valacyclovir (Valtrex), foscarnet (Foscavir), cidofovir (Vistide) Secondary prophylaxis (only if subsequent episodes are frequent or severe): acyclovir (Zovirax), famciclovir (Famvir), valacyclovir (Valtrex)
Histoplasma capsulatum	Pneumonia: fever, cough, weight loss Meningitis: CNS manifestations; disseminated disease	Treatment: amphotericin B (Fungizone), itraconazole (Sporanox), fluconazole (Diflucan) Secondary prophylaxis (to prevent recurrence of documented disease): itraconazole (Sporanox), amphotericin B (Fungizone)
Influenza virus	Fever (usually high, 38°C–40°C), headache, extreme tiredness, dry cough, sore throat, runny or stuffy nose, muscle aches; nausea, vomiting, and diarrhea can occur	Primary prevention: inactivated trivalent influenza virus vaccine; provided annually, before influenza virus season; revaccination if initial vaccine was given when $CD4^+$ T cell count was <200/mcL Treatment: supportive therapy

Organism and Disease	Clinical Manifestations	Prophylaxis* and Treatment†
JC papovavirus	Progressive multifocal leukoencephalopathy, CNS manifestations, mental and motor declines	Treatment: supportive therapy
Kaposi's sarcoma (caused by HHV-8)	Vascular lesions on the skin, mucous membranes, and viscera, with wide range of presentation: firm, flat, raised, or nodular; pinpoint to several centimetres in size; hyperpigmented, multicentric; can cause lymphedema and disfigurement, particularly when confluent; not usually serious unless it occurs in the respiratory or GI systems	Treatment (dependent on severity of lesions): cancer chemotherapy, α-interferon, local irradiation; cryotherapy for skin lesions
Mycobacterium avium complex	Gastro-enteritis, watery diarrhea, weight loss	Primary prophylaxis (initiate when $CD4^+$ T cell count is <50/mcL): clarithromycin (Biaxin) or azithromycin (Zithromax), rifabutin (Mycobutin). Prophylaxis may be stopped when $CD4^+$ T cell count of >100/mcL is documented for 6–12 mo; restarted if $CD4^+$ T cell count falls to <50/mcL. Disseminated disease or TB must be ruled out. Treatment: clarithromycin (Biaxin), ethambutol (Etibi), rifabutin (Mycobutin), azithromycin (Zithromax), ciprofloxacin (Cipro), levofloxacin (Levaquin), amikacin
Multicentric Castleman's disease (caused by HHV-8)	Fever, anemia, elevated C-reactive protein levels, widespread lymphadenopathy, weight loss, respiratory symptoms, edema, pulmonary and pericardial effusions and splenomegaly	Treatment: gancyclovir (Cytovene), systemic chemotherapy (CHOP) and rituximab (Rituxan)
Mycobacterium tuberculosis	Respiratory and disseminated disease; productive cough, fever, night sweats, weight loss	See Chapter 30 (first-line drug therapy for TB; [see Table 30.6], drug regimen options for treatment of TB [see Table 30.7])
Pneumocystis jiroveci pneumonia	Pneumonia, nonproductive cough, hypoxemia, progressive shortness of breath, fever, night sweats, fatigue	Primary prophylaxis: initiate when $CD4^+$ T cell count is <200/mcL: TMP/SMX (Septra), dapsone, dapsone with pyrimethamine, folinic acid, aerosolized pentamidine, atovaquone (Mepron). Adverse effects of TMP/SMX and dapsone (especially rash, fever, and anemia) are common and may limit use. Treatment: TMP/SMX, pentamidine, dapsone, trimethoprim, clindamycin, primaquine, atovaquone (Mepron); with hypoxia, use corticosteroids
Toxoplasma gondii	Encephalitis, cognitive dysfunction, motor impairment, fever, altered mental status, headache, seizures, sensory abnormalities	Primary prophylaxis: (1) TMP/SMX *or* (2) dapsone + pyrimethamine + leukovorin *or* (3) atovaquone ± pyrimethamine + leukovorin Treatment: (1) sulphadiazine *or* (2) clindamycin + pyrimethamine + leukovorin *or* (3) atovaquone + pyrimethamine + leukovorin *or* (4) azithromycin + pyrimethamine + leukovorin

Organism and Disease	Clinical Manifestations	Prophylaxis* and Treatment†
Varicella-zoster virus (VZV)	Shingles: erythematous maculopapular rash along dermatomal planes, pain, pruritus Ocular: progressive outer retinal necrosis	Primary prophylaxis: varicella-zoster immune globulin administered only after significant exposure to chicken pox or shingles for patients with no history of disease or negative result of VZV antibody test Treatment: acyclovir (Zovirax), famciclovir (Famvir), valacyclovir (Valtrex)

*If available. In most cases, effective antiretroviral therapy is the best prevention for all opportunistic diseases.

†In most cases, adequate antiretroviral therapy is the best treatment for all opportunistic diseases.

CHOP, cyclophosphamide, hydroxydaunomycin, Oncovin, prednisone; *CMV,* cytomegalovirus; *CNS,* central nervous system; *GI,* gastro-intestinal; *HAV,* hepatitis A virus; *HHV-8,* human herpesvirus 8; *HIV,* human immunodeficiency virus; *IgG,* immunoglobulin G; IV, intravenous; *JC,* "John Cunningham" virus; *TB,* tuberculosis; *TMP/SMX,* trimethoprim-sulphamethoxazole.

Diagnostic Studies

Diagnosis of Human Immunodeficiency Virus Infection

The most useful screening tests for HIV are those that detect HIV-specific antibodies. The major problem with these tests is that there is a median delay of 2 months after infection before antibodies can be detected (see Figure 17-1). However, there is a newer test, the fourth-generation enzyme immunoassay (EIA), which combines antibody detection with p24 antigen. This test has a shorter window period. The window period is concerning because in an infected individual, an HIV antibody test will not yield positive results during this time, even though the individual is infected. HIV-antibody screening is generally done in the sequence shown in Table 17-12. This process produces highly accurate results. New "rapid"

HIV-antibody tests provide results in 20 minutes. Rapid testing is highly reliable and provides immediate feedback to patients, who can then be counselled about treatment and prevention. Positive rapid tests must be confirmed as described in Table 17-12, but results can be given to the patient as soon as they are available. This is an important advantage because many people do not return to get their test results, which is necessary when other tests are used.

TABLE 17-12
HIV-ANTIBODY TEST SCREENING PROCESS

All HIV testing should be accompanied by pretest and post-test counselling. The following additional steps are used in the process of testing blood for antibodies to HIV:

1. A highly sensitive EIA is performed to detect serum antibodies that bind to HIV antigens on test plates. Blood samples with negative findings on this test are reported as negative. The EIA testing can be done either with a conventional blood sample or with a rapid point-of-care test.
    - Post-test counselling should include an assessment of risk behaviours and especially seek to identify recent risks.
    - If recent risks are identified, patient should be encouraged to undergo retesting 3 weeks, 6 weeks, and 3 months later.
2. If the EIA of the blood shows positive findings, the test is repeated.
3. If the findings of the EIA of the blood are repeatedly positive, a more specific confirming test, such as the WB or IFA, is done.
    - WB testing involves the use of gel electrophoresis on purified HIV antigens. These are incubated with serum samples. If antibody in the serum is present, it can be detected.
    - IFA is used to identify HIV in infected cells. Blood is treated with a fluorescent antibody against p17 or p24 antigen and then examined under a fluorescent microscope.
4. Blood that is reactive in all of the first three steps is reported as positive for HIV antibodies.
5. If the results are inconclusive, the following steps are taken:
    - If in-depth risk assessment reveals that the individual does not have a history of high-risk activities, reassure the patient that he or she is extremely unlikely to be infected with HIV, and suggest retesting in 3 months.
    - If in-depth risk assessment reveals that the individual does have a history of high-risk activities, repeat antibody test at 1, 2, and 6 months; discuss harm reduction measures to protect partners from infection; consider tests for HIV-antigen detection such as an NAAT.

EIA, enzyme immunoassay; *HIV*, human immunodeficiency virus; *IFA*, immunofluorescence assay; *NAAT*, nucleic antigen amplification test; *WB*, Western blot.

Laboratory Studies in Human Immunodeficiency Virus Infection

The progression of HIV infection is monitored by two tests: $CD4^+$ T-cell counts and CD4 fraction. As the disease progresses, there is usually a decrease in the number of $CD4^+$ T cells, a marker for

decreased immune function (see Figure 17-1). However, $CD4^+$ T-cell counts, although extremely important, reveal only part of the clinical picture because even in uninfected people, CD4 counts vary greatly from day to day, which makes accurate assessment of immune status difficult. In contrast, CD4 fraction is a stable number for most people, with a normal range of 27% to 60%. A CD4 fraction of less than 15% is associated with immune compromise. Laboratory tests that measure viral activity also allow a better assessment of clinical status and disease progression. Viral load (also referred to as *viral burden*) is the number of viral particles in a sample of blood. Viral loads can be determined with HIV RNA polymerase chain reaction (PCR) or branched-chain DNA (bDNA) tests. Viral load is reported either as less than 40 copies per millilitre, as a definitive number between 40 and 10 million, or as more than 10 million. These tests provide information that helps determine when to initiate therapy, the efficacy of therapy, and whether clinical goals are being met.

Various abnormal results of laboratory tests of the blood are common in untreated HIV infection and may be caused by HIV, opportunistic diseases, or complications of drug or radiation therapy. The white blood cell count is often decreased, especially neutrophil counts (neutropenia); low platelet counts (thrombocytopenia) may be caused by antiplatelet antibodies or drug therapy; and anemia is associated with the chronic disease process, as well as with common adverse effects of some of the antiretroviral agents. Altered results of liver function tests are common. These may be caused by disease processes or drug therapy and may be more common with newer drug therapy. Co-infection with hepatitis B virus (HBV) or hepatitis C virus must be identified early because these infections may have a more serious course in a patient with HIV infection and may ultimately limit options for ART (Gunthard, Aberg, Eron, et al., 2014).

It is now possible to test for resistance to antiretroviral drugs in people being treated for HIV infection. Two types of assays are used: genotype and phenotype. The genotype assay detects drug-resistant viral mutations that are present in the reverse transcriptase and protease genes. The phenotype assay is a measure of the growth of the virus in various concentrations of antiretroviral drugs (much like

bacteria–antibiotic sensitivity tests). These assays are especially useful in making decisions about new drug combinations in patients who are not responding to their current therapies. Genotyping is usually done before the patient starts his or her first treatment regimen because it is possible to acquire resistant virus. The PHAC (2015c) estimated that approximately 9.8% of infected individuals have resistant virus at the time of infection.

Another test that is frequently done before patients begin ART is a human leukocyte antigen (HLA) B5701 antigen test. If this test result is positive, the patient will probably have a hypersensitivity to abacavir (Ziagen), one of the nucleoside reverse transcriptase inhibitors.

A test that may be performed is therapeutic drug monitoring. This test is indicated for patients who continue to have replicating virus in the presence of ART without evidence of nonadherence. It reveals whether the patient is effectively metabolizing her or his ART regimen and has a therapeutic level of drug in her or his system.

Collaborative Care

Collaborative management of the HIV-infected patient focuses on monitoring HIV disease progression and immune function, initiating and monitoring ART, preventing the development of opportunistic diseases, detecting and treating opportunistic diseases, managing symptoms, and preventing or decreasing the complications of treatment. Ongoing assessment and health care provider–patient interactions are required to accomplish these objectives.

The initial visit provides an opportunity to gather baseline data and to establish rapport. A complete history and physical examination, including an immunization history and psychosocial and dietary evaluations, should be conducted. Findings from the history, assessment, and laboratory tests help determine the patient's needs. This is a good time to initiate patient education related to the spectrum of HIV disease, treatment, preventing transmission to others, improving health, and family planning. Patient input should be used to develop a plan of care, and necessary referrals can be made. Of importance is that a patient with newly diagnosed

infection may be in a state of shock or denial and be unable to understand or retain information. The nurse should be prepared to repeat and clarify information over the course of several months. If case reports are required by the public health department, they should be completed at this time.

Drug Therapy for Human Immunodeficiency Virus Infection

The goals of drug therapy in HIV infection are to (a) decrease the viral load, (b) maintain or raise $CD4^+$ T-cell counts, (c) delay the development of HIV-related symptoms and opportunistic diseases, and (d) prevent transmission. Guidelines on the use of antiretroviral agents are updated regularly (Gunthard, Aberg, Eron, et al., 2014). HIV treatment guidelines incorporate the use of the following principles:

1. Treatment decisions should be individualized by risk for disease progression, indicated by higher viral loads and lower $CD4^+$ T-cell counts and by a patient's desires for therapy.
2. Combination ART suppresses HIV replication and limits the potential for antiretroviral resistance, which is the major factor that limits treatment effect. The most effective means to suppress HIV replication is simultaneous initiation of at least three effective antiretroviral drugs from at least two different drug classes in optimum schedules and full dosages. In general, therapy begins with two nucleoside (or nucleotide) reverse transcriptase inhibitors and a nonnucleoside reverse transcriptase inhibitor or a protease inhibitor that is boosted with ritonavir. The nucleosides and nucleotides are considered the foundation of ART.
3. Infected women should receive optimal ART even if pregnant.
4. HIV-infected persons, even those with viral loads below detectable limits and those receiving effective ART, should be considered infectious and should avoid behaviours

associated with transmission of HIV and other infectious pathogens. There is evidence, however, that the risk of HIV transmission decreases with lower viral loads. There is an increasing acceptance of the need to start ART at a higher $CD4^+$ T-cell count because it has become clear that a suppressed viral load leads to significantly lower infectivity (Montaner, 2011).

Recommendations for starting therapy in the chronically infected patient are summarized in Table 17-13.

TABLE 17-13

DRUG THERAPY
Recommendations for Initiating Antiretroviral Therapy in Treatment-Naive Adults With Established HIV-1 Infection*

Measure	Recommendation (Rating)
Symptomatic HIV disease	Treatment is recommended regardless of $CD4^+$ T cell count. The strength of the recommendation increases as the $CD4^+$ T cell count decreases and in the presence of certain conditions.
Asymptomatic HIV disease	
• $CD4^+$ T cell count <500 microlitres	Antiretroviral therapy recommended
• $CD4^+$ T cell count ≥500 microlitres†	Antiretroviral therapy recommended
Pregnant women	Treatment recommended
HIV RNA load >100,000 copies/mL	Treatment recommended
Rapid decline in $CD4^+$ T cell count of >100 mcL/yr	Treatment recommended
Active hepatitis B or C co-infection	Treatment recommended
Active or high risk for cardiovascular disease	Treatment recommended
HIV-associated nephropathy	Treatment recommended
Symptomatic primary HIV infection	Treatment recommended
High risk for secondary transmission (e.g., serodiscordant couples)	Treatment recommended

*In nonpregnant adults only. For all individuals, regardless of whether they are receiving treatment, intensive counselling to prevent secondary transmission is recommended.

†Considerations include high viral load (>100,000 HIV RNA copies/mL), rapid decline in $CD4^+$ T cell count (>100/mcL/yr), high risk of cardiovascular disease, active hepatitis B or C co-infections, or presence of HIV-associated nephropathy.

ART, antiretroviral therapy; *HIV,* human immunodeficiency virus.

Source: Gunthard, Aberg, Eron, et al. (2014). Antiretroviral treatment of adult HIV infection: 2014 Recommendations of the International AIDS Society—USA panel. *Journal of the American Medical Association, 304*(3), 321–333.

Currently approved drugs include four groups that inhibit the ability of HIV to make a DNA copy early in replication, one group that inhibits the ability of the virus to reproduce in the late stages of

replication, and one group that prevents entry of HIV into the cell (Table 17-14). *Nucleoside reverse transcriptase inhibitors, nonnucleoside reverse transcriptase inhibitors* (NNRTIs), and *nucleotide reverse transcriptase inhibitors* work by inhibiting the activity of reverse transcriptase; *protease inhibitors* work by interfering with the activity of the enzyme protease, and *integrase inhibitors* work by interfering with the enzyme integrase. *Fusion inhibitors* (entry inhibitors) work by inhibiting the binding of HIV to cells. A major problem with most drugs used in ART is that resistance develops rapidly when they are used alone or taken in inadequate doses. For that reason, combinations of three or more antiretroviral drugs, prescribed at full strength, should be used. Protease inhibitors and NNRTIs also have a number of dangerous and potentially lethal interactions with other commonly used drugs, including over-the-counter drugs and herbal therapies. For example, St. John's wort can interfere with ART by lowering the blood levels of protease inhibitors and non-nucleoside reverse transcriptase inhibitors (AIDS InfoNet, 2014). Some herbs (e.g., echinacea, astragalus) should not be used because they can enhance the replication of HIV.

TABLE 17-14

DRUG THERAPY
Mechanisms of Action of Drugs Used to Treat HIV Infection

Drug Classification	Mechanism of Action
Nonnucleoside reverse transcriptase inhibitors	Combine with reverse transcriptase enzyme to block the process needed to convert HIV RNA into HIV DNA
Nucleoside reverse transcriptase inhibitors	Insert a bit of protein (a nucleoside) into the developing HIV DNA chain, blocking further development of the chain and leaving the production of the new strand of HIV DNA incomplete
Nucleotide reverse transcriptase inhibitors	Inhibit the action of reverse transcriptase
Protease inhibitors	Prevent the protease enzyme from cutting HIV proteins into the proper lengths needed to allow viable virions to assemble and bud out from the cell membrane
Integrase inhibitors	Prevents viral DNA integration into the $CD4^+$ cell chromosome
Fusion inhibitors (entry inhibitors)	Prevent binding of HIV to cells, thus preventing entry of HIV into healthy cells

HIV, human immunodeficiency virus; *RNA*, ribonucleic acid.

Treatment protocols can reduce viral loads by 90% to 99% in most cases, but adverse effects and other problems are common (Gunthard, Aberg, Eron, et al., 2014). Antiretroviral agents used in HIV infection and their adverse effects are detailed in Table 17-15. Some patients are not able to use combination therapies because of the expense, adverse effects, or inability to adhere to required schedules.

TABLE 17-15
DRUG THERAPY
Antiretroviral Agents Used to Treat HIV Infection*†

Drug	Adverse Effects
Nucleoside reverse transcriptase inhibitors	Common adverse effects: Lactic acidosis with hepatic steatosis, a rare but potentially life-threatening problem; lipodystrophy, especially fat atrophy and mitochondrial toxicity
• Abacavir (Ziagen)	Nausea; hypersensitivity reaction, including fever, nausea, vomiting, diarrhea, lethargy, malaise, sore throat, shortness of breath, cough, rash; may produce life-threatening event if hypersensitivity is rechallenged
• Didanosine (Videx-EC)	Headache, nausea, vomiting, diarrhea, rash
• Emtricitabine (FTC, Emtriva)	Headache, diarrhea, nausea, rash, skin discoloration
• Lamivudine (3TC)	Minimal toxic effects, nausea, nasal congestion
• Zidovudine (AZT, Retrovir)	Nausea, vomiting, anemia, leukopenia, fatigue, headache, insomnia, pancreatitis
Nucleotide reverse transcriptase inhibitor	
• Tenofovir disoproxil fumarate (Viread)	Nausea, vomiting, diarrhea
Nonnucleoside reverse transcriptase inhibitors	Common adverse effects: rash, erythema multiforme, increased liver enzymes, hepatotoxicity
• Delavirdine (Rescriptor)	Headache, fatigue, GI upset, neutropenia, pruritus
• Efavirenz (Sustiva)	Dizziness, trouble concentrating, unusual dreams, confusion, anxiety, depression, diarrhea, encephalopathy; false-positive cannabinoid test
• Etravirine (Intelence)	Rash, diarrhea, nausea, flatulence, abdominal pain
• Nevirapine (Viramune)	GI upset, headache, generalized rash
• Rilpivirine (Edurant)	Depression, insomnia, headache
Protease inhibitors	Common adverse effects: dysglycemia, hyperlipidemia, lipodystrophy
• Atazanavir (Reyataz)	Nausea, diarrhea, hyperbilirubinemia
• Darunavir (Prezista)	Diarrhea, nausea, headache
• Fosamprenavir (Telzir)	Diarrhea, nausea, vomiting, headache
• Indinavir (Crixivan)	Nausea, diarrhea, asymptomatic hyperbilirubinemia, interstitial nephritis, kidney stones (patient should drink 2–4 L of fluid a day)
• Nelfinavir (Viracept)	Diarrhea, flatulence, nausea, rash
• Ritonavir (Norvir)—most often used in low doses with other protease inhibitors to boost effect	Nausea, diarrhea, vomiting, taste perversion, circumoral and perioral paresthesia, hepatitis
• Tipranavir (Aptivus)	Nausea, diarrhea, headache, clinical hepatitis, increased serum transaminases, hepatic decompensation, symptoms of sulpha allergy, rash, or photosensitivity
• Kaletra (lopinavir + ritonavir combination)	Nausea, diarrhea, taste perversion, perioral and circumoral paresthesia, hepatitis
Integrase inhibitors	
• Dolutegravir (Tivicay)	Rash, increased liver enzymes, tiredness, fever, insomnia, headache
• Raltegravir (Isentress)	Diarrhea, nausea, headache, fever
Entry inhibitors	
• Enfuvirtide (Fuzeon)	ISRs, fatigue, nausea, diarrhea, insomnia, peripheral neuropathy, hypersensitivity reaction, pneumonia
• Maraviroc (Celsentri)	Persistent cough, URT infections, and GI upset

Drug	Adverse Effects
Combination therapy	
• Atripla (tenofovir + emtricitabine + efavirenz)	Nausea and vomiting, cough, increased pigmentation on soles of feet and palms of hands, diarrhea, drowsiness, indigestion, headache, strange dreams, fatigue
• Combivir (lamivudine + zidovudine)	Headache, nausea, vomiting, unexpected tiredness, diarrhea, loss of appetite, insomnia, muscle pain
• Complera (rilpivarine + emtricitabine + tenofovir disoproxil fumarate)	Dizziness, feeling sleepy during the daytime, headache, rash, nausea, stomach pain
• Genvoya (elvitegravir + cobicistat + tenofovir alefanamide + emtricitabine)	Headache, fatigue, nausea, diarrhea
• Kivexa (abacavir + lamivudine)	Unexpected tiredness, diarrhea, nausea, headache
• Prezcobix (darunavir + cobicistat)	Diarrhea, rash, headache, nausea, vomiting
• Stribild (elvitegravir + cobicistat + truvada emtricitabine + tenofovir)	Headache, diarrhea, nausea, vomiting, vivid dreams, anxiety, rash, dizziness, insomnia, loss of appetite
• Triumeq (dolutegravir + abacavir + lamivudine)	Nausea, vomiting, diarrhea, headache, abdominal discomfort/pain
• Trizivir (lamivudine + zidovudine + abacavir)	Diarrhea, nausea, vomiting, loss of appetite, headache, insomnia, unexpected tiredness, muscle pain
• Truvada (tenofovir and emtricitabine)	Dizziness, headache, nausea, vomiting, flatulence

*Current recommendations for therapy mandate combinations of three or more of these drugs. Treatment with only one drug is rarely acceptable.

†Many of these drugs cause serious and potentially fatal interactions when used in combination with other commonly used drugs, some of which are available over the counter.

GI, gastro-intestinal; *ISRs,* injection site reactions; *URT,* upper respiratory tract.

Drug Alert

Efavirenz (Sustiva)

- In pregnant patients, efavirenz can be used after the first 8 weeks of pregnancy.
- Once-a-day doses should be taken at bedtime (at least initially) to help patients cope with adverse effects, including dizziness and confusion.
- Patients should be informed that many people who use the drug have reported vivid and sometimes bizarre dreams.

Preventing Transmission of Human Immunodeficiency Virus

A new and emerging use of ART is pre-exposure prophylaxis (PrEP), which is a comprehensive HIV-prevention strategy to reduce the risk of sexually acquired HIV infection in adults at high risk (Gunthard, Aberg, Eron, et al., 2014). PrEP should be used in conjunction with other proven prevention interventions such as condoms, risk reduction counselling, and regular HIV testing.

The combination of tenofovir with emtricitabine, known as *Truvada,* is used to reduce the risk of HIV infection in uninfected individuals who are at significant risk of acquiring HIV. Truvada is also currently used in combination with other antiretroviral agents for the treatment of HIV-infected people.

Drug Therapy for Opportunistic Diseases

Management of HIV is complicated by the many opportunistic diseases that can develop as the immune system deteriorates. A preferred approach to opportunistic diseases is to prevent their occurrence. A number of opportunistic diseases associated with HIV can be delayed or prevented through the use of adequate ART, vaccines (including hepatitis B, influenza, and pneumococcal), and disease-specific prevention measures. Prophylaxis, used according to established criteria, contributes significantly to preventing morbidity and mortality. Although it is usually not possible to eradicate opportunistic diseases once they occur, treatments are available that can control them. Advances in the prevention, diagnosis, and treatment of opportunistic diseases have contributed significantly to

increased life expectancy. Table 17-11 lists prophylaxis and treatments for some common HIV-related opportunistic diseases.

Vaccination

Despite considerable research, a vaccine for HIV still eludes scientists. The problems that impede HIV vaccine development are numerous. HIV lives inside cells, where it can "hide" from circulating immune factors. HIV also mutates rapidly, so that infected individuals develop HIV variants that may not all respond to a simple vaccine (Greenwood, Salisbury, & Hill, 2011). In addition, two strains of HIV (HIV-1 and HIV-2) cause AIDS, and at least nine clades (subtypes) of HIV-1 exist around the world. A vaccine developed for one clade may not be effective against the others.

There are also social, ethical, and economic issues related to vaccination. Vaccine efficacy will eventually have to be established in human testing: How will volunteers be recruited? How will true protection be determined? Will volunteers be exposed to HIV after immunization to test immunity? Because HIV is a global problem, with developing countries bearing the brunt of the epidemic, there is also concern about developing a vaccine that can be widely distributed in a short amount of time at an acceptable cost. Will vaccines, once developed, be accepted? Despite the overwhelming nature of these issues, considerable research is in progress. Vaccines in various stages of development are being tested. The development of a successful vaccine would be extremely helpful in controlling the epidemic but would not replace current prevention methods because no vaccine is likely to be 100% effective.

Nursing Management Human Immunodeficiency Virus Infection

Nursing Assessment

Nursing assessment for an individual not known to be infected with HIV should focus on behaviours that could put the person at risk for HIV infection and other sexually transmitted and bloodborne diseases. Nurses can help individuals assess risks by asking four basic questions: (a) “Have you ever had a blood transfusion or used clotting factors? If so, was it before 1985?” (b) “Have you ever shared needles, syringes, or other injecting equipment with another person?” (c) “Have you ever had a sexual experience in which your penis, vagina, rectum, or mouth came into contact with another person's penis, vagina, rectum, or mouth?” and (d) “Have you ever had an STI?” These questions elicit the minimum data needed to initiate a risk assessment. A positive response to any of these questions necessitates an in-depth exploration of the issues specific to the identified risk.

Further assessment is needed when an HIV infection is diagnosed. Subjective and objective data that should be obtained are presented in Table 17-16. Nursing assessments should be ongoing because early recognition and treatment of problems can decrease the progression of HIV infection. A complete history and a thorough systems review can help the nurse identify problems in a timely manner.

TABLE 17-16
NURSING ASSESSMENT
HIV-Infected Patient

Subjective Data	
Important health information	*Past health history:* Route of infection; hepatitis; other STIs; tuberculosis; foreign travel; frequent viral, fungal, or bacterial infections; alcohol and drug use *Medications:* Use of immuno-suppressive drugs
Symptoms	Malaise, chronic fatigue, weight loss, anorexia, nausea, vomiting; lesions, bleeding, or ulcerations of lips, mouth, gums, tongue, or throat; sensitivity to acidic, salty, or spicy foods; difficulty swallowing; abdominal cramping Skin rashes, lesions, or colour changes; pruritus; nonhealing wounds Persistent diarrhea, change in character of stools; painful urination Cough, shortness of breath Insomnia; night sweats Headaches, stiff neck, chest pain, rectal pain, retrosternal pain Blurred vision, photophobia, diplopia, loss of vision; hearing impairment; confusion, forgetfulness, attention deficit, changes in mental status, memory loss, personality changes, muscle weakness, difficulty walking; paresthesias, hypersensitivity in feet Lesions on genitalia (internal or external), pruritus or burning sensation in vagina, painful sexual intercourse, changes in menstruation, vaginal or penile discharge
Objective Data	
General	Lethargy, persistent fever, lymphadenopathy, peripheral wasting, fat deposits in truncal areas and upper back; social withdrawal
Integumentary	Decreased skin turgor, dry skin, or diaphoresis; pallor, cyanosis; lesions, eruptions, discolorations, or bruises of skin and mucous membranes; vaginal or perianal excoriation; alopecia, delayed wound healing
Eyes	Presence of exudate; retinal lesions or hemorrhage; papilledema
Respiratory	Tachypnea, dyspnea, intercostal retractions; crackles, wheezing, productive or nonproductive cough
Cardiovascular	Pericardial friction rub, murmur, bradycardia, tachycardia
Gastro-intestinal	Mouth lesions, including blisters (HSV), white-grey patches (*Candida*), painless white lesions on lateral aspect of the tongue (hairy leukoplakia), discolorations (Kaposi's sarcoma); gingivitis, tooth decay or loosening; redness or white patchy lesions of throat; vomiting, diarrhea, incontinence; rectal lesions; hyperactive bowel sounds, abdominal masses, hepatosplenomegaly
Musculo-skeletal	Muscle wasting
Neurological	Ataxia, tremors, lack of coordination; sensory loss; slurred speech, aphasia; memory loss, apathy, agitation, depression, inappropriate behaviour; decreasing levels of consciousness, seizures, paralysis, coma
Reproductive	Genital lesions or discharge, abdominal tenderness secondary to pelvic inflammatory disease
Possible findings	Positive result of HIV antibody assay (EIA or ELISA, confirmed by WB or IFA); viral load levels detectable by bDNA or PCR, ↓ $CD4^+$ lymphocytes, reversal of CD4:CD8 ratio; ↓ WBC count, lymphopenia, anemia, thrombo-cytopenia; electrolyte imbalances; abnormal results of liver function tests; ↑ cholesterol, triglyceride, and blood glucose levels

bDNA, branched-chain deoxyribonucleic acid; *EIA*, enzyme immunoassay; *ELISA*, enzyme-linked immunosorbent assay; *HIV*, human immunodeficiency virus; *HSV*, herpes simplex virus; *IFA*, immuno-fluorescence assay; *PCR*, polymerase chain

reaction; *STIs,* sexually transmitted infections; *WB,* Western blot; *WBC,* white blood cell count.

Evidence-Informed Practice

Translating Research Into Practice

A nurse in an HIV clinic is counselling Mr. Simms, a 25-year-old gay man, and his partner. Mr. Simms is receiving antiretroviral therapy. His viral load is very low, and his $CD4^+$ T cell count is normal. He tells the nurse that since the medications are working, he and his partner (who is not infected with HIV) have decided to forgo the use of condoms. They tell the nurse that they are in a committed relationship and have no other partners. The nurse spends time explaining to both of them the risks of unprotected sex: his partner may get infected with HIV even with a low viral load (although the risk is decreased).

Best Available Evidence	Clinician Expertise	Patient Preferences and Values
One of the best ways to prevent HIV transmission from an infected person to an uninfected person is by using condoms.	The nurse knows that risk-reducing sexual activities in this situation include the continued use of condoms. However, the nurse also knows that a very low viral load decreases the risk of HIV transmission.	After listening, the patient tells the nurse that he and his partner do not like using condoms. Both understand the risks and believe that while the medications are working, the risk is low and worth the risk.

Decision and Action

The nurse must respect Mr. Simm's decision. The nurse reminds him of the importance of maintaining his medication regimen and attending his appointments at the clinic. The nurse explains that this will be even more important now to keep Mr. Simms's infection under control.

Reference for Evidence

Cohen MS, McCauley M, Gamble TR. HIV treatment as prevention and HPTN 052. *Current opinion in HIV and AIDS*. 2012;7(2):99; 10.1097/COH.0b013e32834f5cf2.

Nursing Diagnoses

Nursing diagnoses related to HIV infection are dictated by several variables: the stage (e.g., is prevention of HIV infection the issue? Are there concerns related to ongoing infection? Is the patient in a terminal phase of the disease?), presence of specific etiological problems (e.g., respiratory distress, depression, wasting), and social factors (e.g., issues related to self-esteem, sexuality, family interactions, finances). Because HIV infection is a complex and individually experienced disease, a broad spectrum of nursing diagnoses may include, but not be limited to, those presented in Table 17-17.

TABLE 17-17
NURSING DIAGNOSES: HIV INFECTION

- Anxiety
- Breathing pattern, ineffective
- Body image, disturbed
- Caregiver role strain
- Coping, ineffective
- Confusion, acute or chronic
- Decisional conflict
- Denial, ineffective
- Diarrhea
- Disuse syndrome, risk for
- Fatigue
- Family processes, interrupted
- Fear
- Grieving
- Headache
- Health management, ineffective
- Hyperthermia
- Nutrition, imbalanced: less than body requirements
- Oral mucous membrane integrity, impaired
- Pain, acute or chronic
- Powerlessness
- Relocation stress syndrome
- Self-care deficits
- Self-esteem, chronic low
- Self-esteem, situational low
- Sleep pattern, disturbed
- Social isolation
- Spiritual distress

Planning

Prevention of HIV infection presents a number of challenges for the patient, many of which are related to the difficulties of behaviour change. Nurses can be instrumental in this process. Nursing interventions to prevent disease transmission depend on assessment of the patient's individual risk behaviours, knowledge, and skill deficits. Nursing orders based on these assessments will encourage the patient to learn safer, healthier, and less risky behaviours. Infection with HIV affects the entire range of a person's life: not only physical health but also social, emotional, economic, and spiritual well-being. Once a person is infected, current treatment cannot eliminate HIV from the body. The overriding goals of therapy are therefore to keep the viral load as low as possible for as long as

possible; to maintain or restore a functioning immune system; to improve the patient's quality of life; to reduce the potential for transmission of the virus; to reduce HIV-related disease, disability, and death; and to prevent reinfection. Nursing interventions can assist the patient to (a) adhere to drug regimens; (b) promote a healthy lifestyle; (c) prevent opportunistic disease; (d) protect others from HIV; (e) maintain or develop healthy, supportive relationships; (f) maintain activities and productivity; (g) come to terms with issues related to disease, death, and spirituality; and (h) cope with the frequent symptoms caused by HIV and its treatments (Canadian Association of Nurses in AIDS Care [CANAC], 2013). Goals are individualized and change as new treatment protocols develop or as HIV disease progresses.

Nursing Implementation

The complexity of HIV disease is related to its chronic nature. As with most chronic and infectious diseases, primary prevention and health promotion are the most effective health care strategies. When prevention fails, however, disease results. HIV infection has no cure and continues for life. If a patient does not receive ART, it causes increasing physical disability, contributes to impaired health, and ultimately causes death.

Nursing interventions at every stage of HIV disease can be instrumental in improving the quality and quantity of the patient's life. Nurses who emphasize a holistic and individualized approach to care are well suited to and capable of providing optimal care to these patients. Table 17-18 presents a synopsis of nursing goals, assessments, and interventions at each stage of HIV infection.

TABLE 17-18
NURSING INTERVENTIONS IN HIV DISEASE

Levels of Care; Goals	Assess	Interventions
Health Promotion		
1. Prevent HIV infection 2. Detect HIV infection early	*Risk factors:* What behaviours or social, physical, emotional, pathological, and immune factors place the patient at risk? Does the patient need to be tested for HIV?	Education, including knowledge, attitudes, and behaviours, with an emphasis on risk reduction, to accomplish the following: • General population: covering general information • Pregnant women: covering general information and information specific to HIV infection and pregnancy; offering prenatal HIV testing in the first trimester Individual patient: specific to assessed need Empowering patients to take control of prevention measures Providing HIV-antibody testing with pretest and post-test counselling
Acute Intervention		
1. Promote health and limit disability 2. Manage problems caused by HIV infection	*Physical health:* Is patient experiencing problems? *Mental health status:* How is the patient coping? *Resources:* Does the patient have family and social support? Is the patient accessing community services? Is money or insurance a problem? Does the patient have access to spiritual support?	Case management Education regarding HIV, the spectrum of infection, options for care, signs and symptoms to watch for, treatment options, immune enhancement, harm reduction, and ways to adhere to treatment regimens Referral to needed resources Establishing long-term, trusting relationship with patient, family, and significant others Providing emotional and spiritual support Providing care during acute exacerbations: recognition of life-threatening developments, life support, rapid intervention with treatments and drugs, patient and family emotional support during crisis, comfort, and hygiene needs Developing resources for legal needs: discrimination prevention, wills and powers of attorney, child care wishes Empowering patient to identify needs, direct care, and seek services
Ambulatory and Home Care		

Levels of Care; Goals	Assess	Interventions
1. Maximize quality of life 2. Resolve life and death issues	*Physical health:* Are new symptoms developing? Is the patient experiencing drug adverse effects or interactions? *Mental health:* How is the patient coping? What adjustments have been made? *Finances:* Can the patient maintain health care and basic standards of living? *Family, social, and community supports:* Are these available? Is the patient using supports in an effective manner? Do family or significant others need education, encouragement, or stress relief? *Spirituality issues:* Does the patient desire support from a religious organization? Are spirituality issues private and personal? What assistance does the patient need?	Continuing case management Educating about changing treatment options and continued adherence Empowering patient to continue to direct care and to make desires known to family members and significant others Continuing physical care for chronic disease process: treatments, drugs, comfort, and hygiene needs Supporting patient and family and significant others in a trusting relationship Referral to resources that will assist in meeting identified needs Promoting health maintenance measures Assistance with end-of-life issues: resuscitation orders, comfort measures, funeral plans, and the like Referral to palliative care

HIV, human immunodeficiency virus.

Health Promotion.

A major goal of health promotion is to prevent disease. Even with recent successes in the treatment of HIV, prevention is crucial for control of the epidemic. Another goal of health promotion is to detect disease early so that if primary prevention has failed, early intervention can be implemented.

Informatics in Practice

Use of Internet and Mobile Devices to Manage Human Immunodeficiency Virus Infection

- Reputable websites such as government agencies (e.g., Health Canada) and well-known academic and medical institutions offer resources and support for patients that can assist them in

coping with their illness and educate them about signs and symptoms of serious illness. (See also the Resources at the end of this chapter.)

- By monitoring their health and quickly spotting warning signs of serious illnesses, patients are able to alert their physicians and receive earlier treatment.
- These systems can help the patient manage antiretroviral therapy by sending medication reminders by text or email.

Prevention of Human Immunodeficiency Virus Infection.

HIV infection is preventable. At this time, education and behaviour change are the most effective prevention tools. Educational messages should be specific to the patient's need, culturally sensitive, language appropriate, and age specific. Nurses are excellent resources for this type of education, but nurses must be comfortable with and know how to talk about sensitive topics such as sexuality and drug use (CANAC, 2013).

Prevention behaviours have been known and recommended since the mid-1980s. The nurse must remember that a range of activities can reduce the risk of HIV infection and that individuals will choose different techniques. The goal is for the person to develop safer, healthier, and less risky behaviours than are currently being used. These techniques can be divided into *safe activities* (those that eliminate risk) and *risk-reducing activities* (those that decrease risk but do not eliminate it). The more consistently and correctly prevention methods are used, the more effective they are in preventing HIV infection.

Research shows that the majority of new HIV infections were transmitted by individuals who were not aware that they were infected. An estimated 21% of HIV-infected people in Canada do not know that they are infected (PHAC, 2015c). These facts helped British Columbia develop the Seek and Treat for Optimal Prevention of HIV/AIDS (STOP) program. As a result of this program, HIV testing has been expanded to populations not historically considered to be at risk, and the program also ensures that all individuals in

whom HIV is diagnosed get rapid access to treatment, which is known to prevent transmission.

Decreasing Risks Related to Sexual Intercourse.

Safe sexual activities significantly decrease the risk of exposure to HIV in semen and vaginal secretions. Abstaining from all sexual activity is the most effective way to accomplish this goal, but there are safe options for those who cannot or do not wish to abstain. *Outercourse* (limiting sexual behaviour to activities in which the mouth, penis, vagina, or rectum does not come into contact with a partner's mouth, penis, vagina, or rectum) is safe because there is no contact with blood, semen, or vaginal secretions. Outercourse includes massage, masturbation, mutual masturbation, telephone sex, and other activities that meet the "no contact" requirements. *Insertive sex* between partners who are not infected with HIV or not at risk of becoming infected with HIV is considered to be safe, although it is important for a person to know his or her partner's status.

Reducing the risk of sexual activities through the use of barriers decreases the risk of contact with HIV. Barriers should be used during insertive sexual activity (oral, vaginal, or anal) with a partner who is known to be HIV infected or with a partner whose HIV status is not known. The most commonly used barrier is the male condom. Male condoms have been shown to be almost 100% effective in preventing the transmission of HIV when used correctly and consistently. Major points for the correct use of male condoms are discussed in Table 17-19. Female condoms are also available. Use can be complicated, and so careful instruction and practice are necessary (Table 17-20). In addition, squares of latex (known as dental dams) or plastic food wrap can be used to cover the external female genitalia during oral sexual activity.

TABLE 17-19

PATIENT & CAREGIVER TEACHING GUIDE
Proper Use of the Male Condom

- Use only condoms (“rubbers”) that are made out of latex or polyurethane. “Natural skin” condoms have pores that are large enough for HIV to penetrate.
- Store condoms in a cool, dry place and protect them from trauma. The friction caused by carrying them in a back pocket, for instance, can wear down the latex.
- Do not use a condom if the expiration date has passed or if the package looks worn or punctured.
- Lubricants used in conjunction with condoms must be water soluble. Oil-based lubricants can weaken latex and increase the risk of tearing or breaking.
- Nonlubricated, flavoured, or unflavoured condoms can provide protection during oral intercourse.
- The condom must be placed on the erect penis before any contact is made with the partner's mouth, vagina, or rectum to prevent exposure to pre-ejaculatory secretions that may contain HIV.
- Remove the penis and condom from the partner's vagina or rectum immediately after ejaculation and before the erection is lost. Hold the condom at the base of the penis and remove both penis and condom at the same time. This keeps semen from leaking around the condom as the penis becomes flaccid.
- Remove the condom after use, wrap in tissue, and discard. Do not flush down the toilet because this can cause plumbing problems.
- Condoms are not reusable! A new condom must be used for every act of intercourse.

HIV, human immunodeficiency virus.

TABLE 17-20

PATIENT & CAREGIVER TEACHING GUIDE
Proper Use of the Female Condom

Female condoms consist of a polyurethane sheath with two spring-form rings.

- The smaller ring is inserted into the vagina and holds the condom in place internally. This ring can be removed if the condom is to be used for anal intercourse. It should not be removed if the condom is to be used for vaginal intercourse.
- The larger ring surrounds the opening to the condom. It functions to keep the condom in place while protecting the external genitalia.

Use only water-soluble lubricants with female condoms.

- Female condoms come prelubricated and with a tube of additional lubricant.
- Lubrication is needed to protect the condom from tearing during sexual intercourse and can also decrease the noise that results from friction of the penis against the condom.

Some men have reported that the female condom feels better than the male condom. Other men like male condoms better. The only way to find out which type of condom works best is to try both.

Practise inserting the female condom. Lubrication makes the condom slippery, but do not get discouraged; just keep trying.

During sexual intercourse, ensure that the penis is inserted into the female condom through the outer ring. It is possible for the penis to miss the opening, thus making contact with the vagina and defeating the purpose of the condom.

Do not use a male condom at the same time as a female condom.

After intercourse, remove the condom before standing up.

- Twist the outer ring to keep the semen inside, gently pull the condom out of the vagina, and discard.

Do not flush down the toilet because this can cause plumbing problems.

Do not reuse a female condom.

Decreasing Risks Related to Substance Misuse.

Misuse of substances, including alcohol and tobacco, is harmful. It can cause immune suppression and malnutrition, as well as a host of psychosocial problems. However, substance use in and of itself does not cause HIV infection. The major risk for HIV infection is related to sharing injecting equipment or having unsafe sexual experiences while under the influence of substances. The basic rules are as follows: (a) Do not inject illicit drugs; (b) If you do inject illicit drugs, do not share equipment; and (c) Do not have sexual intercourse when under the influence of any drug (including alcohol) that impairs decision-making ability (HIV.gov, 2014).

The safest mechanism is to abstain from substance misuse. Although this is the best option for people who do not currently misuse substances, it may not be a viable alternative for users who are not prepared to quit or for those who have no access to treatment services. The risk of HIV infection for individuals who misuse drugs can be eliminated if they use alternatives to injecting, such as smoking, snorting, or ingesting the drug. Risk for HIV can also be eliminated if users do not share injecting equipment. Injecting equipment ("works") includes needles, syringes, cookers (spoons or bottle caps used to mix the drug), cotton, and rinse water. None of this equipment should be shared. Another safe tactic is for the user to have access to sterile equipment. This can be accomplished through community needle and syringe exchange programs and supervised injection sites that provide sterile equipment to users in exchange for used equipment. Opposition to these programs is supported by the fear that ready access to injecting supplies will increase drug use. However, studies have shown that in communities where exchange programs have been established, drug use does not increase, rates of HIV infection are controlled, and there are overall economic benefits (Arkin, 2011).

Cleaning equipment before use is a risk-reducing activity. It decreases the risk for those who share equipment (Table 17-21). This process takes time and may be difficult for a person who begins to suffer drug withdrawal during the process.

TABLE 17-21

PATIENT & CAREGIVER TEACHING GUIDE
Proper Use of Injection Equipment

- When drugs are injected, it is always preferable to use new, sterile syringes, needles, cookers, and cotton (works).
- Find out if there is a needle and syringe exchange program in your community. If there is, take used equipment in, and you will be provided with new works.
- Swab skin with an alcohol preparation before injecting.
- Use a tourniquet to assist in locating veins.
- Always inject with the bevel facing up on the needle.
- If you must share your equipment, it is very important to clean the works thoroughly with bleach before use.
- First, rinse the used needle and syringe twice with tap water.
- Then, fill the syringe with full-strength household bleach, shake for 30 seconds, and squirt the bleach out.
- Repeat the bleaching process a second time, being sure to shake the bleach-filled syringe for 30 seconds.
- Finally, rinse equipment twice with tap water.
- Do not share your bleach or rinse water.
- Do not share your cooker. If you must share your cooker, clean it with bleach and water before using it again.
- Supervised injection sites are another viable alternative for preventing the spread of infection, and there is political will to open such sites in various parts of the country.

Decreasing Risks of Perinatal Transmission.

The best way to prevent HIV infection in infants is to prevent HIV infection in women. Women who are already infected with HIV should be asked about their reproductive desires. Women who choose not to have children need to have birth control methods discussed in detail. Should they become pregnant, abortion may be desired and should be discussed in conjunction with other options.

If HIV-infected pregnant women are appropriately treated during pregnancy, the rate of perinatal transmission can be decreased from 25% to less than 1%. The current standard of care is that all women who are pregnant or contemplating pregnancy should be counselled about HIV infection, informed of their choices, routinely offered access to voluntary HIV-antibody testing, and, if infected, offered optimal ART (Burdge et al., 2003).

Decreasing Risks at Work.

The risk of infection from occupational exposure to HIV is low but real. The Canadian Centre for Occupational Health and Safety

requires employers to protect workers from exposure to blood and other potentially infectious materials. Precautions and safety devices decrease the risk of direct contact with blood and body fluids. Precautions for the prevention of occupational exposure to bloodborne diseases are discussed earlier in this chapter. Should significant exposure to HIV-infected fluids occur, postexposure prophylaxis with combination ART that is based on the type of exposure, the volume of the exposure, and the status of the source patient has been shown to significantly decrease the risk of infection. The possibility of treatment makes reporting of all blood exposures even more critical.

Human Immunodeficiency Virus Testing and Counselling.

Testing is the only sure way to determine whether a person has HIV infection. Any individual who is at risk for HIV infection should be encouraged to be tested. When findings are negative, testing can relieve anxieties about past behaviours and provide opportunities for prevention education. When findings are positive, testing provides the needed impetus to seek treatment and to protect sexual and drug-using partners. All testing for HIV should be accompanied by pretest and post-test counselling (Table 17-22) as mandated by the World Health Organization (2015b).

TABLE 17-22

PRETEST AND POST-TEST COUNSELLING ASSOCIATED WITH HIV-ANTIBODY TESTING

General Guidelines

1. Many people who are being tested for HIV are fearful about the test results:
    - The nurse should establish rapport with the patient.
    - The nurse should assess the patient's ability to understand HIV counselling.
    - The nurse must determine the patient's ability to access support systems.
2. The benefits of testing should be explained:
    - Testing provides an opportunity for education that can decrease the risk of new infections.
    - Infected individuals can be referred for early intervention and support programs.
3. Adverse aspects of testing should be discussed:
    - Confidentiality issues: breaches of confidentiality have led to discrimination.
    - A positive test result affects all aspects of the patient's life (e.g., personal, social, economic) and can raise difficult emotions (anger, anxiety, guilt, and thoughts of suicide).

Pretest Counselling

1. Determining the patient's risk factors and when the last risk factor occurred; counselling should be individualized according to these parameters.
2. Providing education to help the patient reduce future risk of exposure.
3. Providing education that will help the patient protect sexual and drug-sharing partners.
4. Discussing problems related to the delay between infection and an accurate test. Testing will have to be repeated at intervals for up to 6 months after each possible exposure. Discuss the need to use measures to decrease the risks to the patient and the patient's partners during that interval.
5. Discussing the possibility of false-negative tests, which are most likely to occur during the window period.
6. Assessing support systems. Provide telephone numbers and resources as needed.
7. Discussing the responses the patient anticipates having to the test results (positive and negative).
8. Outlining assistance that will be offered if the test result is positive.

Post-Test Counselling

1. If the test result is negative, pretest counselling and prevention education should be reinforced. The patient should be reminded that the test must be repeated at intervals for up to 6 months after the most recent high-risk exposure.
2. If the test result is positive, the nurse must understand that the patient may be in emotional shock and not hear much of what the nurse says.
3. The nurse should provide resources for medical and emotional support and help the patient get immediate assistance:
    - Evaluating suicide risk and follow-up as needed.
    - Determining need to test others who have had high-risk contact with the patient.
    - Discussing retesting to verify results. This tactic supports hope for the patient, but, of more importance, it keeps the patient in the health care system. While waiting for the second test result, the patient has time to think about and adjust to the possibility of having HIV infection.
    - Encouraging optimism.
4. The nurse should remind the patient that effective treatments are available; HIV infection is not a death sentence.
5. Health habits that can improve the immune system should be reviewed.
6. The nurse should arrange for the patient to speak to HIV-infected people who are willing to share with and assist patients with new diagnoses during the time between when the test results are available and treatment begins.
7. The nurse should emphasize that a positive HIV test result means that the patient is infected but does not necessarily mean that the patient has AIDS.
8. The patient should be educated to prevent new infections. HIV-infected people should be instructed to avoid donating blood, organs, or semen; to avoid sharing razors, toothbrushes, or other household

items that may contain blood or other body fluids; and to protect sexual and needle-sharing partners from blood, semen, and vaginal secretions.

AIDS, acquired immune deficiency syndrome; *HIV*, human immunodeficiency virus.

Acute Intervention

Early Intervention.

Early intervention after detection of HIV infection can promote health and limit or delay disability. Because the course of HIV is variable, assessment is very important. Nursing interventions are based on and tailored to patient needs noted during assessment. The nursing assessment in HIV disease should focus on early detection of symptoms, opportunistic diseases, and psychosocial problems (see Table 17-18).

Initial Response to a Diagnosis of Human Immunodeficiency Virus Infection.

Reactions to a positive result of an HIV-antibody test are similar to the reactions of people who are diagnosed with any life-threatening, debilitating, or chronic illness. They include anxiety, panic, fear, depression, denial, hopelessness, thoughts of suicide, anger, and guilt (French, Greeff, Watson, et al., 2015). Many of these reactions are also experienced by the patient's family members, friends, and caregivers. As time passes, patients and their loved ones must confront common issues associated with a life-threatening illness. These include difficult treatment decisions; feelings of loss, anger, powerlessness, depression, and grief; social isolation imposed by self or others; altered concepts of the physical, social, emotional, and creative self; thoughts of suicide; and the possibility of death. The nurse can help the patient obtain control over treatment and life decisions. Empowerment is particularly important because many individuals with HIV infection experience multiple losses, including that of control, which can be overwhelming. Empowerment is facilitated by education and honest discussions about the patient's health status and treatment options.

Antiretroviral Therapy.

Multidrug therapy protocols have been shown to significantly reduce viral loads and reverse clinical progression of HIV (Gunthard, Aberg, Eron, et al., 2014). However, nurses must be aware that the protocols are complex, the drugs have adverse effects and interactions, and they do not work for everyone. These factors can contribute to problems with adherence to treatment regimens, a dangerous situation because of the high risk of developing drug resistance. Nurses are often the health care providers that work the most closely with patients who are trying to cope with these issues. Interventions include teaching about (a) advantages and disadvantages of new treatments, (b) dangers of poor adherence to therapeutic regimens, (c) how and when to take each drug, (d) drug interactions to avoid, and (e) adverse effects that must be reported to the health care provider. Table 17-23 provides guidance for patient teaching in these areas.

TABLE 17-23

PATIENT & CAREGIVER TEACHING GUIDE
Use of Antiretroviral Drugs

Resistance to antiretroviral drugs is a major problem in treating HIV infection. To decrease the risk of developing resistance:

1. Take at least three different antiretroviral drugs at a time; discuss other options with your health care provider.
2. Know what medications you are taking and how to take them (some have to be taken with food, some must be taken on an empty stomach, some cannot be taken together). If you do not understand, ask. Get your nurse to write the instructions clearly for you.
3. Take the full dose prescribed, and take it on schedule. If you cannot take the drug because of adverse effects or other problems, report it to your health care provider.
4. Take all of the drugs prescribed. It is important that you take them more than 95% of the time. Do not quit taking one drug while continuing the others. If you cannot tolerate one of your drugs, your health care provider will recommend a completely new set of drugs.
5. Many of the antiretroviral drugs interact with other drugs, including a number of common drugs you can buy without a prescription. Be sure your health care provider and pharmacist know all of the drugs that you are taking, and do not take any new drugs without checking for possible interactions.
6. The goal of antiretroviral therapy is to decrease the amount of virus in your blood. This is called your viral load. Viral load can be determined by tests such as the PCR or bDNA. The results are reported in absolute numbers. The goal is to get your viral load to an undetectable level. Most health care providers will check this number on a regular basis regardless of whether you are taking antiretroviral agents.
7. In 2 to 4 weeks after you start on drug therapy (or change your therapy), your health care provider will test your viral load to find out whether the drugs are working. These results are reported in absolute numbers or in "logs" (logarithms: a mathematical concept). All you have to know is that you want to see the viral load drop. If reports are in logs, you want to see a drop of at least 1 log, which means that 90% of your viral load has been eliminated. If your viral load drops by 2 logs, your viral load will have been 95% eliminated. If your viral load drops by 3 logs, your viral load will have been 99% eliminated.
8. An undetectable viral load means that the amount of virus is extremely low and viruses cannot be found in the blood through the use of the current technology. It does not mean that the virus is gone, for much of the virus will be in lymph nodes and organs where the tests cannot detect it. It also does not mean that you are no longer able to transmit HIV to others; you will need to continue protecting all of your sexual and drug-using partners.

AIDS, acquired immune deficiency syndrome; *bDNA*, branched-chain DNA; *HIV,* human immunodeficiency virus; *PCR*, polymerase chain reaction.

When to Start Antiretroviral Therapy.

ART has been in a state of continuous change since the first antiretroviral drug became available in 1987. When new drugs were developed, health care providers had the ability to combine and substitute drugs. However, as new treatments have improved the quality and quantity of patients' lives, problems have emerged. For a while, the preferred treatment strategy was known as "hit it early, hit it hard." This was thought to be appropriate because decreasing the viral load provides for better health outcomes. However, adverse

effects and lack of regimen adherence caused many patients to question their ability to sustain ART for long periods of time. Because of this, for several years, treatment was delayed until the $CD4^+$ T-cell count dropped below 500. However, it has become clear that when viral load is suppressed, the possibility of transmission of the virus is reduced. For this reason, current recommendations are that all people infected with HIV should receive treatment, regardless of their $CD4^+$ T-cell count (Gunthard, Aberg, Eron, et al., 2014).

Given patient readiness, without which lack of adherence may be a problem, treatment should be initiated at the time of diagnosis because suppressing viral loads is helpful in reducing transmission rates (Montaner, 2011) and because it has become apparent that a $CD4^+$ T-cell count of less than 500 is associated with non–AIDS-related issues such as cardiovascular disease, renal disease, and some cancers (Gunthard, Aberg, Eron, et al., 2014). Nurses can provide in-depth education and counselling for patients as they struggle to make this decision (CANAC, 2013).

Adherence.

Adherence to drug regimens is a critical component of drug therapy for people with HIV infection and an area in which nurses are particularly well prepared to provide assistance (Enriquez & McKinsey, 2011). Taking drugs as ordered (right dose and time) every day is important for all drug therapy. Taking drugs as prescribed (right dose and time) is important for all drug therapy, but with HIV infection, missing even a few doses can lead to drug resistance. The difficulty of adhering consistently is clear to anyone who has tried to take a 10-day course of antibiotics. Patients with HIV infection have to take anywhere from 3 to 20 pills a day, at precise times during the day. This process must be repeated every day for the rest of their lives, even though they often suffer uncomfortable adverse effects. Patients can be helped to adhere to difficult treatment regimens with electronic reminders, beepers, timers on pillboxes, and calendars. Group support and individual counselling can also help, but the best approach is to learn about the

patient's lifestyle and assist with problem solving related to taking medications within the confines of that life (CANAC, 2013).

Health Promotion.

HIV disease progression may also be delayed by promoting a healthy immune system, regardless of whether the patient chooses to use ART. Useful interventions for HIV-infected patients include (a) nutritional support to maintain lean body mass and ensure appropriate levels of vitamins and micronutrients; (b) moderation or elimination of alcohol intake, smoking, and drug use; (c) adequate rest and exercise; (d) stress reduction; (e) avoidance of exposure to new infectious agents; (f) mental health counselling; and (g) involvement in support groups and community activities. In the absence of ART, however, disease progression can be delayed only for a finite amount of time.

Patients should be taught to recognize symptoms that may indicate disease progression or drug adverse effects so that prompt medical care can be initiated. Table 17-24 provides an overview of symptoms that patients should report. In general, patients should have as much information as needed to make informed decisions about health care. These decisions then dictate the appropriate interventions.

TABLE 17-24

PATIENT & CAREGIVER TEACHING GUIDE
Signs and Symptoms That Patients With HIV Infection Need to Report

Report the Following Signs and Symptoms Immediately to a Health Care Provider
• Any change in level of consciousness: lethargy, difficulty arousing, inability to arouse, unresponsiveness, unconsciousness • Headache accompanied by nausea and vomiting, changes in vision, or changes in ability to perform coordinated activities, or after any head trauma • Vision changes: blurry or black areas in vision field, new floaters • Persistent shortness of breath related to activity and not relieved by a short rest period • Nausea and vomiting accompanied by abdominal pain • Dehydration: inability to eat or drink because of nausea, diarrhea, or mouth lesions; severe diarrhea or vomiting; dizziness with standing • Yellow discoloration of the skin • Any bleeding from the rectum that is not related to hemorrhoids • Pain in the flank with fever and inability to urinate for more than 6 hours • New onset of weakness in any part of the body, new onset of numbness that is not obviously related to pressure, new onset of difficulty speaking • Chest pain not obviously related to cough • Seizures • New rash accompanied by fever • New oral lesions accompanied by fever • Severe depression, anxiety, hallucinations, delusions, or being a possible danger to self or others
Report the Following Signs and Symptoms Within 24 Hours
• New or different headache; constant headache not relieved by aspirin or acetaminophen • Headache accompanied by fever, nasal congestion, or cough • Burning, itching, or discharge from the eyes • New or productive cough • Vomiting two or three times a day • Vomiting accompanied by fever • New, significant, or watery diarrhea (>6 times a day) • Painful urination, bloody urine, urethral discharge • New, significant rash (widespread, painful, itchy, or following a path down the leg or arm, around the chest, or on the face) • Difficulty eating because of mouth lesions • Vaginal discharge, pain, or itching

Acute Exacerbations.

Chronic diseases are characterized by acute exacerbations of recurring problems. This is especially true in HIV disease, in which infections, cancers, debility, and psychosocial and economic issues may interact to overwhelm the patient's ability to cope. Nursing care becomes more complex if the patient's immune system deteriorates and new problems arise to compound existing difficulties. When opportunistic diseases or difficult adverse effects of treatment

develop, symptom management, education, and emotional support are necessary (CANAC, 2013).

Nursing care assumes primary importance in helping patients prevent the many opportunistic diseases associated with HIV infection. The best prevention of opportunistic disease is adequate treatment of the underlying HIV infection.

Ongoing Care.

HIV-infected patients share problems experienced by all individuals with chronic diseases, but these problems are exacerbated by social constructs surrounding HIV. Chronic diseases are characterized by negative social attitudes that label the patient as weak-willed or immoral for being sick. In HIV, this stigma is compounded by several factors. HIV-infected people may be seen as lacking control over urges to have sex or use drugs. It is then easy to jump to the conclusion that they brought the disease on themselves and, therefore, somehow deserve to be sick. Behaviours associated with HIV infection may be viewed as immoral (e.g., homosexuality, having many sexual partners) and are sometimes illegal (e.g., injecting heroin, sex work). The fact that infected individuals can transmit the virus to others furthers the negative, stigmatizing social concept of HIV. Social stigmatization supports discrimination in all facets of life. According to the Canadian Human Rights Commission (1996) policy on HIV/AIDS, all Canadians have the right to equality and dignity without discrimination, regardless of HIV/AIDS status.

The chronic nature of HIV infection can cause family stress, social isolation, dependence, frustration, lowered self-image, loss of control, and economic pressures. An interesting observation is that all of these variables may have contributed to the patient's infection in the first place. Low self-esteem, searching for social contact, frustration, and economic difficulties all contribute to drug use and risky sexual behaviours.

Disease and Drug Adverse Effects.

Physical problems related to HIV disease or the treatment of HIV can interrupt the patient's ability to maintain a desired lifestyle. HIV-infected patients frequently experience anxiety, fear, diarrhea,

depression, peripheral neuropathy, pain, nausea and vomiting, and fatigue. These are symptoms that nurses deal with routinely, and the interventions for them do not change significantly on the basis of the primary diagnosis. Individual considerations do, of course, influence the way that the nurse approaches the patient. Nursing management of diarrhea, for instance, still includes helping patients collect specimens, recommending dietary changes, encouraging fluid and electrolyte replacement, instructing the patient about skin care, and managing skin breakdown around the perianal area. Nursing approaches for HIV-related fatigue include teaching patients to assess fatigue patterns, determine contributing factors, set activity priorities, conserve energy, schedule rest periods, exercise, and avoid substances such as caffeine, nicotine, alcohol, and other drugs that may disturb sleep.

A new set of metabolic disorders has emerged among HIV-infected patients, especially those who have been infected for a long time and who have been receiving ART. These disorders include changes in body shape (fat deposits in the abdomen, the upper back, and the breasts, along with fat loss in the arms, the legs, and the face) caused by lipodystrophy (Figure 17-8); dyslipidemia (elevated triglycerides and decreases in high-density lipoproteins); insulin resistance and hyperglycemia; bone disease (osteoporosis, osteopenia, avascular necrosis); lactic acidosis; and cardiovascular disease. It is still not clear why these disorders develop, but the reason is probably a combination of factors such as long-term infection with HIV, adverse effects of ART, genetic predisposition, and chronic stress (Leung & Glesby, 2011).

FIGURE 17-8 Manifestations of lipodystrophy. Source: James, W. D., Berger, T., & Elston, D. (2006). *Andrews' diseases of the skin: Clinical dermatology* (10th ed.) St. Louis: Saunders.

Management of metabolic disorders currently focuses on detecting problems early, dealing with the symptoms, and helping the patient cope with new problems and additional drugs. It is important to recognize and treat these problems early, especially because cardiovascular disease and lactic acidosis are potentially fatal complications. A frequent first intervention is to change ART because some drugs are more often associated with these problems than are others (see Table 17-15). Lipid abnormalities are generally treated with lipid-lowering drugs, dietary changes, and exercise. Insulin resistance is treated with hypoglycemic drugs and weight loss. Bone disease may be improved with exercise, dietary changes, and calcium and vitamin D supplements.

Body changes that combine fat accumulation and wasting are major problems for patients with this syndrome. Human growth hormone, testosterone, and anabolic steroids have been used to help

resolve these changes, but the results are inconclusive. Some patients may undergo plastic surgery procedures such as liposuction or facial implants to deal with the body changes associated with fat redistribution. There is little evidence that exercise or dietary changes make any difference. Nursing interventions must focus on helping the patient make treatment decisions and on dealing with negative changes in body image (CANAC, 2013).

End-of-Life Care.

Despite new developments in the treatment of HIV infection, many patients eventually experience disease progression, disability, and death. Sometimes these occur because treatments do not work for the patient. Sometimes the patient's HIV infection becomes resistant to all available drug therapies. In addition, ART is now allowing people living with HIV to live longer and to develop diseases of aging, such as cardiovascular and endocrine problems that lead to death. Nursing care during the terminal phase of any disease must focus on keeping the patient comfortable, facilitating emotional and spiritual acceptance of the finite nature of life, and helping the patient's significant others deal with grief and loss. Nurses become pivotal care providers during the terminal phase of illness, especially in HIV disease, for which patients and families often choose terminal care at home. (End-of-life care is discussed in Chapter 13.)

Ethical Dilemmas

Duty to Treat

Situation

A nurse in a community clinic has just discovered that Ms. Joyce Ming, a patient with respiratory problems, has human immunodeficiency virus (HIV) infection. The nurse is concerned about contact with Ms. Ming and her body fluids. She requests that she not be assigned to Ms. Ming's care. The nurse believes that she

has the right to refuse to care for Ms. Ming because she has her own family to support and protect.

Important Points for Consideration

- According to the Canadian Nurses Association's *Code of Ethics,* the nurse must not discriminate in the provision of nursing care on the basis of cultural or socioeconomic background or health status.
- Health care providers have contact with patients every day who may have infectious blood or other body fluids.
- Infection precautions are instituted to protect health care workers from potentially infectious blood or other body fluids.
- There are two situations in which nurses can refuse to care for patients if employers are notified in advance: (a) when caring for a patient would conflict with a nurse's deeply held religious belief or (b) when there might be greater potential harm to the nurse than benefit to the patient (e.g., if the nurse were immuno-compromised).
- The Canadian Human Rights Commission Policy (1996) on HIV/AIDS (acquired immune deficiency syndrome) prohibits discrimination based on HIV/AIDS status.
- If a nurse's primary concern is personal safety, the nurse needs to re-examine her or his commitment to the nursing profession.

Clinical Decision-Making Questions

1. How should a nurse address this issue if a colleague refused to provide care for a patient with HIV infection?
2. If nurses could select which patients they would care for, how would that affect their ability to care for patients in general?

Evaluation

The expected outcomes are that the patient at risk for HIV infection will do the following:

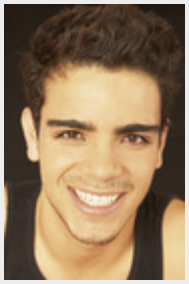
- Analyze personal risk factors
- Develop and implement a personal plan to decrease risks
- Get tested for HIV infection

The expected outcomes are that the patient with HIV infection will do the following:

- Describe basic aspects of the effects of HIV on the immune system
- Compare and contrast various treatment options for HIV disease
- Work with a team of health care providers to achieve optimal health
- Prevent transmission of HIV to others

Case Study

At Risk for Human Immunodeficiency Virus Disease



Source: Blend Images/Shutterstock.com.

Patient Profile

Mr. Emilio Chavez, a 20-year-old university student, comes to the student health centre with pain on urination.

Subjective Data

- Describes pain as "Just like it felt when I had the clap last year"
- Provides a history of sexual activity since age 15; reports lifetime sexual partners as six women and two men
- Denies injected-drug use, tobacco use, or corticosteroid therapy
- Uses alcohol (mainly beer) at weekend parties and has smoked marijuana, but not recently
- Recent sexual activity has been on weekends during or after beer parties

Objective Data

Physical Examination

- 180 cm tall, 76 kg, temperature 38°C, purulent urethral discharge noted

Laboratory Studies

- Urine test for *Neisseria gonorrhoeae* yields positive result

Collaborative Care

- Intramuscular injection with ceftriaxone, 250 mg
- Doxycycline, 100 mg orally, twice daily for 7 days

Discussion Questions

1. Why should Mr. Chavez be encouraged to be tested for human immunodeficiency virus (HIV)?
2. How will the nurse counsel Mr. Chavez about the testing process? How can the nurse help him prepare for the test and the test results?
3. What further questions will the nurse need to ask Mr. Chavez before the nurse can determine his educational needs?
4. Ask a classmate to be "Mr. Chavez" and role-play HIV risk assessment, risk-reduction counselling, pretest and post-test counselling.
5. ***Priority Decision:*** What are the main considerations to cover when teaching about barrier methods of protection? Are there cultural components that may affect the nurse's approach to teaching about condoms?
6. How will the nurse discuss the issue of partner notification with Mr. Chavez?
7. ***Priority Decision:*** Mr. Chavez's HIV test result comes back positive. What are the priority nursing decisions? What psychosocial issues would the nurse consider? What are the most important things for Mr. Chavez to know at the first meeting with him after he gets his diagnosis? How might he react, and how should the nurse deal with it?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. What are nursing responsibilities regarding emerging and re-emerging infections? *(Select all that apply)*
   a. Educating clients about risks of developing emerging and re-emerging infections
   b. Maintaining awareness of unusual disease patterns
   c. Participating in immunization programs
   d. Using infection control procedures
   e. Examining prescribing practices to ensure appropriate antibiotic use
2. Which of the following antibiotic-resistant organisms are resistant to normal hand soap?
   a. Vancomycin-resistant enterococci
   b. Methicillin-resistant *Staphylococcus aureus*
   c. Penicillin-resistant *Streptococcus pneumoniae*
   d. β-Lactamase–producing *Klebsiella pneumoniae*
3. How is human immunodeficiency virus (HIV) transmitted?
   a. Most commonly as a result of sexual contact
   b. In all infants born to women with HIV infection
   c. Only when there is a large viral load in the blood
   d. Frequently in health care workers with needle-stick exposures
4. Which is the common physiological change after HIV infection?
   a. The virus replicates mainly in B lymphocytes before spreading to $CD4^+$ T cells in lymph nodes.
   b. The immune system is impaired predominantly by infection and destruction of $CD4^+$ T cells.
   c. Infection of monocytes may occur, but these cells are destroyed by antibodies produced by oligodendrocytes.

d. A long period develops during which the virus is not found in the blood and there is little viral replication.

5. Which of the following statements is false?
   a. "Infection with HIV results in a chronic disease with acute exacerbations."
   b. "Untreated HIV infection can remain in the early chronic stage for a decade or more."
   c. "Late-stage infection is often called *acquired immune deficiency syndrome (AIDS).*"
   d. "Opportunistic diseases occur more often when the $CD4^+$ T-cell count is high and the viral load is low."
6. When is AIDS diagnosed in an HIV-infected person?
   a. When an AIDS-defining illness develops.
   b. When the amount of HIV in the blood increases.
   c. When the CD4:CD8 ratio is reversed to less than 2 : 1.
   d. When the person has oral hairy leukoplakia, an infection caused by Epstein-Barr virus.
7. What does screening for HIV infection generally involve?
   a. Laboratory analysis of blood to detect HIV antigen
   b. Electrophoretic analysis of HIV antigen in plasma
   c. Laboratory analysis of blood to detect HIV antibodies
   d. Analysis of lymph tissues for the presence of HIV RNA
8. What is the indication for use of antiretroviral drugs?
   a. Cure acute HIV infection
   b. Treat opportunistic diseases
   c. Decrease viral RNA levels
   d. Supplement radiation therapy and surgery
9. Which statement about metabolic adverse effects of ART is true? *(Select all that apply)*
   a. "These are annoying symptoms that are ultimately harmless."

b. “ART-related body changes include central fat accumulation and peripheral wasting.”

c. “Lipid abnormalities include increases in triglycerides and decreases in high-density cholesterol.”

d. “Insulin resistance and hyperlipidemia can be treated with drugs to control glucose and cholesterol.”

e. “Insulin resistance and hyperlipidemia are more difficult to treat in HIV-infected clients than in uninfected people.”

10. Which of the following descriptions of opportunistic diseases in HIV infection is correct?

a. Usually occur one at a time

b. Generally slow to develop and progress

c. Occur in the presence of immuno-suppression

d. Curable with appropriate pharmacological intervention

11. Of the following, which is the most appropriate nursing intervention to help an HIV-infected client adhere to the treatment regimen?

a. Give the client a DVD and a brochure to view and read at home.

b. Volunteer to “set up” a drug pillbox for a week at a time.

c. Inform the client that the adverse effects of the drugs are bad but that they go away after a while.

d. Assess the client's lifestyle and find adherence cues that fit into the client's lifestyle.

12. Which strategy can the nurse teach the client to eliminate the risk of transmission of HIV?

a. Using sterile equipment to inject drugs

b. Cleaning equipment used to inject drugs

c. Taking zidovudine (azidothymidine [AZT], ZDV, Retrovir) during pregnancy

d. Using latex barriers to cover genitals during sexual contact

1. a, b, c, d, e; 2. a; 3. a; 4. b; 5. d; 6. a; 7. c; 8. c; 9. b, c, d; 10. c; 11. d; 12. a.

CHAPTER 18

Cancer

Written by, Carolee Polek

Adapted by, Rosemary Cashman

LEARNING OBJECTIVES

1. Describe the prevalence, the incidence, and the death rates of cancer in Canada.
2. Describe the biological processes involved in cancer.
3. Differentiate the three phases of cancer development.
4. Describe the role of the immune system in relation to cancer.
5. Describe the use of the classification systems for cancer.
6. Explain the role of the nurse in the prevention and detection of cancer.
7. Explain the use of surgery, radiation therapy, chemotherapy, and biological therapy in the treatment of cancer.
8. Differentiate between external beam radiation and brachytherapy.
9. Identify the classifications of chemotherapeutic agents and methods of administration.
10. Describe the effects of radiation therapy and chemotherapy on normal tissues.
11. Identify the types and effects of biological therapy agents.
12. Describe the nursing management of patients receiving radiation therapy, chemotherapy, and biological therapy.
13. Describe the nutritional therapy for patients with cancer.
14. Describe the complications that can occur in advanced cancer.
15. Describe the appropriate psychosocial support of a patient with cancer and the patient's family.

Definition and Incidence

Cancer is a group of more than 200 diseases characterized by uncontrolled and unregulated growth of cells. It can occur in persons of all ages and all ethnicities and is a major health problem. In 2016, the Canadian Cancer Society's Steering Committee on Cancer Statistics estimated that 202 400 new cancer cases (excluding 78 300 nonmelanoma skin cancers) would be diagnosed and that 78 000 people would die from cancer in Canada. As the population ages, the incidence of cancer rises. Among people with cancer, 43% of new cases and 62% of deaths caused by cancer occur in those who are at least 70 years of age. Cancer is more common among women between the age of 20 and 59, primarily because of breast and thyroid cancer. In all other age groups, cancer is more common in male patients. Cancer incidence and death rates also increase from west to east across the country. Of the 202 400 new cases of cancer predicted in 2016, it was estimated that slightly more than half (50.4%) would be lung, breast, colorectal, or prostate cancers. Because thousands of Canadians are expected to die from cancer every year, there are significant repercussions on Canadian families and the economy (Canadian Cancer Society's Steering Committee on Cancer Statistics, 2016). Estimated cancer incidences and mortality rates by site (type) and sex are presented in Tables 18-1 and 18-2.

TABLE 18-1

NEW CASES FOR CANCER BY SITE (TYPE) AND SEX, CANADA, 2016

Male		Female	
Type	**New Case Estimate**	**Type**	**New Case Estimate**
Prostate	21 600	Breast	25 700
Lung	14 400	Lung	14 000
Colorectal	14 500	Colorectal	11 600
Non-Hodgkin's lymphoma	4 400	Non-Hodgkin's lymphoma	3 600
Bladder	6 600	Uterus	6 600
Kidney	4 100	Thyroid	5 300

TABLE 18-2

ESTIMATED DEATHS FOR CANCER BY SITE AND SEX, CANADA, 2016

Male		Female	
Type	**Deaths**	**Type**	**Deaths**
Lung	10 900	Lung	9 800
Prostate	4 000	Breast	4 900
Colorectal	5 000	Colorectal	4 300
Pancreas	2 400	Pancreas	2 400
Bladder	1 650	Ovary	1 750

Source: Canadian Cancer Society's Steering Committee on Cancer Statistics. (2016). *Canadian Cancer Statistics 2016.* Toronto: Canadian Cancer Society.

Prevalence is the total number of people who are living with a diagnosis of cancer. Advances in research in the areas of early detection, treatment, and supportive therapies have resulted in more people surviving cancer, especially in the pediatric population. Prevalence is, therefore, more often and more usefully defined as patients still alive 10 years after the initial diagnosis with cancer. Over a lifetime, it is estimated that two in five Canadians (45% of male Canadians and 42% of female Canadians) will develop cancer and one in four (29% of male Canadians and 24% of female Canadians) will die from it (Canadian Cancer Society's Steering Committee on Cancer Statistics, 2016). In 2012, cancer was the leading cause of death in Canada, accounting for 30% of all deaths, with cardiovascular diseases (heart and cerebro-vascular diseases) in second place (25% of deaths; Statistics Canada, 2015). Lung cancer remains the leading cause of premature death from cancer (Canadian Cancer Society's Steering Committee on Cancer Statistics, 2016), and tobacco use has long been recognized as a significant risk for the development of this and other types of cancer. Smoking prevalence and amount have declined in the Canadian population overall; however, smoking rates among Indigenous peoples

are more than twice as high as those in the non-Indigenous population (39% versus 20.5%; Gionet & Roshanafshar, 2013).

Cancer incidence and mortality are tracked by province and territory through cancer registries. Statistics document the incidence and prevalence of cancer but cannot reveal the physiological and psychosocial effect of cancer on individuals, families, and society. Nurses play a critical role in shaping attitudes and promoting behaviours that prevent the development of cancer and facilitate adjustment to living with cancer.

Progress Made in Cancer Prevention: Modifiable Risk Factors

Many well-known and common cancer risk factors are preventable. For example, in addition to tobacco use, known risk factors include excessive body weight, lack of physical activity, unhealthy eating habits, alcohol consumption, and excessive exposure to the sun. Several of these factors are related to other chronic diseases such as diabetes, kidney failure, chronic obstructive lung disease, and cardiovascular disease. The Canadian Cancer Society reported a worrisome rising trend in obesity: The percentage of obese Canadians increased from 15% in 2003 to 18% in 2010 (Gotay, Katzmarzyk, Janssen, et al., 2012). In addition, as recently as 2014, 46% of Canadians were physically inactive (Statistics Canada, n.d.). All of these risk factors are within the control of each individual. If these lifestyle factors were modified, the rates of cancers and other chronic diseases would be reduced (Table 18-3). Concerted efforts in health promotion and disease prevention strategies are required in every province to alert and educate the public about what they can do to achieve improvements in health and longevity.

TABLE 18-3

MODIFIABLE RISK FACTORS FOR SELECTED CANCER TYPES

Cancer Type	Risk Factor								
	Smoking	Overweight/Obesity	Physical Activity	Poor Diet	Sun Exposure/Outdoor Tanning	Alcohol Consumption	Infections (Viruses and Bacteria)	Pharmaceuticals	Occupa Exposu
Bladder	X								X
Body of uterus		X	X					X

Biological Processes of Cancer

The term *cancer* encompasses many diseases of multiple causes that can arise in any cell of the body capable of evading regulatory controls over proliferation and differentiation. Two major dysfunctions present in the process of cancer are defective cellular *proliferation* (growth) and defective cellular *differentiation.*

Defects in Cellular Proliferation

Normally, most tissues of the human adult contain a population of predetermined, undifferentiated cells known as *stem cells. Predetermined* means that the stem cells of a particular tissue will ultimately differentiate and become mature, functioning cells of that tissue and only that tissue.

Cell proliferation originates in the stem cell and begins when the stem cell enters the cell cycle (Figure 18-1). The time from when a cell enters the cell cycle to when the cell divides into two identical cells is called the *generation time of the cell.* A mature cell continues to function until it degenerates and dies.

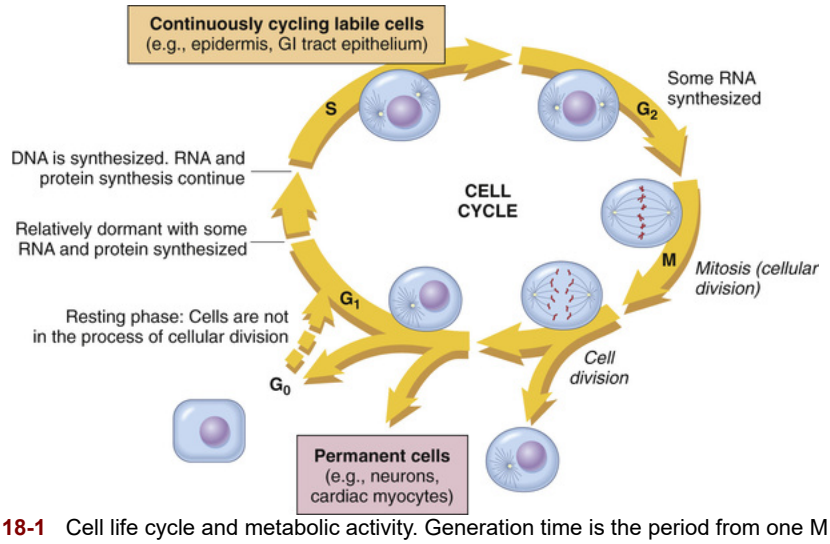

FIGURE 18-1 Cell life cycle and metabolic activity. Generation time is the period from one M (mitosis) phase to the next. Cells not in the cycle but capable of division are in the resting phase (G_0). *DNA*, deoxyribonucleic acid; *GI*, gastro-intestinal; *RNA*, ribonucleic acid. Source: Adapted from Kumar, V., Abbas, A. K., Fausto, N., et al. (2010). *Robbins and Cotran pathologic basis of disease* (8th ed., p. 86). Philadelphia: W. B. Saunders.

All cells of a tissue are controlled by an intracellular mechanism that determines when cellular proliferation is necessary. Under normal conditions, a state of dynamic equilibrium is constantly maintained (i.e., rate of cellular proliferation equals rate of cellular degeneration). Normally, the process of cellular division and proliferation is activated only in the event of cellular degeneration or death. Cellular proliferation also occurs if the body has a physiological need for more cells. For example, the white blood cell (WBC) count normally increases in the presence of infection.

Another mechanism for proliferation control in normal cells is *contact inhibition.* Normal cells "respect" the boundaries and territory of the cells surrounding them; they do not invade a territory that is not their own. The neighbouring cells are thought to inhibit cellular growth through the physical contact of the surrounding cell membranes. Cancer cells grown in tissue culture are characterized by loss of contact inhibition. These cells breach cellular boundaries and will grow on top of one another and also on top of or between normal cells.

The rate of normal cellular proliferation differs in each body tissue. In some tissues, such as bone marrow, hair follicles, and epithelial lining of the gastro-intestinal (GI) tract, the rate of cellular proliferation is rapid. In other tissues, such as myocardium, neurons, and cartilage, cellular proliferation is slow or does not occur at all.

Cancer cells usually proliferate in the manner and at the same rate as the normal cells of the tissue from which they arise. However, cancer cells respond differently than normal cells to the intracellular signals that regulate the state of dynamic equilibrium. Whereas normal cell proliferation is regulated according to the body's needs, cell division in cancer is dysregulated and haphazard, and proliferation of cancer cells is indiscriminate and continuous. In this way, with each cell division creating two or more offspring cells, the tumour mass continuously doubles in size: 1 cell → 2 cells → 4 cells → 8 cells → 16 cells, and so on. This is termed the *pyramid effect.* The time required for a tumour mass to double in size is known as its *doubling time.*

According to the stem cell theory, the loss of intracellular control of proliferation results from a mutation of the stem cells (Tannock, Hill, Bristow, et al., 2013). The stem cells are viewed as the target or the origin of cancer development. The DNA of the stem cell is substituted or permanently rearranged. When this happens, the stem cell has mutated. Once the cell has mutated, one of three things can occur: (a) the cell can die, either from the damage resulting from the mutation or from initiation of a programmed cellular suicide called *apoptosis;* (b) the cell can recognize the damage and repair itself; or (c) the mutated cell can survive and pass along the damage to its daughter cells. Mutated cells that survive have the potential to become malignant (i.e., cells with invasive and metastatic potential), especially if the progeny cells acquire additional mutations.

Proliferating cells rely on a genetic blueprint for tissues and organs, which is found on chromosomes within the nucleus of the cell. Structures called *telomeres,* consisting of a repeated DNA code, are found at the end of chromosomes and serve to protect the genetic data within the chromosomes and facilitate normal cell division. Each time a cell divides, the telomere becomes shorter, and a small sequence of genetic material is not copied. Ultimately, the cell is unable to undergo further division, becomes inactive (senescent), and dies. Cancer cells produce an enzyme called *telomerase* that prevents telomere shortening and allows the cells to escape senescence and death. Telomerase thus promotes the immortalization of cells and has a role in the development of cancer, as well as in the process of aging.

Defects in Cellular Differentiation

Cellular differentiation is normally an orderly process in which the cell progresses from a state of immaturity to a state of maturity. Because all body cells are derived from fertilized ova, all cells have the potential to perform all body functions. As cells differentiate, this potential is narrowed, and the mature cell is capable of performing only specific functions (Figure 18-2).

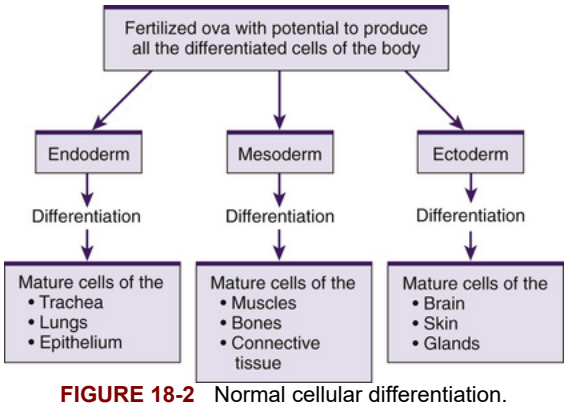

FIGURE 18-2 Normal cellular differentiation.

In cellular differentiation, the phasing out of cellular potential is stable and orderly. Under normal conditions, the differentiated cell is stable and does not *dedifferentiate* (i.e., revert to a previous undifferentiated state).

The exact mechanism that controls cellular differentiation and proliferation is not completely understood. Two types of normal genes are important regulators of normal cellular processes: **Proto-oncogenes** promote growth, whereas **tumour suppressor genes,** such as tumour protein 53, suppress growth. Both can be affected by mutations. Those that alter the expression of proto-oncogenes can

activate them to function as **oncogenes** (tumour-inducing genes). Mutations that alter tumour suppressor genes render them inactive, which results in a loss of their tumour suppressor ability.

The proto-oncogene has been described as the genetic lock that keeps the cell in its mature functioning state. When this lock is "unlocked," as may occur through exposure to **carcinogens** (cancer-causing agents capable of producing cellular alterations) or oncogenic viruses, genetic alterations and mutations occur. The abilities and properties that the cell had during fetal development are again expressed. Oncogenes interfere with normal cell expression under some conditions, causing the cell to become malignant. This cell regains fetal properties and function. For example, some cancer cells produce new proteins, such as those characteristic of the embryonic and fetal periods of life. These proteins, located on the cell membrane, include carcinoembryonic antigen (CEA) and alpha-fetoprotein. They can be detected in human blood by laboratory studies (see "Role of the Immune System" section). Other cancer cells, such as small cell carcinoma of the lung, produce hormones (see "Complications Resulting From Cancer" section) that are ordinarily produced by cells arising from the same embryonic cells as the tumour cells.

Tumours can be classified as benign or malignant. In general, **benign neoplasms** are well-differentiated, and **malignant neoplasms** are undifferentiated. Malignant tumour cells have the ability to invade and metastasize, unlike benign neoplasms. Other differences between benign and malignant neoplasms are listed in Table 18-4.

TABLE 18-4

COMPARISON OF BENIGN AND MALIGNANT NEOPLASMS

Characteristic	Benign	Malignant
Encapsulated	Usually	Rarely
Differentiated	Normally	Undifferentiated
Metastasis	Absent	Frequently present
Recurrence	Rare	Possible
Vascularity	Slight	Moderate to marked
Mode of growth	Expansive	Infiltrative and expansive
Cell characteristics	Fairly normal; similar to those of parent cells	Abnormal; bear little resemblance to those of parent cells

Development of Cancer

In this section, a theoretical model of the development of cancer is described. The cause and development of each type of cancer are likely to be multifactorial. It is not known how many tumours have a chemical, environmental, genetic, immunological, or viral origin. Cancers may arise spontaneously from causes that are thus far unclear.

It is a common misunderstanding that the development of cancer is a rapid, haphazard event. However, the natural history of cancer is an orderly process comprising several stages and occurring over a period of time. These stages are *initiation, promotion,* and *progression* (Figure 18-3).

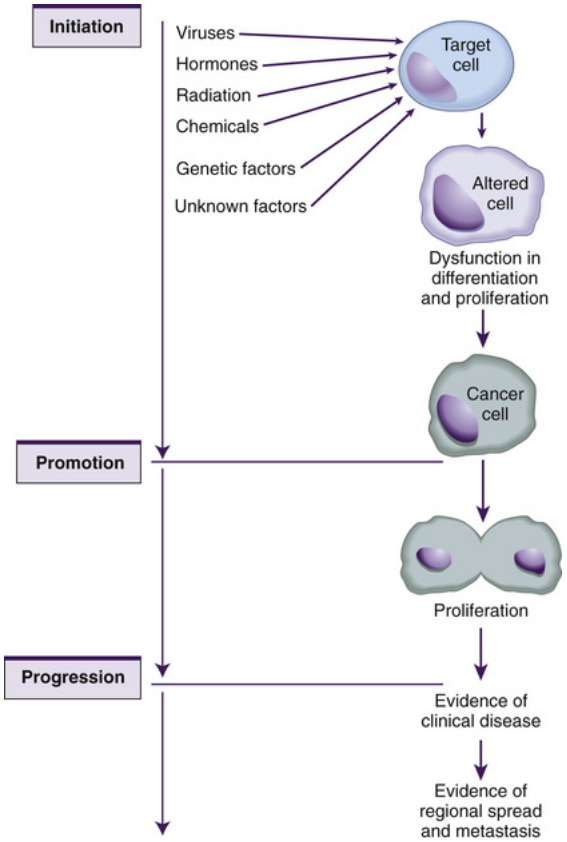

FIGURE 18-3 Process of cancer development.

Initiation.

The first stage, *initiation,* is a mutation in the cell's genetic structure resulting from an inherited mutation, an error that occurs during DNA replication or after exposure to a carcinogen. This altered cell has the potential for developing into a *clone* (progeny of a single cell) of neoplastic cells.

Many carcinogens are detoxified by protective enzymes and harmlessly excreted. If this protective mechanism fails, carcinogens can enter a cell's nucleus and alter its DNA. The cell may die or repair itself. However, if cell death or repair does not occur before cell division, the cell replicates into daughter cells, each with the same genetic alteration. Carcinogens may be chemical, radioactive, or viral in nature. In addition, some genetic anomalies increase the susceptibility of individuals to certain cancers. Common characteristics of carcinogens are that their effects in the stage of initiation are usually irreversible and additive.

Chemical Carcinogens.

Chemicals were identified as cancer-causing agents in the latter part of the 18th century, when Percival Pott noted that chimney sweeps had a higher incidence of cancer of the scrotum in association with exposure to soot residues in chimneys. Over time, more chemical agents were identified as actual and potential carcinogens. Evidence indicated that individuals undergoing sustained exposure to certain chemicals had a greater incidence of certain cancers than others. Because of the long latency period from the time of exposure to the development of cancer, identifying cancer-causing chemicals is difficult. Chemicals that cause cancer in animals may or may not cause the same specific cancer in humans. Some chemicals are cancer causative in their environmental form, but others must first undergo specific changes to become carcinogenic.

Certain drugs have also been identified as carcinogens. Drugs that are capable of interacting with DNA (e.g., alkylating agents) and immuno-suppressive agents have the potential to cause neoplasms in humans. The use of alkylating agents (e.g., cyclophosphamide and nitrogen mustards), either alone or in

combination with radiation therapy, has been associated with an increased incidence of acute myelogenous leukemia in persons treated for Hodgkin's disease, non-Hodgkin's lymphomas, and multiple myeloma. These secondary leukemias are relatively refractory to treatment. Secondary leukemia has also been observed in persons who have undergone transplantation surgery and taken immuno-suppressive drugs.

Radiation.

Early in the 20th century, ionizing radiation (described later) was found to cause cancer in almost any human body tissue. The safe threshold for exposure to radiation is not known, and there is considerable debate surrounding the effect of exposure to low-dose radiation over time. Radiation damages cellular DNA. Certain malignancies have been linked to radiation:

1. Leukemia, lymphoma, thyroid cancer, and other cancers increased in incidence in the general population of Hiroshima and Nagasaki after the atomic bomb explosions.
2. A higher incidence of bone cancer occurs in persons exposed to radiation in certain occupations, such as radiologists, radiation chemists, and uranium miners.
3. Thyroid cancer has a higher incidence among persons who have received radiation to the head and neck area for treatment of a variety of disorders, such as acne, tonsillitis, sore throat, or enlarged thyroid gland.
4. The incidence of childhood cancer is higher among children exposed to radiation during fetal life.

Ultraviolet radiation has long been associated with melanoma, squamous cell carcinoma, and basal cell carcinoma of the skin. Skin cancer is by far the most common type of cancer in North America. Melanoma is a particularly aggressive skin cancer that responds poorly to treatment. Although the cause of melanoma is probably multifactorial, mounting evidence suggests that ultraviolet radiation secondary to sunlight exposure is linked to the development of melanoma.

Viral and Bacterial Carcinogens.

Certain DNA and RNA viruses, termed *oncogenic viruses,* can transform the cells they infect and induce malignant transformation. Viruses have been identified as causative agents of cancer in animals and humans. For example, cells from patients with Burkitt's lymphoma have consistently shown evidence of the presence of the Epstein-Barr virus (EBV) in vitro. This virus also causes infectious mononucleosis; it is unclear which precise process results in infectious disease versus lymphoma. Persons with acquired immunodeficiency syndrome (AIDS), which is caused by a retrovirus, have a higher incidence of Kaposi's sarcoma (see Chapter 17). Other viruses that have been linked to the development of cancer include hepatitis B and C viruses, associated with hepatocellular carcinoma, and human papillomavirus, associated with squamous cell carcinomas such as cervical, anal, and head and neck cancers. *Helicobacter pylori* is a bacterium found in the stomach of two-thirds of the world's population and is implicated in the development of gastric and duodenal ulcers, as well as of some gastric cancers.

Genetic Susceptibility.

Cancer-related genes have been identified that increase an individual's susceptibility to the development of certain cancers. For example, a woman with mutations in the gene *BRCA1* or *BRCA2* has a 40% to 85% risk of developing breast cancer in her lifetime. However, 95% of women who develop breast cancer do not possess these genetic mutations. On the basis of current knowledge, it is believed that only 5% to 10% of cancers have a strong genetic link (Loud & Hutson, 2011).

Promotion.

A single alteration of the genetic structure of the cell is not sufficient to result in cancer. However, the odds of cancer development are increased with the presence of promoting agents. *Promotion,* the second stage in the development of cancer, is characterized by the reversible proliferation of the altered cells. Consequently, with an increase in the altered cell population, the likelihood of sustained mutagenesis is increased.

An important distinction between initiation and promotion is that the activity of promoters is reversible. This is a key concept in cancer prevention. Promoting factors include dietary fat, obesity, cigarette smoking, and alcohol consumption. The withdrawal or reduction of these factors can reduce the risk of cancer development.

Several promoting factors exert activity against specific types of body tissues or organs, and these agents tend to promote the development of specific kinds of cancer. For example, cigarette smoke is a promoting agent in bronchogenic carcinoma and, in conjunction with alcohol intake, promotes the development of esophageal and bladder cancers. Some carcinogens *(complete carcinogens)* are capable of both initiating and promoting the development of cancer. Tobacco is an example of a complete carcinogen, capable of initiating and promoting the development of cancer.

A period of time, ranging from 1 to 40 years, elapses between the initial genetic alteration and the actual clinical evidence of cancer. This period, called the *latency period,* is now theorized to comprise both the initiation and the promotion stages in the natural history of cancer (DeVita, Lawrence, & Rosenberg, 2014). The variation in the length of time that elapses before the cancer becomes clinically evident is associated with the mitotic rate of the tissue of origin and environmental factors. For most cancers, the process of developing takes years or even decades.

For the disease process to become clinically evident, the cells must reach a "critical mass." A 1-cm tumour (the size usually detectable on palpation) contains 1 billion cancer cells. A 0.5-cm tumour is the smallest that can be detected by current diagnostic measures, such as magnetic resonance imaging (MRI).

Progression.

Progression is the final stage in the natural history of a cancer. This stage is characterized by increased growth rate of the tumour, as well as by increased invasiveness and spread of the cancer to a distant site **(metastasis).** Certain biochemical and morphological alterations take place during this stage, enabling the tumour to survive and thrive in its primary environment and throughout the process of metastasis.

Some cancers metastasize early in the process of development (e.g., premenopausal breast cancer), whereas others spread regionally and rarely metastasize (e.g., glioblastoma multiforme, basal cell carcinoma of the skin). Certain cancers seem to have an affinity for a particular tissue or organ as a site of metastasis (e.g., colon cancer spreads to the liver); other cancers are unpredictable in their pattern of metastasis (e.g., melanoma). Frequent sites of metastasis are the lungs, the brain, the bone, the liver, and the adrenal glands (Figure 18-4). Metastasis is a multistep process beginning with the rapid growth of the primary tumour (Figure 18-5). As the tumour increases in size, development of its own blood supply is crucial for its survival and growth. The process of the formation of blood vessels within the tumour itself is termed **tumour angiogenesis** and is facilitated by tumour angiogenesis factors produced by the cancer cells. As the tumour grows, it can begin to mechanically invade surrounding tissues, growing into areas of the least resistance.

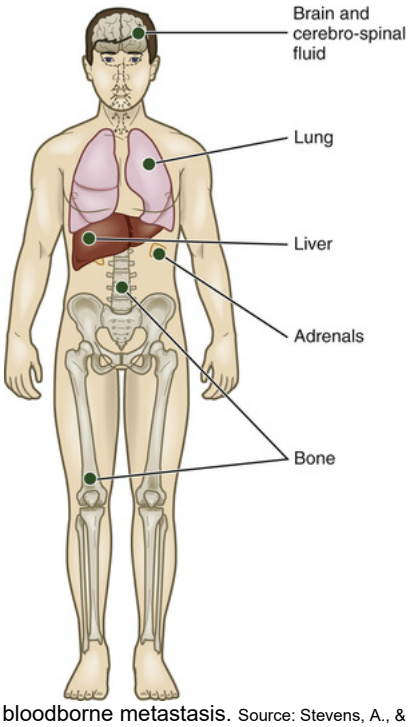

FIGURE 18-4 Main sites of bloodborne metastasis. Source: Stevens, A., & Lowe, J. (2000). *Pathology: Illustrated review in color* (2nd ed.). London: Mosby.

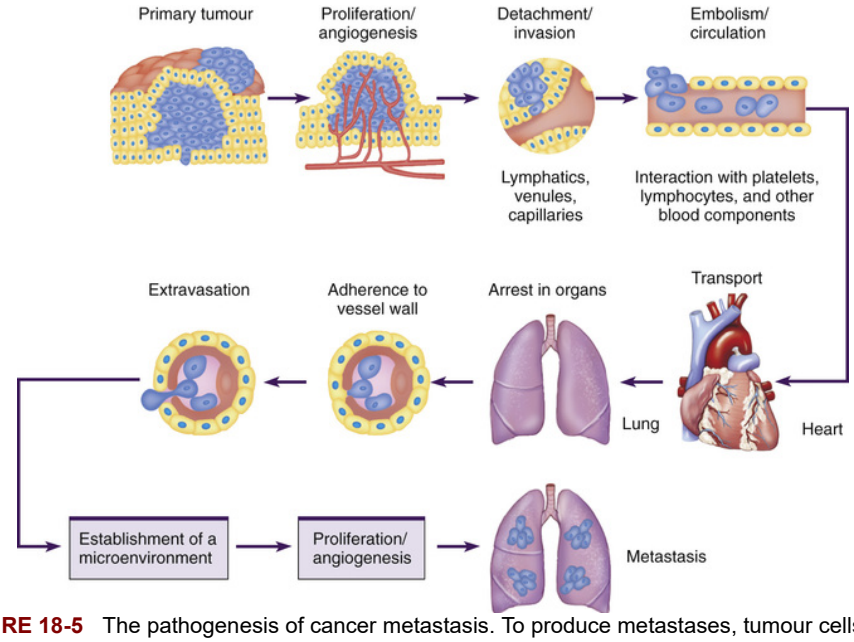

FIGURE 18-5 The pathogenesis of cancer metastasis. To produce metastases, tumour cells must detach from the primary tumour and enter the circulation, survive in circulation, adhere to capillary basement membrane, obtain entrance into the organ parenchyma, respond to growth factors, proliferate and induce angiogenesis, and evade host defences. Source: Reprinted by permission from Macmillan Publishers Ltd: NATURE REVIEWS CANCER, Fidler, I. T. (2003). The pathogenesis of cancer metastasis: the 'seed and soil' hypothesis revisited, 3, 453-458, copyright © 2003.

Certain subpopulations of tumour cells are able to detach from the primary tumour, invade the tissue surrounding the tumour, and penetrate the walls of lymphatic or vascular vessels for metastasis to a

distant site. Unique capabilities of some tumour cells facilitate this process. First, rapid proliferation of malignant cells causes mechanical pressure that lead to penetration of surrounding tissues. Second, certain cells have decreased cell-to-cell adhesion in comparison with normal cells. This property allows these cancer cells to physically detach from their site of origin and invade vascular and organ structures. In addition, motility factors are produced by both tumour and normal cells, and changes in the tumour's cytoskeleton further facilitate movement of tumour cells. Some cancer cells produce matrix metalloproteases, a family of lytic enzymes that can erode the basement membrane (a tough barrier surrounding tissues and blood vessels) of the tumour itself, as well as lymph and blood vessels, muscles, nerves, and most epithelial boundaries, which allows for the spread of the tumour. Once free from the primary tumour, metastatic tumour cells frequently travel to distant organ sites via lymphatic and haematogenous routes. Because these two routes are interconnected, it is theorized that tumour cells metastasize via both routes.

Haematogenous metastasis involves several steps, beginning with the penetration of blood vessels by primary tumour cells through the release of metalloproteases, as described previously. The tumour cells then enter the circulation, adhere to small blood vessels of distant organs, and penetrate these vessels, again with the assistance of metalloproteases. Most tumour cells do not survive this process and are destroyed by mechanical mechanisms (e.g., turbulence of blood flow) and cells of the immune system. However, the formation of a combination of tumour cells, platelets, and fibrin deposits may protect some tumour cells from destruction in blood vessels.

In the lymphatic system, tumour cells may be "trapped" in the first lymph node confronted, or they may bypass regional lymph nodes and travel to more distant lymph nodes. This phenomenon, termed *skip metastasis*, is exhibited in certain malignancies, such as esophageal cancers, and is the basis for questions about the effectiveness of dissection of regional lymph nodes for the prevention of some distant metastases. Tumour cells that do survive the process of metastasis must create and maintain an environment in the distant organ site that is favourable to their growth and development. This is facilitated by the ability of tumour cells to evade cells of the immune system and to produce a vascular supply within the metastatic site similar to that developed in the primary tumour site. Vascularization is critical for the supply of nutrients to the metastatic tumour and for the removal of waste products. Metalloproteases contribute to vascularization through release of angiogenesis promoters such as vascular endothelial growth factor (VEGF).

Cells of the primary tumour and metastatic site may develop from a single cell or may be *clones* (cells derived from a single cell of origin). However, as the primary and metastatic sites develop, the cells quickly become more heterogeneous as they repeatedly undergo spontaneous genetic mutations. The heterogeneous nature of the cells in primary and metastatic tumours makes them difficult to treat, inasmuch as they are more likely to become resistant to chemotherapy and radiation therapy. Surgical removal may be effective for some small, circumscribed tumours.

Role of the Immune System

This section is limited to a discussion of the role of the immune system in the recognition and destruction of tumour cells. (For a detailed discussion of immune system function, see Chapter 16.)

The immune system has the potential to distinguish normal (self) from abnormal (nonself) cells. For example, cells of transplanted organs can be "perceived" by the immune system as nonself entities and thus elicit an immune response. This response can ultimately result in the rejection of the organ. Similarly, cancer cells can be perceived as nonself entities and elicit an immune response that results in their rejection and destruction. However, unlike transplanted cells, cancer cells arise from normal "self" cells, and although mutated and thus different, the immune response that is mounted against cancer cells may be inadequate to reject and destroy the cancer cells.

Some cancer cells have changes on their cell surface antigens as a result of malignant transformation. These altered antigens are termed **tumour-associated antigens** (Figure 18-6). It is believed that one of the functions of the immune system is to respond to tumour-associated antigens. The response of the immune system to antigens of the malignant cells is termed **immunological surveillance.** Lymphocytes continually check cell surface antigens and detect and destroy cells with abnormal or altered antigenic determinants. It has been proposed that malignant transformation occurs continuously and that the malignant cells are destroyed by the immune response. Under most circumstances, immunological surveillance prevents these transformed cells from developing into clinically detectable tumours.

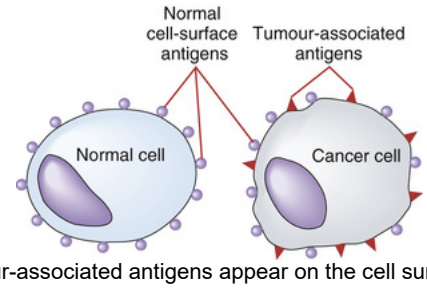

FIGURE 18-6 Tumour-associated antigens appear on the cell surface of malignant cells.

Virtually every cell type involved in normal immune responses and every function used to inactivate or remove antigens have been demonstrated in immune responses to tumours. These immune responses involve cytotoxic T cells, natural killer (NK) cells, macrophages, and B lymphocytes.

Cytotoxic T cells are thought to play a dominant role in resisting tumour growth. These cells are capable of killing tumour cells. T cells are also important in the production of cytokines (e.g., interleukin-2 [IL-2] and interferon-gamma [IFN-gamma], which stimulate T cells), NK cells, B cells, and macrophages.

NK cells are able to directly lyse tumour cells spontaneously without any prior sensitization. These cells are stimulated by IFN-gamma and IL-2 (released from T cells), which results in increased cytotoxic activity.

Monocytes and macrophages have several important roles in tumour immunity. Macrophages can be activated by IFN-gamma (produced by T cells) to kill tumour cells, but they may also injure normal cells. Macrophages also secrete cytokines, including interleukin-1 (IL-1), tumour necrosis factor (TNF), and colony-stimulating factors. The release of IL-1, coupled with the presentation of the processed antigen, stimulates activation and production of T lymphocytes. Interferon-alfa augments the killing ability of NK cells. TNF causes hemorrhagic necrosis of tumours and exerts cytocidal or cytostatic actions against tumour cells. Colony-stimulating factors regulate the production of various blood cells in the bone marrow and stimulate the function of various WBCs.

B lymphocytes produce specific antibodies that bind to and destroy tumour cells by complement fixation and lysis. These antibodies are often detectable in the serum and the saliva of an affected patient.

Mechanisms of Escape From Immunological Surveillance.

The process by which cancer cells evade the immune system is termed *immunological escape.* Theorized mechanisms by which cancer cells can escape immunological surveillance include (a) suppression of factors that stimulate T cells to react to cancer cells, (b) weak surface antigens that allow cancer cells to "sneak through" immunological surveillance, (c) the development of tolerance of the immune system to some tumour antigens, (d) suppression of the immune response by products secreted by cancer cells, (e) the induction of suppressor T cells by the tumour, and (f) blocking antibodies that bind tumour-associated antigens, thus preventing their recognition by T cells (Figure 18-7).

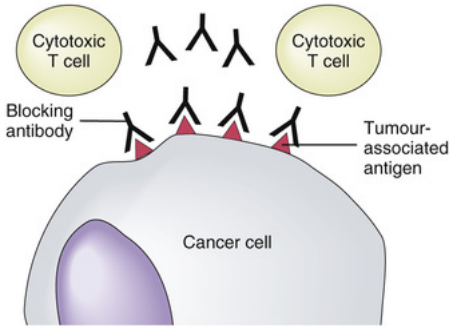

FIGURE 18-7 Blocking antibodies prevent T cells from interacting with tumour-associated antigens and from destroying the malignant cell.

Oncofetal Antigens.

Oncofetal antigens are a type of tumour antigen. They are found on both the surface and the inside of cancer cells, as well as on and inside fetal cells. These antigens are an expression of the shift of cancerous cells to a more immature metabolic pathway, an expression usually associated with embryonic or fetal periods of life. The reappearance of fetal antigens in malignant disease is not well understood, but it is believed to occur as a result of the cell's regaining its embryonic capability to differentiate into many different cell types.

Examples of oncofetal antigens are CEA and alpha-fetoprotein. CEA is found on the surface of cancer cells derived from the GI tract and from normal cells from the fetal gut, liver, and pancreas. Normally, it disappears during the last 3 months of gestation. CEA was originally isolated from colon cancer cells. However, elevated CEA levels have also been found in nonmalignant conditions (e.g., cirrhosis of the liver, ulcerative colitis, and heavy smoking). At present, the major value of CEA is its use as an indicator of the success of cancer treatment. For example, the persistence of elevated preoperative CEA titres after surgery indicates that the tumour was not completely removed. A rise in CEA levels after chemotherapy or radiation therapy may indicate recurrence or spread of the cancer.

Alpha-fetoprotein is produced by malignant liver cells, as well as fetal liver cells. Alpha-fetoprotein levels have also been found to be elevated in some cases of testicular carcinoma, viral hepatitis, and nonmalignant liver disorders. Alpha-fetoprotein has diagnostic value in primary cancer of the liver (hepatoma), but it is also produced in metastases to the liver. The detection of alpha-fetoprotein is of value in tumour detection and determination of tumour progression.

Other examples of oncofetal antigens currently being studied are CA-125, found in ovarian carcinoma; CA-19-9, found in pancreatic, colon, and breast cancer; and prostate-specific antigen, found in prostate cancer.

Classification of Cancer

Tumours can be classified according to anatomical site, histological analysis (grading), and extent of disease (staging). Tumour classification systems are intended to provide a standardized way to (a) communicate the cancer status of a patient to the members of the health care team, (b) assist in determining the most effective treatment plan, (c) evaluate the treatment plan, (d) help determine the prognosis, and (e) compare patients with similar conditions for statistical purposes.

Anatomical Site Classification

In the *anatomical classification* of tumours, the tumour is identified by the tissue of origin, the anatomical site, and the behaviour of the tumour (i.e., benign or malignant; Table 18-5). A **carcinoma** originates from embryonal *ectoderm* (skin and glands) and *endoderm* (mucous membrane linings of the respiratory, GI, and genito-urinary tracts). A **sarcoma** originates in the connective tissue of the body (fat, muscles, blood vessels, nerves, bones, or cartilage). Lymphomas and leukemias originate from the hematopoietic system.

TABLE 18-5

ANATOMICAL CLASSIFICATION OF TUMOURS

Site	Benign	Malignant
Epithelial Tissue Tumours*	Suffix: *-oma*	Suffix: *-carcinoma*
Surface epithelium	Papilloma	Carcinoma
Glandular epithelium	Adenoma	Adenocarcinoma
Connective Tissue Tumours†	Suffix: *-oma*	Suffix: *-sarcoma*
Fibrous tissue	Fibroma	Fibrosarcoma
Cartilage	Chondroma	Chondrosarcoma
Striated muscle	Rhabdomyoma	Rhabdomyosarcoma
Bone	Osteoma	Osteosarcoma
Nervous Tissue Tumours	Suffix: *-oma*	Suffix: *-oma*
Pineal region	Pineocytoma	Pineoblastoma
Nerve cells	Ganglioneuroma	Neuroblastoma
Hematopoietic Tissue Tumours		
Lymphoid tissue	—	Hodgkin's disease, non-Hodgkin's lymphoma
Plasma cells	—	Multiple myeloma
Bone marrow	—	Lymphocytic and myelogenous leukemia

*Body surfaces, lining of body cavities, and glandular structures.

†Supporting tissue, fibrotic tissue, and blood vessels.

Histological Analysis Classification

In **histological grading** of tumours, the appearance of cells and the degree of differentiation are evaluated. For many tumour cells, four grades are used:

- *Grade I:* Cells differ slightly from normal cells (mild dysplasia) and are well differentiated.
- *Grade II:* Cells are more abnormal (moderate dysplasia) and moderately differentiated.
- *Grade III:* Cells are very abnormal (severe dysplasia) and poorly differentiated.
- *Grade IV:* Cells are immature and primitive (anaplasia) and undifferentiated; cell of origin is difficult to determine.

Classifying Extent of Disease

Classifying the extent and spread of disease is termed **staging.** This classification system is based on a description of the extent of the disease rather than on cell appearance. The extent to which the disease has spread has important ramifications for prognosis. Although there are similarities in the staging of cancers, there are many differences between them, and thus they are based on a thorough knowledge of the natural history of each specific type of cancer.

Clinical Staging.

The clinical staging classification system determines the extent of the disease process of cancer within the body by stages:

- *Stage 0:* cancer in situ
- *Stage I:* tumour limited to the tissue of origin; localized tumour growth
- *Stage II:* limited local spread
- *Stage III:* extensive local and regional spread
- *Stage IV:* metastasis

This classification system has been used as a basis for staging in cancer of the cervix (see Chapter 56, Table 56-11) and Hodgkin's disease (see Chapter 33, Figure 33-14).

TNM Classification System.

The *TNM classification system* represents the standardization of the clinical staging of cancer by the Geneva-based International Union Against Cancer. This classification system (Table 18-6) is used to determine the extent of the disease process of cancer according to three parameters: tumour size (T), degree of regional spread to the lymph nodes (N), and metastasis (M).

TABLE 18-6

TNM CLASSIFICATION SYSTEM

Primary Tumour Size (T)	
T_0	No evidence of primary tumour
T_{is}	Carcinoma in situ
T_1–T_4	Ascending degrees of increase in tumour size and involvement
T_X	Primary tumour cannot be assessed
Involvement of Regional Lymph Nodes (N)	
N_0	No evidence of disease in lymph nodes
N_1–N_3	Ascending degrees of nodal involvement
N_x	Regional lymph nodes cannot be assessed
Distant Metastases (M)	
M_0	No distant metastases
M_1	Distant metastases
M_X	Distant metastases cannot be assessed

Staging of the disease may be performed initially and at repeated intervals. Clinical diagnostic staging is performed at the time of diagnosis to determine the most effective treatment plan. Examples of diagnostic studies that may be performed to assess for spread of disease include bone and liver scanning, ultrasonography, computed tomography, positron emission tomography, and MRI.

Surgical staging is used to describe the extent of the disease process after biopsy or surgical exploration. For example, a laparotomy and a splenectomy may be performed in the staging of Hodgkin's disease. During staging laparotomy, lymph node biopsy samples are obtained, and margins of any masses are marked with metal clips. These clips are used as markers when radiotherapy is used as a treatment modality.

After the extent of the disease is determined, the stage classification is not changed. The original description of the extent of the tumour remains part of the original record. If additional treatment is needed, or if treatment fails, restaging is performed to determine the extent of the disease process at the time of re-treatment.

Carcinoma in situ is a commonly used term in classification of cancer. It is defined as a lesion with all the histological features of cancer except invasion. If left untreated, carcinoma in situ eventually becomes invasive.

In addition to tumour classification systems, there are also classification systems that can be used to describe the functional status of patients with cancer. The Karnofsky Performance Status scale is an example of a functional assessment scale (see the Resources at the end of this chapter).

Prevention and Detection of Cancer

The nurse has a prominent role in the prevention and detection of cancer. Early detection and prompt treatment are directly responsible for increased survival rates among patients with cancer. Public education should include the following recommendations:

1. Reduce or eliminate exposure to carcinogens and cancer promoters, such as cigarette smoke and sun exposure.
2. Eat a balanced diet that includes fresh fruits, vegetables, omega-3 fatty acids, and fibre. Following *Eating Well With Canada's Food Guide* helps to ensure a healthy diet (Health Canada, 2011; see Chapter 42, Figure 42-1).
3. Participate regularly (a minimum of 30 minutes, 5 times per week) in mild to moderate physical activity such as biking, walking, or running.
4. Maintain a healthy weight for your body type.
5. Limit alcohol use to one or two drinks per day.
6. Get to know your body. Learn and practise self-examination (e.g., breast self-examination, testicular self-examination). Report any changes to your doctor or dentist.
7. Follow cancer screening guidelines (see the Resources at the end of this chapter). Early detection of cancer has a positive effect on prognosis.
8. Know the seven warning signs of cancer (Table 18-7).

TABLE 18-7

SEVEN WARNING SIGNS OF CANCER

C	**C**hange in bowel or bladder habits
A	**A** sore that does not heal
U	**U**nusual bleeding or discharge from any body orifice
T	**T**hickening or a lump in the breast or elsewhere
I	**I**ndigestion or difficulty in swallowing
O	**O**bvious change in a wart or mole
N	**N**agging cough or hoarseness

When the public is educated about cancer, care should be taken to minimize the fear that surrounds the diagnosis. Teaching strategies that address the specific needs of the target audience (e.g., the needs of older adults in comparison with those of high school students or new immigrants to Canada) are most effective. Although the general public requires information that supports healthy behaviours, those at an increased risk of cancer are the target population for effective cancer control. These individuals must be motivated to learn to change negative health behaviours in order to achieve and maintain an optimal state of health. Nurses can have a definite effect in convincing people that change in lifestyle patterns will have a positive influence on health. To be successful, nurses must identify potential challenges and barriers and develop appropriate strategies to facilitate uptake of information about effective cancer control.

Diagnosis of Cancer

The threat of a cancer diagnosis creates tremendous anxiety for an individual and his or her family. Patients typically undergo several days to weeks of diagnostic studies. During this time, fear of the unknown may be more stressful than the actual diagnosis of cancer.

While the patient is waiting for the results of the diagnostic studies, the nurse should be available to actively listen to the patient's concerns. Communication plays a pivotal role in optimal patient care. Essential elements of the establishment of a therapeutic relationship with the patient are the ability to listen, ask questions sensitively, and avoid false reassurances. During this time of high anxiety, the patient needs repetition and reinforcement of information, the opportunity to ask questions, and clarification of the diagnostic workup. Explanations should be clear and tailored to meet the specific needs of patients and families. Content that is particularly threatening or detailed may overwhelm patients, and the nurse should thus be sensitive to the individual's ability to absorb the information. Written information at the level of the patient's literacy is helpful for reinforcement of verbal information.

A diagnostic plan for the person in whom cancer is suspected includes health history, potential or actual risk factors, physical examination, and specific diagnostic studies. (The specifics of the health history and the screening physical examination are presented in Chapter 3.)

The health history includes particular emphasis on risk factors, such as family history of cancer, exposure to or ingestion of known carcinogens (e.g., cigarette smoking, exposure to occupational pollutants or chemicals), diseases characterized by chronic inflammation (e.g., ulcerative colitis), and drug ingestion (e.g., hormone therapy). Other important information is related to dietary habits, ingestion of alcohol, lifestyle, and patterns and degree of coping with perceived stressors.

The physical examination should be thorough, with particular attention to the respiratory system, the GI system (including the colon, rectum, and liver), the lymphatic system (including the spleen), the breasts, the skin, the reproductive system (testes and prostate gland in men; cervix, uterus, and ovaries in women), and the musculo-skeletal and neurological systems.

The choice of diagnostic studies depends on the suspected primary or metastatic site or sites of the cancer. (Specific procedures related to each body system are discussed in the respective assessment chapters.) Studies that may be conducted in the process of diagnosing cancer include the following:

1. Cytology studies (e.g., Papanicolaou [Pap] test)
2. Hematology and chemistry studies (e.g., complete blood cell count [CBC], liver and renal function tests)
3. Sigmoidoscopic or colonoscopic examination (including fecal occult blood test)
4. Radiological studies (e.g., chest radiography, mammography, computed tomography, MRI)
5. Radioisotope scanning (e.g., bone, lung, liver, brain)
6. Assays for the presence of oncofetal antigens (such as CEA and alpha-fetoprotein) or of genetic markers (such as *BRCA1* and *BRCA2*)
7. Bone marrow examination (if a haematolymphoid malignancy is suspected)
8. Biopsy

Biopsy.

The *biopsy* procedure is the definitive means of diagnosing cancer, and the results guide treatment decisions. In a biopsy, a piece of tissue is surgically removed from the suspect area for histological examination by a pathologist. This examination helps determine whether the tissue is benign or malignant, the anatomical tissue from which the tumour arises, and the degree of cellular differentiation (i.e., how closely the specimen cells resemble the normal cells of the tissue).

The procedure may be a needle biopsy, an incisional biopsy, or an excisional biopsy. In a *needle biopsy,* cells and tissue fragments are obtained through a large-bore needle guided into the tissue of investigation (e.g., bone marrow, prostate gland, breast, liver, or kidney tissues).

Incisional biopsy performed with a scalpel or dermal punch is a common technique for obtaining a tissue sample from, for example, a skin lesion. The premise that incisional biopsy may contribute to the spread of cancer has not been proven.

- *Excisional biopsy* involves removal of the entire tumour. It is usually used for small tumours (<2 cm in diameter), skin lesions, intestinal polyps, and breast masses. This procedure can be therapeutic in addition to diagnostic. When a tumour is not easily accessible, a major surgical procedure (laparotomy, thoracotomy, craniotomy) is necessary to obtain the tumour tissue. Biopsy specimens from the GI tract, respiratory tract, and genitourinary system can usually be obtained by endoscopic procedures, such as flexible sigmoidoscopy.

Collaborative Care

Goals and Modalities

The goal of cancer treatment is cure, control, or palliation (Figure 18-8). Factors determining the therapeutic approach include the cell type of the cancer, the location and size of the tumour, and the extent of the disease. The patient's physiological and psychological status and personal desires are also important elements in determining the treatment plan. All factors influence the goals of care, the modalities chosen for treatment, and the length of time the treatment is administered. Evidence-informed treatment guidelines have been developed in a number of provinces and territories to guide treatment decisions. Examples include provincial guidelines in British Columbia and Ontario (see the Resources at the end of this chapter).

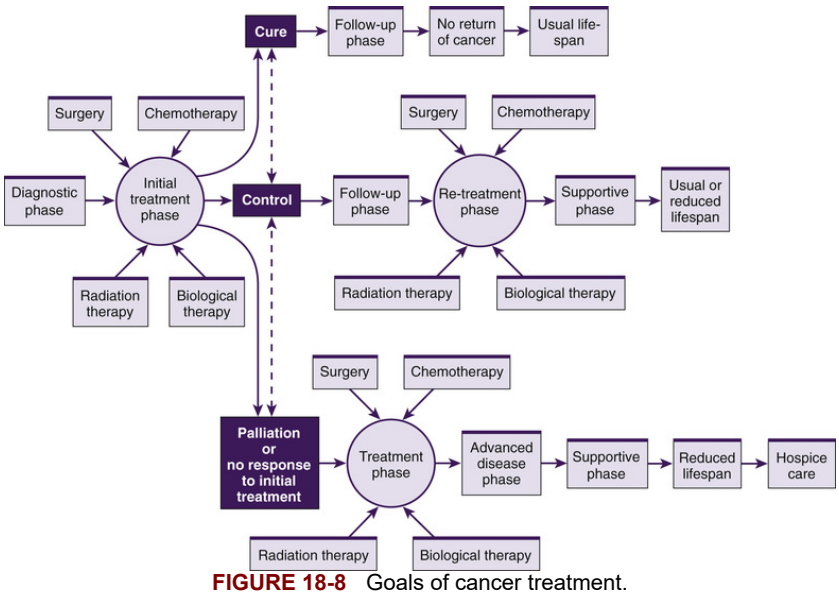

FIGURE 18-8 Goals of cancer treatment.

When caring for patients with cancer, the nurse should know the goals of the treatment plan to communicate with and support patients. When cure is the goal, treatment that has the greatest likelihood of eradicating the disease is offered. With many kinds of cancer, therapy has the potential for inducing permanent remission; therapy may be an initial course of treatment or treatment that extends for several weeks, months, or years. Basal cell carcinoma of the skin is usually cured by surgical removal of the lesion or by several weeks of radiation therapy. Acute lymphocytic leukemia in children has the potential for cure. The treatment plan for this type of cancer includes the administration of several chemotherapeutic drugs on a scheduled basis over a span of 6 months to several years. Head and neck cancers may be cured with combination therapy that includes surgery and radiation, with or without chemotherapy. The risk of disease recurrence differs according to the tumour type. In general, the risk for recurrent disease is greatest after completion of treatment and gradually decreases with the passage of time. Tumours with a rapid mitotic rate (e.g., testicular cancer) are considered to be in remission if cancer is not detected in a 2-year time span after treatment. For tumours that have a slower mitotic rate (e.g., postmenopausal breast cancer), the patient must be free of disease 20 years or longer before he or she can be considered cured of cancer.

Control is the goal of the treatment plan for many cancers that cannot be completely eradicated but are responsive to cancer therapies. Such cancers usually are not cured but are controlled by therapy for variably extended periods in a manner similar to other chronic illnesses, such as diabetes mellitus, chronic lung disease, and heart failure. An example of this type of cancer is chronic lymphocytic leukemia (see Chapter 33). The affected patient undergoes the initial course of therapy and continues

maintenance therapy for a time or is monitored closely so that early signs and symptoms of disease recurrence or progression can be detected.

Palliation may also be a goal of the treatment plan. With palliation, relief or control of symptoms and the optimization of quality of life are the primary objectives, rather than cure or control of the disease process. Radiation therapy to relieve the pain of bone metastasis is an example of a palliative cancer treatment. Palliative care may be undertaken for days, weeks, months, or years.

The goals of cure, control, and palliation are achieved through the use of four treatment modalities: surgery, radiation therapy, chemotherapy, and biological therapy. These modalities can be used alone or in any combination in the initial treatment phase, as well as in the repeated treatment phases of cancer. For many cancers, two or more of the treatment modalities (referred to as *concurrent, combined-modality,* or *multimodality therapy*) are used to achieve the goal of cure or control for a long period.

Informatics in Practice

Managing Symptoms of Cancer

- When patients arrive at some clinics, they are handed a tablet computer. While in the waiting room or chemotherapy infusion unit, they use the touch of a finger to select the symptoms they have been experiencing.
- Health care providers can review the information and provide care aimed at managing patients' specific symptoms.
- After the visit, the notes are stored in the patient's electronic health record. This system can assist with quality of care by determining whether standards of care were followed.

Clinical Trials

A *clinical trial* is a research study conducted on humans and designed with the intent of evaluating new treatments or supportive care interventions. The evaluation of treatments in cancer research begins in the laboratory with animal studies. From these studies, the treatments determined to be most effective, with mild or medically manageable levels of toxicity, are further evaluated in a series of studies on patients with cancer. Progress in cancer care depends on research. New drugs or treatments, evaluated for the first time in human beings, are studied in three phases:

- In *phase I trials,* researchers test a new drug or treatment in a small group of people (20 to 80) for the first time to evaluate its safety, determine a safe dosage range, and identify adverse effects.
- In *phase II trials,* the study drug or treatment is given to a larger group of people (100 to 300) to determine whether it is effective for a specific medical problem and to further evaluate its safety and adverse effects.
- In *phase III trials,* the study drug or treatment is given to large groups of people (1000 to 3000) to confirm its effectiveness, monitor adverse effects, compare it with commonly used treatments, and collect information that will allow the drug or treatment to be used safely.

Institutional review boards in each agency that conducts research closely guard the rights of the patients participating in clinical trials. These boards not only review clinical trials at their inception but also continue to review and monitor each study until its completion. Informed consent is a process in which the clinical trial physician and nurse give the patient full information regarding the nature of the treatment being evaluated and the potential risks and benefits of entering the clinical trial. The patient

must understand that he or she may decide to leave a clinical trial at any time or refuse to participate in the trial without threat of compromised care or treatment.

The guidelines for the administration of a research protocol are included in the study's protocol and are monitored closely by the study investigators and clinical trial nurses to ensure safe and uniform treatment of patients.

Surgical Therapy

Surgery is the oldest form of cancer treatment and was for many years the only method of cancer diagnosis and treatment. Removal of the tumour and a margin of the surrounding normal tissue may cure localized cancers, but it is ineffective if the cancer has metastasized to other locations.

Cure and Control

Several principles are applicable when surgery is used to cure or control the disease process of cancer (Figure 18-9):

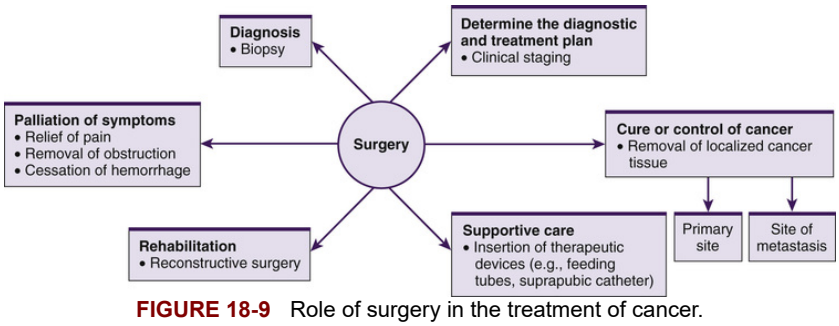

FIGURE 18-9 Role of surgery in the treatment of cancer.

1. Cancer that arises from a tissue with a slow rate of cellular proliferation or replication is the most amenable to surgical treatment.
2. A margin of normal tissue surrounding the tumour should be resected along with the tumour.
3. Only as much tissue as necessary is removed.
4. When appropriate, adjuvant therapy is used to eliminate residual micrometastases. The risk for metastatic disease is tumour dependent. The decision regarding adjuvant therapy is customized to the patient's tumour type, stage, comorbid conditions, and preferences.
5. Preventive measures are used to reduce the surgical seeding of cancer cells.
6. The usual sites of regional spread may be surgically removed for diagnostic or therapeutic purposes.

Examples of surgical procedures used for cure or control of cancer include radical neck dissection, lumpectomy, mastectomy, pneumonectomy, orchiectomy, thyroidectomy, and bowel resection.

A *debulking* or *cytoreductive* procedure may be used if the tumour cannot be completely removed (e.g., is attached to a vital organ). When this occurs, as much tumour as possible is removed, and the patient may be given chemotherapy or radiation therapy. This type of surgical procedure may increase the effectiveness of chemotherapy or radiation therapy because the target disease is reduced in volume.

Supportive and Palliative Surgical Procedures

Surgical procedures can also be used to provide supportive care and palliate symptoms throughout the disease process of cancer. Examples of supportive surgical procedures include the following:

1. Insertion of feeding tubes in the stomach for patients with head and neck cancers or cancer of the esophagus.
2. Creation of a colostomy to allow healing of rectal abscess.
3. Suprapubic cystostomy in cases of advanced prostatic cancer.

When cure or control of cancer is no longer possible, relief from distressing symptoms may be achieved through surgical procedures, including the following:

1. Debulking of tumour to relieve pain or pressure.
2. Colostomy for the relief of a bowel obstruction (see Chapter 45).
3. Laminectomy for the relief of spinal cord compression.

Rehabilitative Management

Cancer surgery may cause a change in a person's body image or function. It may be challenging for patients to cope with these changes on top of the distress of a diagnosis of cancer. As the treatment for certain cancers becomes more effective, the length of time that a patient must live with an alteration created by treatment will be increased. If quality of life is to be maintained, the body image must be one that a patient is able to adapt to and cope with on a daily basis. The rehabilitative role of surgery in cancer care has grown in prominence to improve patients' quality of life. Breast reconstruction after a mastectomy is an example of a rehabilitative surgical procedure. The use of prostheses, such as artificial eyes or limbs, and the care of ostomies are other major contributions to rehabilitative management.

Chemotherapy

The use of chemicals as a systemic therapy for cancer has been evolving. In the 1940s, chemotherapy was in its infancy. Nitrogen mustard, a chemical warfare agent used in World Wars I and II, was used in the treatment of lymphoma and acute leukemia, and a folic acid antimetabolite (5-fluorouracil) was found to have antitumour activity. In the 1970s, chemotherapy was established as an effective treatment modality for cancer. Chemotherapy is now used in the treatment of many solid tumours and is the primary therapy for hematological malignancies, including leukemia and lymphoma. Chemotherapy has evolved significantly to become a therapeutic option that can cure some cancers, control others, or palliate symptoms when cure or control is no longer achievable (Figure 18-10). Although practice standards in different provinces and territories vary, nurses administering chemotherapy must be specifically trained in the protocols, administration, and possible adverse effects (Canadian Association of Nurses in Oncology, 2011).

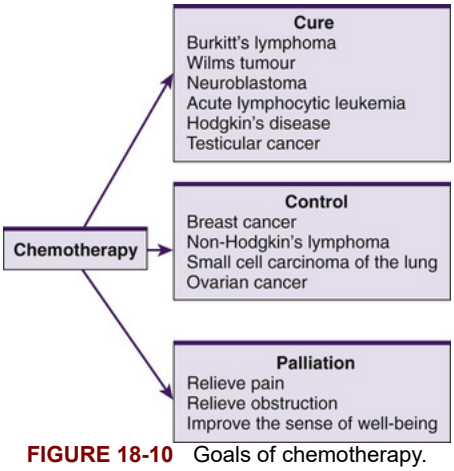

FIGURE 18-10 Goals of chemotherapy.

Effect on Cells

The effect of chemotherapy is at the cellular level. All cells, whether malignant or normal, enter the cell cycle for replication and proliferation (see Figure 18-1). The effects of the chemotherapeutic agents may be described in relationship to the cell cycle. The two major categories of chemotherapeutic drugs are cell cycle phase–nonspecific and cell cycle phase–specific drugs.

Cell cycle phase–nonspecific chemotherapeutic drugs have their effect on the cells that are in the process of cellular replication and proliferation, as well as those in the resting phase (G_0).

Cell cycle phase–specific chemotherapeutic drugs have their effect on cells that are in the process of cellular replication or proliferation (G_1, S_1, G_2, or M). These drugs exert their most significant effect during specific phases of the cell cycle. Cell cycle phase–specific and cell cycle phase–nonspecific agents are often administered in combination with one another. The aim of this approach is to promote a better response through the use of agents that function by differing mechanisms and at different points in the cell cycle.

The goal of chemotherapy is to reduce the number of cancer cells present in the primary and metastatic tumour site or sites. Several factors determine the response of cancer cells to chemotherapy:

1. *Mitotic rate of the tissue from which the tumour arises.* The more rapid the mitotic rate, the greater the response to chemotherapy. Chemotherapy is the treatment of choice for acute leukemia, Wilms tumour (in conjunction with surgery), and neuroblastoma. These cancer cells have a rapid rate of cellular proliferation.

2. *Size of the tumour.* The lower the tumour burden (i.e., the fewer cancer cells), the greater the response to chemotherapy.
3. *Age of the tumour.* The "younger" the tumour, the greater the response to chemotherapy. Developing tumours have a higher percentage of proliferating cells.
4. *Location of the tumour.* Certain anatomical sites provide a protected environment, or "sanctuary," from the effects of chemotherapy. For example, only a few drugs (such as nitrosoureas and temozolomide) cross the blood–brain barrier.
5. *Presence of resistant tumour cells.* Mutation of cancer cells within the tumour mass can result in variant cells that are resistant to chemotherapy. Resistance can also occur because of the biochemical inability of some cancer cells to convert the drug to its active form. This resistance is passed on to new daughter cells.

As a tumour first begins to grow, most of its cells are actively dividing. As the tumour increases in size, more cells become inactive and convert to a resting state (G_0). Because many chemotherapeutic agents are most effective against dividing cells, cells can escape death by staying in the G_0 phase. The major challenge of chemotherapy for cancer is overcoming the drug resistance of resting and noncycling cells.

Classification of Chemotherapeutic Drugs

Chemotherapeutic drugs are categorized or classified according to their structure and mechanisms of action (Table 18-8). Each drug in a particular classification has many similarities, but major differences among the drugs are also evident.

TABLE 18-8

DRUG THERAPY
Classification of Chemotherapeutic Drugs

Mechanisms of Action	Examples
Alkylating Agents	
Cell Cycle Phase–Nonspecific Agents	
Damage DNA by causing breaks in the double-strand helix (similar to the effect of radiation therapy); if repair does not occur, cells die immediately (cytocidal) or when they attempt to divide (cytostatic)	Mechlorethamine (formerly known as *nitrogen mustard*), cyclophosphamide (Procytox), chlorambucil (Leukeran), melphalan (Alkeran), busulfan (Myleran), dacarbazine (DTIC), lomustine (CCNU, CeeNU), oxaliplatin (Eloxatin), streptozocin (Zanosar), cisplatin, carboplatin
Antimetabolites	
Cell Cycle Phase–Specific Agents (Primarily S Phase)	
Interfere with enzyme function and synthesis of DNA by mimicking naturally occurring metabolites required by the cell for synthesis of DNA and RNA (cytocidal)	Methotrexate, cytarabine (Cytosar), fluorouracil (5-FU), mercaptopurine (6-MP), thioguanine (6-TG), fludarabine (Fludara), hydroxyurea (Hydrea), gemcitabine (Gemzar), cladribine (Leustatin)
Antitumour Antibiotics	
Cell Cycle Phase–Nonspecific Agents	
Modify function of DNA and interfere with transcription of RNA (cytocidal or cytostatic)	Doxorubicin (Adriamycin), bleomycin (Blenoxane), mitomycin, daunorubicin (Daunomycin), dactinomycin (Cosmegen), idarubicin (Idamycin), epirubicin (Ellence), mitoxantrone
Plant Alkaloids (Mitotic Inhibitors)	
Cell Cycle Phase–Specific Agents (G_2 and M Phases)	
Interrupt cellular replication in mitosis at metaphase (cytocidal)	Vinblastine, vincristine, etoposide (VePesid), paclitaxel (Taxol), docetaxel (Taxotere), teniposide (Vumon)
Nitrosoureas	
Cell Cycle Phase–Nonspecific Agents	
Similar to alkylating agents; break DNA helix and interfere with DNA replication (cytocidal or cytostatic)	Carmustine (BCNU), lomustine (CCNU, CeeNU)
Corticosteroids	
Cell Cycle Phase–Nonspecific Agents	
Disrupt the cell membrane and inhibit synthesis of protein; decrease circulating lymphocytes; inhibit mitosis; depress immune system; increase feeling of well-being	Cortisone, hydrocortisone (Cortef), methylprednisolone (Medrol), prednisone, dexamethasone
Hormone Therapy	
Cell Cycle Phase–Nonspecific Agents	
Interfere with hormone receptors and proteins, inhibiting tumour growth	Androgens (testosterone), estrogens, progestins
Aromatase Inhibitors	
Inhibit the enzyme aromatase, a cytochrome P450 enzyme involved in estrogen synthesis	Anastrozole (Arimidex), letrozole (Femara), exemestane (Aromasin)
Selective Estrogen Receptor Modulator (SERM)	
Selectively modulates estrogen receptors, thus acting as an estrogen antagonist	Raloxifene (Evista)
Miscellaneous	
Destroys exogenous supply of L-asparagine, which is needed for cellular proliferation; L-asparagine can be synthesized by normal cells but not by cancer cells	L-Asparaginase (Elspar)
Antiestrogens used in breast cancer	Tamoxifen (Nolvadex), fulvestrant (Faslodex)
Suppress mitosis at interphase; appear to alter preformed DNA, RNA, and protein	Procarbazine (Matulane)

DNA, deoxyribonucleic acid; *RNA*, ribonucleic acid.

Note: Each cancer agency in Canada has a formulary of protocols and practice guidelines; strict adherence to these guidelines is critical in the clinical setting. With new clinical trial research, drug protocols change; thus, the list in this table may not remain current.

Preparation and Administration of Chemotherapeutic Agents

It is very important to know the specific guidelines for administration of chemotherapeutic drugs. These drugs may also pose occupational hazards for health care providers. A health care provider preparing or administering chemotherapeutic agents may absorb the drug through inhalation of particles and through skin contact when reconstituting a powder in an open ampule. There may also be some risk in handling the body fluids and excreta of patients receiving chemotherapy. Guidelines for the safe handling of chemotherapeutic agents have been developed by the National Institute for Occupational Safety and Health (NIOSH) and the Oncology Nursing Society (see the Resources at the end of this chapter).

Methods of Administration

Several routes are used to administer chemotherapeutic agents (Table 18-9). The oral and intravenous routes are the most commonly used. The major concerns associated with the intravenous administration of antineoplastic drugs are the potential for irritation or damage to the vessels; problems with the venous access device or catheter, including infection; and **extravasation** (infiltration of drugs into tissues surrounding the infusion site), which causes local tissue damage. Many chemotherapeutic drugs are irritants or **vesicants,** agents that cause severe local tissue breakdown and necrosis when accidentally infiltrated into the skin (Figure 18-11).

TABLE 18-9

DRUG THERAPY
Methods of Administration of Chemotherapeutic Drugs

Method	Examples
Oral	Cyclophosphamide
Intramuscular	Bleomycin
Intravenous	Doxorubicin, vincristine
Intracavitary (pleural, peritoneal)	Radioisotopes, alkylating agents, methotrexate
Intrathecal	Methotrexate, cytarabine
Intra-arterial	Dacarbazine (DTIC), 5-fluorouracil (5-FU), methotrexate, floxuridine
Perfusion	Alkylating agents
Continuous infusion	5-FU, methotrexate, cytarabine
Subcutaneous	Cytarabine

FIGURE 18-11 Extravasation injury from infiltration of chemotherapeutic drug. Source: Weinzweig, N. & Weinzweig, J. (2005). *The mutilated hand.* Philadelphia: Mosby.

Pain is the cardinal symptom of extravasation, although extravasation has been known to occur without causing pain. Swelling, redness, and the presence of vesicles on the skin are other signs of extravasation. After a few days, the tissue may begin to ulcerate and necrose, and closure with skin grafts is often required.

To minimize these risks and to avoid physical discomfort, chemotherapeutic drugs may be administered by means of a central venous access device. Cancer care increasingly involves combination therapies that entail venous access; therefore, the use of these devices has increased. Central venous access devices are placed in large blood vessels and enable frequent, continuous, or intermittent administration of chemotherapeutic agents, biological therapeutic agents, and other products. They are indicated in instances of limited venous access, intensive chemotherapy, continuous infusion of vesicant agents, and projected long-term need for venous access. (Central venous access devices are discussed further in Chapter 19.)

The advantages of venous access devices are that they provide for rapid dilution of chemotherapeutic agents, decreased incidence of extravasation, and reduced need for venipuncture. In addition to their usefulness in administration of chemotherapeutic agents, venous access devices can be used to administer additional fluids such as blood products, parenteral nutrition, or other drugs, as well as for venous blood sampling. The disadvantages are that the presence of central catheters can lead to increased incidence of blood clots, and they can be a source of systemic infection, particularly if a patient becomes immuno-suppressed during therapy. Three major types of venous access devices used in oncology care are tunnelled catheters, peripherally inserted central catheters, and implanted infusion ports. (See Chapter 19 for a detailed discussion of these venous access devices.)

Infusion Pumps.

Infusion pumps are used primarily for the continuous infusion of chemotherapeutic agents by intravenous, subcutaneous, intra-arterial, and epidural routes. Infusion pumps can be worn externally or implanted surgically.

Implanted infusion pumps are used primarily for intra-arterial administration of chemotherapeutic agents (Figure 18-12). This approach enables continuous infusion of the chemotherapeutic agent directly to the area of the tumour while sparing patients the systemic effects of the drug. Some implanted pumps have two silicone septa. The second septum can be used for bolus medication administration. The most common use of this method of chemotherapeutic administration has been hepatic artery infusion in the treatment of liver metastasis, usually from primary colon cancer.

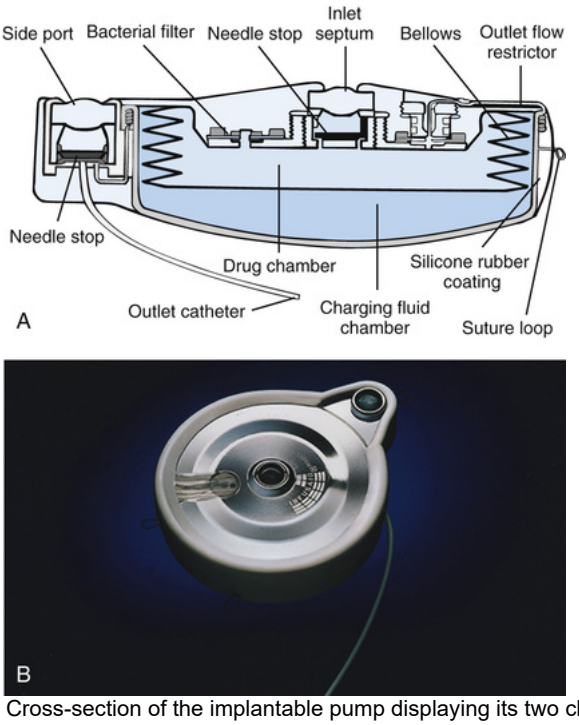

FIGURE 18-12 **A,** Cross-section of the implantable pump displaying its two chambers: the drug chamber (inner) and the charging fluid chamber (outer). As the drug chamber is filled, the bellows expand, compressing the charging fluid in the outer chamber. The resulting increased pressure in the outer chamber forces the drug through a membrane filter and preset flow restrictor, thus ensuring a nearly constant flow. **B,** Infusaid pump. Source: Courtesy Strato/Infusaid, Inc., Norwood, MA.

Implanted pumps also consist of a catheter that is threaded into the designated artery. The catheter is attached to a pump apparatus that consists of two chambers: an inner chamber that serves as the drug reservoir and an outer chamber that contains vapour pressure, which provides a source of power for the pump. The pump is implanted surgically in a subcutaneous pocket. Access to the pump is via a silicone septum with a Huber point needle. Flow rate of the pump can be affected by drug concentration, the length and diameter of the silicone rubber (Silastic) catheter, and the patient's body temperature. Thus dose alterations may be required if the patient experiences a change in temperature or travels to higher altitudes. Complications that have been associated with implanted infusion pumps include infection, thrombosis, clotting of the catheter, and pump malfunction.

Other access devices used in the treatment of the person with cancer include the Tenckhoff catheter, used in the administration of intraperitoneal chemotherapeutic agents, and the Ommaya reservoir, which delivers agents directly to the central nervous system (CNS).

Regional Administration of Chemotherapeutic Agents.

Regional treatment with chemotherapy involves the delivery of the drug directly to the tumour site. The advantage of administering chemotherapy by this method is that higher concentrations of the drug can be delivered to the tumour with reduced systemic toxicity. Several regional delivery methods have been developed, including intra-arterial, intraperitoneal, intrathecal or intraventricular, and intravesical bladder chemotherapy.

Intra-Arterial Chemotherapy.

In intra-arterial chemotherapy, the drug is delivered to the tumour via the arterial vessel supplying the tumour. This method has been used for the treatment of osteogenic sarcoma; cancers of the head and neck, the bladder, the brain, and the cervix; melanoma; primary liver cancer; and metastatic liver disease. One method of intra-arterial drug delivery involves the surgical placement of a catheter that is subsequently connected to an external infusion pump or an implanted infusion pump for infusion of the chemotherapeutic agent. In general, intra-arterial chemotherapy results in reduced systemic toxicity. The type of toxic effects experienced by patients depends on the toxicity profile of the chemotherapy agent and the site of the tumour being treated.

Intraperitoneal Chemotherapy.

Intraperitoneal chemotherapy involves the delivery of chemotherapeutic agents to the peritoneal cavity for treatment of peritoneal metastases from primary colorectal and ovarian cancers and malignant ascites. Temporary Silastic catheters (e.g., Tenckhoff, Hickman, Groshong) are percutaneously or surgically placed into the peritoneal cavity for short-term administration of chemotherapeutic agents. Alternatively, an implanted port can be used to administer chemotherapeutic agents intraperitoneally. Complications of intraperitoneal chemotherapy delivery include abdominal pain; catheter occlusion, dislodgement, and migration; and infection.

Intrathecal or Intraventricular Chemotherapy.

Cancers that metastasize to the CNS—most commonly breast, lung, and GI cancers; leukemia; and lymphoma—are difficult to treat because the blood–brain barrier often prevents distribution of chemotherapeutic agents to this area. One method used to treat metastasis to the CNS is intrathecal chemotherapy. This method involves a lumbar puncture and injection of chemotherapeutic drugs into the subarachnoid space. However, this method has resulted in incomplete distribution of the drug in the CNS, particularly to the cisternal and ventricular areas.

To ensure more uniform distribution of chemotherapeutic drugs to the cisternal and ventricular areas, an Ommaya reservoir is often inserted. An Ommaya reservoir is a Silastic, dome-shaped disc with an extension catheter that is surgically implanted through the cranium into a lateral ventricle. In addition to providing more consistent drug distribution, the Ommaya reservoir averts the need for repeated painful lumbar punctures.

Complications of intrathecal or intraventricular chemotherapy include meningitis and leukoencephalopathy (Beauchesne, 2010).

Intravesical Bladder Chemotherapy.

Many patients with superficial transitional cell cancer of the bladder have recurrent disease after traditional surgical therapy. Instillation of chemotherapeutic agents into the bladder promotes destruction of cancer cells and reduces the incidence of recurrent disease. Additional benefits of this therapy include reduced urinary and sexual dysfunction. The chemotherapeutic agent is instilled into the bladder via a urinary catheter and retained for 1 to 3 hours. Complications of this therapy include dysuria, urinary frequency, hematuria, and bladder spasms.

Effects of Chemotherapy on Normal Tissues

Chemotherapeutic agents cannot selectively distinguish between normal cells and cancer cells. Adverse and toxic effects results from the destruction of normal cells, especially those that proliferate rapidly, such as the cells of the bone marrow, the GI lining, and the integumentary system (Table 18-10). The body's response to the products of cellular destruction in the circulation may cause fatigue, anorexia, and taste alterations.

TABLE 18-10

CELLS WITH RAPID RATE OF PROLIFERATION

Cells and Generation Time	Effect of Cell Destruction
Bone marrow stem cell: 6–24 hr	Myelosuppression; infection, bleeding, anemia
Neutrophils: 12 hr	Leukopenia, infection
Epithelial cells lining the gastro-intestinal tract: 12–24 hr	Anorexia, stomatitis, esophagitis, nausea and vomiting, diarrhea
Ova or testes: 24–36 hr	Reproductive dysfunction
Cells of the hair follicle: 24 hr	Alopecia

The adverse effects of these drugs can be classified as acute, delayed, or chronic. Acute toxic effects include vomiting, allergic reactions, and dysrhythmias. Delayed effects include mucositis, alopecia, and bone marrow suppression. Mucositis can result in mouth sores, gastritis, and diarrhea. Chronic toxicity involves damage to organs such as the heart, the liver, the kidneys, and the lungs.

Treatment Plan

When chemotherapy is used in the treatment of cancer, several drugs may be given in combination. Multidrug regimens have proved to be particularly effective in the treatment of many types of cancer. The drugs given are carefully selected to kill the cancer cells most effectively and yet allow the normal cells to repair themselves and proliferate. The dose of each drug is carefully calculated according to the body weight or the body surface area (i.e., body weight and height) of the patient being treated. The principles of combination chemotherapy include the following:

1. The drugs used in the treatment plan are effective against the cancer being treated.
2. When drugs are given in combination, a synergistic effect occurs.
3. The combination includes cell cycle phase–specific drugs, cell cycle phase–nonspecific drugs, and drugs that have different mechanisms of action.
4. The combination includes drugs that have different toxic adverse effects.
5. The combination includes drugs that cause nadirs at different time intervals. The **nadir** is the lowest level of the peripheral blood cell counts (particularly WBC) that occurs secondary to bone marrow depression. The nadir after administration of most chemotherapeutic drugs occurs in 7 to 28 days.

An example of a treatment regimen is the FOLFOX (**fol**inic acid, **f**luorouracil, and **ox**aliplatin) regimen (Table 18-11). The agents in this drug protocol differ in mechanisms of action, toxic adverse effects, and nadir, but the combination is synergistic in nature, and the dosage schedule includes a time of drug administration and a time of rest from drug administration. The rest period is necessary to allow the normal cells to proliferate and repair the damaged tissue. The patient is evaluated before the administration of each course of chemotherapy to determine how well he or she is tolerating the treatment and whether the normal cells have recovered sufficiently for the next dose to be given.

TABLE 18-11

DRUG THERAPY
FOLFOX Chemotherapeutic Drug Schedule

Schedule: FOLFOX + bevacizumab (Avastin) is given to treat advanced colon cancer. FOLFOX* includes 5-fluorouracil ("FOL") administered as a continuous intravenous infusion over 46 hours on days 1 and 2; leucovorin (folinic acid; "F") administered intravenously over 2 hours on days 1 and 2; and oxaliplatin (Eloxatin [OX]), administered intravenously over 2 hours on day 1. Bevacizumab is administered intravenously over 2 hours on day 1. This schedule is repeated every 2 weeks. The number of cycles depends on a patient's situation.

Drug	Week 1		Week 3		Week 5		Week 7	
	Day 1	Day 2	Day 1	Day 2	Day 1	Day 2	Day 1	Day 2
5-Fluorouracil	X	X	X	X	X	X	X	X
Leucovorin (folinic acid)	X	X	X	X	X	X	X	X
Oxaliplatin (Eloxatin)	X		X		X		X	
Bevacizumab (Avastin)	X		X		X		X	

*There are slightly different versions of the FOLFOX regimen.

Radiation Therapy

Radiation therapy is a local treatment modality for cancer. It is one of the oldest methods of cancer treatment. Historically, workers exposed to radiation had a higher incidence of skin desquamation and developed carcinomas of the fingers. Both Marie Curie and her daughter Irène Joliot-Curie developed leukemia as a result of radiation exposure.

The observation that radiation exposure caused tissue damage led scientists to explore the use of radiation to treat tumours. The hypothesis was that if radiation resulted in the destruction of the highly mitotic skin cells of workers, it could be used in a controlled way to prevent the continued growth of highly mitotic cancer cells. It was not until the 1960s that sophisticated equipment and treatment planning facilitated the delivery of adequate radiation doses to tumours and tolerable doses to normal tissues. Today, radiotherapy has a central role in the treatment of cancer.

Effects of Radiation

Radiation is the emission and distribution of energy through space or a material medium. The energy produced by radiation, when absorbed into tissue, produces ionization and excitation. This local energy and the resultant generation of free radicals break chemical bonds in DNA, which may lead to lethal or sublethal damage. Lethal damage causes sufficient chromosomal disruption that the cell is unable to replicate. Sublethal DNA damage may be repaired between radiation doses or, alternatively, may accumulate with repetitive doses, leading to cell death. Cancer cells are especially vulnerable to the effects of cumulative radiation doses because they are less capable of repairing sublethal damage than are normal cells. When repetitive, *fractionated* (or divided) doses of radiation are delivered to a tumour, damage to malignant cells is maximized, and normal cells are more likely to recover. The principles of radiotherapy dosing and fractionation are guided by cellular response to radiation, known as the *four Rs* of radiobiology: **r**epair of cellular damage, **r**edistribution of cells in the cell cycle, **r**epopulation with normal cells, and **r**eoxygenation of hypoxic tumour areas.

Cellular Death and Tissue Reactions.

Cellular death related to radiation is defined as an irreversible loss of proliferative capacity. Cells may undergo several mitoses and then die. A cell that retains its proliferative capacity is a clonogenic cell because it is able to produce new clones or colonies of similar cells. After radiation, cancer is considered controlled if the cells that remain are nonclonogenic.

Cellular sensitivity to radiation varies throughout the cell cycle; cells are most sensitive in the M and G_2 phases and least sensitive during the S, or synthesis, phase (see Figure 18-1). Cells treated during the M and G_2 phases of the cell cycle are more likely to suffer lethal damage. The damage to DNA in cells that are not in the M phase is expressed when the cells divide.

The amount of time that is required for the manifestations of radiation damage is determined by the mitotic rate of the tissue. Sufficient numbers of cells within the tissue must be killed to establish a noticeable effect. This is true for both normal and cancer cells. Rapidly dividing cells in the GI tract, oral mucosa, and bone marrow die fast or exhibit other early acute responses to irradiation. Tissues with slowly proliferating cells—such as those of cartilage, bone, and kidneys—manifest late responses to irradiation.

This differential rate of cellular death explains the timing of clinical manifestations related to radiation therapy. Normal cells within the radiation field are also affected by treatment. For each normal cell type, there is a maximally tolerated radiation dose. Administration of radiation above the maximally tolerated doses results in limited ability of normal cells to recover from damage and in potentially irreversible adverse effects. Treatment planning and computerized dosimetry ensure that normal tissue tolerance is not exceeded (Behrend, 2011).

Table 18-12 lists the relative radiosensitivities of a variety of tumours. In responsive tumours, even a large tumour burden is affected by therapy. In less responsive tumours, a large tumour burden may result in a slower and perhaps incomplete response.

TABLE 18-12
TUMOUR RADIOSENSITIVITY

High Radiosensitivity	Moderate Radiosensitivity	Mild Radiosensitivity	Poor Radiosensitivity
• Hodgkin's disease • Neuroblastoma • Non-Hodgkin's lymphoma • Ovarian dysgerminoma • Testicular seminoma • Wilms tumour	• Bladder carcinoma • Breast adenocarcinoma • Esophageal carcinoma • Oropharyngeal carcinoma • Prostate carcinoma • Skin carcinoma • Uterine and cervical carcinoma	• Colon adenocarcinoma • Gastric adenocarcinoma • Renal adenocarcinoma • Soft tissue sarcomas (e.g., chondrosarcoma)	• Malignant gliomas • Malignant melanoma • Osteosarcoma • Testicular nonseminoma

Simulation and Treatment

Simulation is a part of radiation treatment planning used to determine the optimal treatment method. The patient lies on a table in the treatment position. The critical normal structures to be included in the treatment field or portal are identified under fluoroscopy. An image is taken to verify the field, and marks are placed on the skin so that the field can be reproduced on a daily basis. Immobilization devices (e.g., casts, bite blocks, thermoplastic face masks) are typically used to help the patient maintain a stable position (Figure 18-13). Computerized dosimetry, accomplished with computed tomographic scanning, is used to produce a treatment plan for delivering the maximum amount of radiation to the tumour within the acceptable dosage limits for normal tissue.

FIGURE 18-13 Immobilization device. Use of a head holder and immobilization mask may be used to ensure accurate positioning for daily treatment of head and neck cancer. Source: Courtesy Jormain Cady, Virginia Mason Medical Center, Seattle, WA.

External Radiation.

Teletherapy *(external beam irradiation)* is the most common form of radiation treatment delivery. With this technique, the patient is exposed to radiation from a megavoltage treatment machine. The radiation source may include cobalt-60, which emits gamma rays from a radioactive source. Therapy may be delivered by a cyclotron, which produces neutrons or protons, or by a linear accelerator, which generates ionizing radiation from electricity and with which multiple levels of energy can be utilized (Figure 18-14).

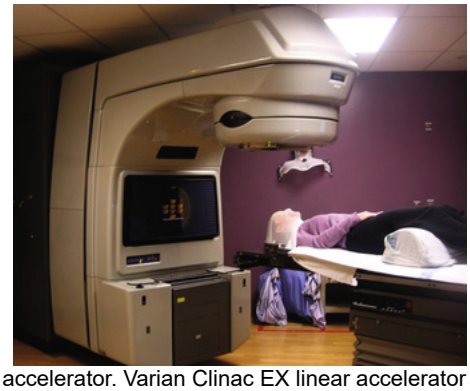

FIGURE 18-14 Linear accelerator. Varian Clinac EX linear accelerator with multiple photon and electron energy levels available for use according to the treatment plan. Patient is positioned on radiation treatment table for treatment of head and neck cancer. Source: Courtesy Jormain Cady, Virginia Mason Medical Center, Seattle, WA.

Internal Radiation.

Another radiation delivery system is **brachytherapy** ("close" treatment). In this method, radioactive materials are implanted or inserted directly into the tumour or close to the tumour. An implant may be temporary; the source is placed into a catheter or tube that is inserted into the tumour area and left in place for several days. This method is commonly used for tumours of the head and neck and for prostate and gynecological malignancies. Implants may also be permanent, whereby radioactive seeds are inserted into tumours: for example, in the prostate. Brachytherapy is clinically appropriate when the radiation dose necessary to eradicate the tumour exceeds the dose tolerance of nearby normal tissues. The sources used in brachytherapy are not as energetic or penetrating as those used in the external beam machines and thus deliver most of the dose locally. External beam radiation therapy and brachytherapy may be used in combination.

To care for a patient with a radiation implant, the nurse must be aware that the patient is radioactive. Patients with temporary implants are radioactive during the time the source is in place. If the patient has a permanent implant, the radioactive exposure to the outside and to other people is low, and the patient may be discharged with precautions. The principles of time, distance, and shielding are used in caring for the patient with an implant. Nursing care should be organized so that time spent in direct contact with the patient is kept to a minimum. The patient should be informed of these restrictions before the implantation procedure. The radiation safety officer determines how much time at a specific distance can be spent with the patient, according to the dose delivered by the implant. Because the source is nonpenetrating, small differences in distance are critical. Only care that must be delivered near the source, such as checking placement of the implant, is performed in close proximity. Shielding, if available, should be used, and the health care provider should not deliver care without wearing a film badge. This badge indicates any radiation exposure. The film badge should not be shared, should not be worn anywhere other than at work, and should be returned according to the employer's protocol.

Measurement of Radiation

Several different units are used to measure radiation (Table 18-13). Grays (Gy) and centigrays (cGy) are the units currently used in clinical practice.

TABLE 18-13

MEASUREMENT OF RADIATION

Unit	Definition
Curie (Ci)	A measure of the number of atoms of a particular radioisotope that disintegrate in 1 second
Roentgen (R)	A measure of the radiation required to produce a standard number of ions in air; a unit of exposure to radiation
Rad	Measurement of radiation dosage absorbed by the tissues
Rem	Measurement of the biological effectiveness of various forms of radiation on the human cell (1 rem = 1 rad)
Gray (Gy)	100 rads = 1 Gy
Centigray (cGy)	1 Gy = 100 cGy

Goals of Radiation Therapy

The goals of radiation therapy are cure, control, and palliation. To accomplish these treatment goals, radiation therapy can be used alone or as an adjuvant treatment modality with surgery, chemotherapy, biological therapy, or some combination of these.

Cure is the goal when radiation therapy is used alone for treating patients with basal cell carcinoma of the skin, tumours confined to the vocal cords, and stage I or IIA Hodgkin's disease. Radiation therapy can be combined with surgery and chemotherapy to cure certain cancers; for example, (a) stages IIB, IIIA, and IIIB Hodgkin's disease (in combination with chemotherapy); (b) Ewing's sarcoma (in combination with chemotherapy); (c) head and neck cancer (in combination with surgery and chemotherapy); and (d) stages I and II breast cancer (in combination with surgery).

Control of the disease process for a time may be a reasonable goal in some situations. Initial treatment is offered at the time of diagnosis, and additional treatment may be instituted if symptoms of disease recur. Most patients enjoy a satisfactory quality of life during the symptom-free period. Radiation therapy can be combined with surgery to further enhance the local control of cancer. It can be given preoperatively to reduce the size of the tumour so that it can be more easily resected, or it can be given postoperatively to destroy any remaining tumour cells. Intraoperative radiation therapy is now available at some research centres. In this procedure, radiation is administered directly to the site of the tumour during surgery.

Inoperable tumours can be treated with radiation therapy. These tumours are large and have extended regionally. An example of an inoperable cancer treated for control with radiation therapy is small (oat) cell cancer of the lung.

Palliation is often the goal of radiation therapy, with the aim of controlling symptoms resulting from the disease process. Tumours can be reduced in size to relieve symptoms such as pain and obstruction. Examples of the use of radiation therapy for palliation include relief from the following:

1. Pain associated with bone metastasis
2. Pain and neurological symptoms associated with brain metastasis
3. Spinal cord compression
4. Intestinal obstruction
5. Superior vena cava obstruction
6. Bronchial or tracheal obstruction
7. Bleeding (e.g., bladder and intrabronchial)

Nursing Management Radiation Therapy and Chemotherapy

The nurse has an important role in educating patients about their treatment regimens and the management of adverse effects and disease symptoms. Teaching should be tailored to the needs and abilities of patients and their families. Nurses can also assist patients to cope with the psychosocial issues associated with a cancer diagnosis. Anxiety and fear may pervade a patient's day-to-day experience and become a barrier to his or her ability to navigate through treatment. The nurse can mobilize a collaborative team of health care providers, community resources, and the patient's family to provide and reinforce information, facilitate transportation to the cancer centre, and ensure adequate physical, emotional, and spiritual support. One of the most important responsibilities of the nurse is that of differentiating between toxic effects of treatments and progression of the malignant process. The nurse must also distinguish tolerable adverse effects from acute toxic effects of chemotherapeutic agents. For example, nausea and vomiting are expected and controllable adverse effects of many drugs. However, if paresthesia occurs with the use of vincristine or if signs of heart failure appear with the use of doxorubicin (Adriamycin), these serious reactions must be reported to the physician so that drug dosages can be modified or the drug discontinued. Some toxic effects associated with chemotherapy may not be reversible. For example, ototoxicity may be an irreversible effect of cisplatin therapy, especially at high doses. Periodic testing of hearing may be necessary to monitor for this toxic effect. A nurse also advises patients about the availability of supportive therapies (e.g., antiemetics, antidiarrheals) to optimize quality of life during treatment.

Common adverse effects and specific nursing considerations related to problems caused by cancer therapy are presented in Table 18-14. Fatigue, anorexia, bone marrow suppression, skin reactions, mucosal reactions, and pulmonary, GI, and reproductive effects are discussed in the following sections. (See NCP 18-1 and NCP 18-2 for care of the patient undergoing radiation or chemotherapy, available on the Evolve website.)

TABLE 18-14

NURSING MANAGEMENT OF PROBLEMS CAUSED BY RADIATION THERAPY AND CHEMOTHERAPY

Problem	Cause	Nursing Management
Gastro-intestinal System		
Stomatitis, mucositis, esophagitis	Destruction of cells in radiation treatment field Destruction of epithelial cells by chemotherapy Inflammation and ulceration, which result from rapid cell destruction	• Be aware that eating, swallowing, and talking may be difficult and necessitate changes in diet and fluid intake. • Encourage patient to use artificial saliva. • Assess oral mucosa daily. Teach the patient to do this, and encourage the patient to practise good oral hygiene. • Use evidence-informed guidelines and protocols to minimize the occurrence or reduce the severity of oral mucositis. • Discourage use of irritants such as tobacco and alcohol, spicy foods, and drinks. • Apply topical anaesthetics, such as lidocaine (Xylocaine Viscous) or oxethazaine.
Nausea and vomiting	Cellular breakdown, which stimulates vomiting centre in brain Drugs, which also stimulate vomiting centre Destruction of GI lining by radiation and chemotherapy	• Counsel the patient to eat and drink when not nauseated. • Administer antiemetics, and teach the patient and family caregiver when to use antiemetic therapy to maximize symptom control.
Anorexia	Release of TNF and IL-1 from macrophages, which has appetite-suppressant effect General reaction to therapy	• Use diversional activities (if appropriate). • Monitor the patient's weight. • Encourage the patient to eat small, frequent meals of high-protein, high-calorie foods (e.g., Ensure or other supplements). • Reassure family caregivers, and teach them to provide gentle encouragement to the patient.
Diarrhea	Denuding of epithelial lining of intestines	• Suggest low-fibre, low-residue diet. • Increase fluids. • Provide antidiarrheal agents as needed.
Constipation	Autonomic nervous system dysfunction Neurotoxic effects of plant alkaloids (vincristine, vinblastine) Use of opioids	• Encourage the patient to use a diary to monitor bowel movements and report to the health care team as needed. • Provide stool softeners and laxatives as needed. • Encourage intake of high-fibre foods.
Hepatotoxicity	Toxic effects from chemotherapeutic drugs	• Monitor liver function values.
Hematological System		
Anemia	Bone marrow depressed as a result of therapy Malignant infiltration of bone marrow by cancer	• Monitor hemoglobin and hematocrit levels. • Encourage intake of foods that promote RBC production (see Chapter 33, Table 33.5).
Leukopenia	Depression of bone marrow as a result of chemotherapy or radiation therapy Febrile neutropenia Infection resulting from immuno-suppression (most frequent cause of morbidity and death in patients with cancer) Infection in respiratory and genitourinary systems (usual sites of infection)	• Monitor WBC count, especially neutrophils. • Educate and counsel patients and family caregivers to do the following: Monitor changes in temperature, and report any elevation immediately to the health care team. Advise the patient to maintain good personal hygiene, including frequent handwashing. Recommend that the patient report any signs of infection (swelling, unusual cough, vomiting, severe headache, redness) immediately at the nearest hospital. Advise the patient to avoid large crowds and people with infections.
Thrombo-cytopenia	Bone marrow depression secondary to chemotherapy Malignant infiltration of bone marrow Spontaneous bleeding, which can occur with platelet counts at or below 20×10^9/L	• Observe for signs of bleeding (e.g., petechiae, ecchymosis). • Monitor hemoglobin, hematocrit, and platelet counts. • Recommend use of a soft-bristle toothbrush and electric razor.
Integumentary System		
Alopecia (usually temporary with chemotherapy and usually permanent in response to radiation)	Destruction of hair follicles by chemotherapy or radiation to scalp	• Suggest ways to cope with hair loss (e.g., hairpieces, scarves, wigs). • Discuss effect of hair loss on self-image. • Recommend cutting long hair before therapy. • Advise the patient to avoid excessive shampooing, brushing, and combing of hair. • Recommend avoiding use of electric hair dryers, curlers, and curling irons.
Skin reactions	Extravasation of vesicant chemotherapeutic drugs Radiation therapy damage to skin	• Protect the patient from extravasation through careful attention to delivery of chemotherapeutic drugs and assessment of venous access. • Recommend lubricating dry skin with nonirritating creams. • Recommend avoiding the use of harsh soaps. • Advise the patient to wear loose clothing and cotton underwear and to avoid tight garments. • Inform the patient that photosensitivity may occur.
Genitourinary System		
Cystitis	Destruction of cells lining the bladder by chemotherapy Adverse effect of radiation when located in treatment field	• Monitor manifestations such as urgency, frequency, and hematuria. • Discuss these changes with the patient.
Reproductive dysfunction	Damage of cells of testes or ova by therapy	• Provide information about effects on fertility and referral to fertility resources (e.g., sperm banking) before delivery of radiation to the pelvis, high-dose chemotherapy, or bone marrow transplantation.

Problem	Cause	Nursing Management
Nephrotoxicity	Accumulation of drugs in the kidney and tumour lysis, which cause necrosis of proximal renal tubules	• Monitor BUN and serum creatinine levels.
Nervous System		
Increased intracranial pressure	Radiation-related edema in central nervous system	• Administer steroids and pain medication. • Monitor neurological status.
Peripheral neuropathy	Paresthesias, areflexia, skeletal muscle weakness, and smooth muscle dysfunction, which can occur as adverse effects of plant alkaloids and cisplatin	• Monitor for such manifestations in patients receiving these drugs.
Respiratory System		
Pneumonitis (develops 2–3 mo after start of treatment) Fibrosis (develops after 6–12 mo and is evident on radiographs)	Radiation Adverse effects of some chemotherapeutic drugs	• Monitor for dry, hacking cough; fever; and exertional dyspnea.
Cardiovascular System		
Pericarditis and myocarditis (complication when chest wall is irradiated; may occur up to 1 yr after treatment)	Inflammation secondary to radiation injury Adverse effect of some chemotherapeutic drugs	• Monitor for clinical manifestations of these disorders. • Monitor heart function with ECG studies and cardiac ejection fractions.
Cardiotoxicity	Some chemotherapeutic drugs (e.g., doxorubicin, daunorubicin) can cause ECG changes and rapidly progressive heart failure	• Drug therapy may have to be modified.
Biochemical		
Hyperuricemia, secondary gout, and obstructive uropathy	Cell destruction by chemotherapy	• Monitor uric acid levels. • Allopurinol (Zyloprim) may be given as a prophylactic measure. • Encourage high fluid intake.
Multidimensional Effects		
Fatigue	Increased metabolic rate Anabolic processes that result in accumulation of metabolites from cell breakdown	• Counsel the patient that fatigue is an expected adverse effect of therapy but that there are ways to manage fatigue, such as sleep hygiene, moderate exercise, and pacing activities. • Encourage the patient to rest when fatigued, to maintain usual lifestyle patterns as closely as possible, and to pace activities in accordance with energy level.
Pain	Compression or infiltration of tumour involving nerves Inflammation, ulceration, or necrosis of tissues	• Use an analgesic ladder to provide basis for pain medication administration. • Teach use of imagery, relaxation therapy, and other alternative measures (see Chapters 8 and 12).

BUN, blood urea nitrogen (serum urea [nitrogen]); *ECG*, electrocardiographic; *GI*, gastro-intestinal; *IL-1*, interleukin 1; *RBC*, red blood cell; *TNF*, tumour necrosis factor; *WBC*, white blood cell.

Nursing Implementation

Fatigue.

Fatigue is a commonly reported adverse effect of cancer therapy, affecting at least 80% of patients with cancer (Harris, Ross, & Sanchez-Reilly, 2014). The pathophysiological mechanisms that result in cancer treatment–induced fatigue are unclear. Accumulation of metabolites from the destruction of cells during treatment is one probable cause. The metabolites include lactate, hydrogen ions, and other end products of cellular destruction and result in decreased muscle strength. Energy production in patients with cancer may also be altered by cachexia, anorexia, fever, and infection. Fatigue associated with radiotherapy generally begins during the third to fourth weeks of treatment, persists after treatment ends, and then gradually subsides. Chemotherapy-related fatigue may become chronic after therapy. Factors such as weight loss, anemia, depression, nausea, and other symptoms exacerbate the sensation of fatigue.

Maintaining good nutrition and adequate hydration, alternating periods of rest and activity, relying on family members for assistance with responsibilities, and managing pain and anxiety may help reduce fatigue. The nurse can prepare patients for the expected adverse effect of fatigue, so that they do not assume that it is a sign of treatment failure. A patient may report more energy on some days than on others. Encouraging a patient to identify days or times during the day when he or she feels better may assist in understanding his or her body's responses and maximizing energy reserves. Ignoring the fatigue or overstressing the body when fatigue is tolerable may lead to an increase in symptoms. Mild physical activity programs are usually within the abilities of patients and have been found to ameliorate symptoms of fatigue, lessen anxiety, and facilitate sleep in patients with cancer (Mustian, Sprod, Janelsins, et al., 2012). Family caregivers of patients with cancer are also prone to fatigue and poor energy levels. Remaining as active as a patient is able has been shown to improve mood and avoid the debilitating cycle of fatigue-depression-fatigue that can occur.

Anorexia.

Anorexia may develop as a general reaction to treatment. The mechanisms underlying the development of anorexia are unclear, but several theories exist. Macrophages release TNF and IL-1 in an attempt to fight the cancer. Both TNF and IL-1 have an appetite-suppressing (anorexic) effect. It is hypothesized that as tumours are destroyed by therapy, increased levels of these factors are released into the system and cross the blood–brain barrier, affecting the satiety centre. Large tumours produce more of these factors, thus resulting in the cachexia observed in patients with advanced cancer. In addition, radiation treatments to the head and neck and the GI system exacerbate eating difficulties. Anorexia peaks at about 4 weeks of treatment and seems to resolve more quickly than fatigue when treatment ends.

Patients with anorexia need to be monitored carefully during treatment to ensure that weight loss does not become excessive. Body weight should be measured at least twice weekly. Small, frequent meals of high-protein, high-calorie foods are better tolerated than large meals (see the Resources at the end of this chapter). Nutritional supplements may be required.

Bone Marrow Suppression.

Myelosuppression is a common and significant effect of many chemotherapeutic modalities and may also occur with radiotherapy. Chemotherapy is a systemic treatment with the ability to affect every vulnerable cell in the body, whereas radiotherapy is delivered locally, so that only the cells within the treatment field are affected. Concurrent chemotherapy and irradiation generally increase the risk of toxic effects on the bone marrow. The onset of bone marrow suppression is related to the lifespan of the blood cell type. WBCs are affected within 1 week, platelets in 2 to 3 weeks, and red blood cells (RBCs) in 2 to 3 months. The severity of myelosuppression is related to the type and the dose of chemotherapeutic drug or the specific radiation field and to the extent of bone marrow reserves. In an adult, about 40% of active marrow is in the pelvis, and 25% is in the thoracic and lumbar vertebrae.

Blood cell counts (including WBCs, neutrophils, RBCs, and platelets) must be closely monitored. Neutropenia is most common in patients receiving chemotherapy and puts them at risk for serious infections or sepsis. WBC growth factors may be used to stimulate regeneration of adequate numbers of leukocytes and prevent treatment delays. Thrombo-cytopenia may cause spontaneous bleeding or hemorrhage and may necessitate a platelet transfusion if counts fall below 20×10^9/L. If anemia occurs and the hemoglobin level drops below 6 mmol/L, the patient may require blood transfusions.

Skin Reactions.

Like the bone marrow, the skin cells are rapidly proliferating and are therefore vulnerable to the effects of radiation and chemotherapy. Both acute and chronic changes can occur in the skin within the radiation field. The skin-sparing property of modern radiation equipment limits the severity of these reactions. Although the skin reaction begins as early as the first treatment, it is initially transitory. Erythema may develop 1 to 24 hours after a single treatment. Erythema is an acute response followed by dry desquamation (Figure 18-15). If the rate of cellular sloughing is faster than the ability of the new epidermal cells to replace dead cells, a wet desquamation occurs, with exposure of the dermis and oozing of serum (Figure 18-16). Skin reactions are particularly evident in areas subjected to pressure, such as behind the ear and in gluteal folds, the perineum, the breast, the collar line, and bony prominences.

FIGURE 18-15 Dry desquamation.

FIGURE 18-16 Wet desquamation.

Although skin care protocols vary among institutions, they are founded on basic skin care principles. Dry reactions are uncomfortable and result in pruritus. Wet reactions result in discomfort and drainage. Dry skin should be lubricated with a lotion or solution that contains no metal, alcohol, perfume, or additives that irritate the skin. Wet reactions must be kept clean and protected from further damage. Prevention of infection and facilitation of wound healing are the therapeutic goals.

Irradiated skin should be protected from extremes of temperature to prevent trauma. Heating pads, ice packs, and hot water bottles cannot be used in the treatment field. Constricting garments, rubbing, harsh chemicals, and deodorants may also traumatize the skin and should be avoided. The use of corticosteroids and hydrogen peroxide is controversial because of their interference with wound healing. The guidelines presented in Table 18-15 are not intended to replace protocols or guidelines developed by the cancer agency or hospital program.

TABLE 18-15

PATIENT & CAREGIVER TEACHING GUIDE
Radiation Skin Reactions

Patient and caregiver teaching for radiation skin reactions should include the following:
1. Gently cleanse the skin in the treatment field with a mild soap (Ivory, Dove), tepid water, and a soft cloth. Rinse thoroughly and gently pat dry.
2. Apply nonmedicated, nonperfumed, moisturizing lotion or creams, such as baby lotion, oil, aloe gel or cream to alleviate dry skin. This substance must be gently cleansed from the treatment field before each treatment and reapplied after. (Note: Care differs from institution to institution.)
3. Rinse the area with saline solution. Expose the area to air as often as possible. If copious drainage is present, nonadhesive absorbent dressings are warranted, and they must be changed as soon as they become wet. Observe the area daily for signs of infection.
4. Avoid wearing tight-fitting clothing such as brassieres, girdles, and belts over the treatment field.
5. Avoid wearing harsh fabrics, such as wool and corduroy. A lightweight cotton garment is best. If possible, expose the treatment field to air.
6. Use gentle detergents such as Ivory Snow to wash clothing that will come in contact with the treatment field.
7. Avoid direct exposure to the sun. If the treatment field is in an area that is exposed to the sun, wear protective clothing such as a wide-brimmed hat during exposure to the sun. (Note: In general, people should avoid sun exposure regardless of whether they are in treatment or not; use of protective clothing and sunscreen on exposed areas should be recommended.)
8. Prevent application of heat from all sources (hot water bottles, heating pads, and sun lamps) on the treatment field.
9. Avoid exposing the treatment area to cold temperatures (ice bags or cold weather).
10. Avoid swimming in salt water or in chlorinated pools during the time of treatment.
11. Avoid the use of all medication, deodorants, perfumes, powders, or cosmetics on the skin in the treatment field. Tape, dressings, and adhesive bandages should also be avoided unless permitted by the radiation therapist. Avoid shaving the hair in the treatment field.
12. Continue to protect sensitive skin after the treatment is completed by doing the following:
a. Continue to avoid direct exposure to the sun. A sunscreen agent and protective clothing must be worn if there is potential for exposure to the sun.
b. If shaving is necessary in the treatment field, use an electric razor.

Alopecia (hair loss) is restricted to the radiation field when caused by radiotherapy but affects all body hair (including eyelashes and eyebrows) when caused by chemotherapeutic agents. For some patients, hair loss causes profound distress. Chemotherapy-induced alopecia is temporary; hair regrowth begins 3 to 4 weeks after therapy is terminated. Radiotherapy-induced hair loss may be temporary or permanent, depending on the dose administered. Patients may be directed to the Canadian Cancer Society's "Look Good, Feel Better" program for support and advice about wigs and head coverings (see the Resources at the end of this chapter).

Oral, Oropharyngeal, and Esophageal Reactions.

The mucosal lining of the GI tract is sensitive to the effects of radiation therapy and to certain antineoplastic drugs, especially 5-fluorouracil. As a result, nutritional status may be compromised by treatment. Salivary flow often decreases, with resultant xerostomia (dry mouth), during radiotherapy to the head and neck. Food must be dissolved in saliva to be tasted. Taste loss is progressive during therapy, and by the end of treatment, many patients report that all food has lost its flavour. Thick saliva is less able to perform the functions of cleansing teeth and moistening food. Difficulty swallowing, which characterizes esophageal reactions, further impedes eating. Patients report feeling that they have a "lump" as they swallow and that "foods get stuck."

Meticulous oral assessment and prompt intervention are essential to prevent infection and facilitate nutritional intake. Oral care includes pretreatment evaluation by a dentist to perform all necessary dental work before the initiation of treatment. The patient must be taught to examine the mouth and gums daily. Mucous membranes, characteristics of saliva, and ability to swallow must be assessed regularly. The patient should also be taught how to perform oral care at least before and after each meal and at bedtime. A saline solution of 1 teaspoon of salt in 1 L of water is an effective cleansing agent. One teaspoon of sodium bicarbonate may be added to the oral care solution to decrease odour, alleviate pain, and dissolve mucin. Tooth brushing and flossing are critical unless contraindicated by decreased platelet counts. Compliance with this protocol significantly reduces the risk of radiation caries, which develops as a result of loss of saliva. Saliva substitutes are available and may be offered to patients, although many patients find that drinking small amounts of water frequently has an equivalent effect.

Antacids, diphenhydramine (Benadryl), and lidocaine (Xylocaine Viscous) have been mixed in equal proportions to use as a component of oral care. The solutions may be swallowed to alleviate esophagitis. Any coating solution must be cleansed and not allowed to build up on the mucosa, where it could serve as a medium for infection. Infection, particularly with *Candida albicans,* can occur in individuals receiving head and neck radiation, and its incidence increases dramatically in protocols involving concomitant chemotherapy. Antifungal agents may be prescribed to treat the infection. Alleviation of mucositis may be achieved through the use of coating and analgesic compounds. Palifermin (Kepivance) may be effective in reducing the severity and duration of oral mucositis in patients receiving stem cell transplants, and cryotherapy involving ice chips helps prevent mucositis associated with 5-fluorouracil and melphalan therapy. The use of sucralfate, chlorhexidine, antimicrobial lozenges, and colony-stimulating factor mouthwash is not recommended (Eilers, Asakura, Blecher, et al., 2014; Lalla, Bowen, Barasch, et al., 2014).

Feedings of soft, nonirritating high-protein and high-calorie foods should be offered frequently throughout the day. Extremes of temperature, as well as tobacco and alcohol, should be avoided. Nutritional supplements (e.g., Ensure) as an adjunct to meals and fluid intake may be encouraged. The patient should be weighed at least twice each week to monitor weight loss. Families are an integral part of the health care team. As taste loss increases, the family's role in assisting the patient to eat becomes increasingly critical. If family members are not available, alternative support, such as visits by volunteers and home aides, is indicated.

Pulmonary Effects.

Pulmonary effects of cancer therapies may be irreversible and progressive. The effects of radiation on the lung include both acute and late reactions. Radiation doses in the lung are magnified because the dose cannot be reduced through tissue. Pneumonitis can be an acute inflammatory reaction related to radiation. This reaction is often asymptomatic, although cough, fever, and night sweats may increase.

Treatment with bronchodilators, expectorants, bed rest, and oxygen is preferable to treatment with corticosteroids.

The most common pulmonary toxic effects associated with chemotherapy include pulmonary edema, interstitial fibrosis, and pneumonitis. The chemotherapeutic agents most strongly associated with these complications include bleomycin, busulfan, carmustine, cyclophosphamide, and some targeted agents (e.g., gefitinib [Iressa]). The pulmonary effects of treatments may be difficult to distinguish from those related to the disease and are frightening to patients because they may involve an exacerbation of the symptoms that precipitated the cancer diagnosis. Cough and dyspnea may increase. The cough becomes more productive because alveoli that had been blocked are opened as the tumour responds to treatment. As treatment continues, the cough can become dry as the mucosa begins to be altered by the radiation. Cough suppressants may be indicated for use at night.

Oxygen, if prescribed for symptomatic pneumonitis, must be used judiciously if a patient has chronic obstructive pulmonary disease (see Chapter 31). Oxygen therapy in such patients can cause carbon dioxide retention and respiratory acidosis and may be lethal. If a patient experiences dyspnea, anxiety may be pronounced. Lying flat on the radiation treatment table and being alone in the room may potentiate anxiety.

Gastro-intestinal Effects.

The mucosa of the GI tract is highly proliferative: Surface cells are replaced every 2 to 6 days, and thus they are highly vulnerable to cancer therapies. The intestinal mucosa is one of the most radiosensitive tissues. Radiation alters gastric secretion by direct injury to cells. The secretion of mucus, hydrochloric acid, and pepsin decreases with further treatment. Nausea, vomiting, and diarrhea are early responses to irradiation of the GI tissue and may occur immediately after the first treatment. The occurrence of these symptoms in response to cancer therapies may be related to the release of serotonin from the GI tract, which then stimulates the chemoreceptor trigger zone and the vomiting centre in the brain. Further GI irritation is related to direct injury to epithelial cells.

Several antiemetic drugs are available (see Chapter 44 and Table 44.1). Metoclopramide, ondansetron (Zofran), granisetron (Kytril), aprepitant (Emend), and dexamethasone have been used to decrease nausea and vomiting caused by chemotherapy. The introduction of antiemetic clinical practice guidelines and effective implementation of the guidelines in the oncology settings are essential methods for managing this treatment adverse effect. Administration of antiemetics before treatment alleviates the nausea and vomiting. Patients may find that eating a light meal of nonirritating food before treatment is also helpful. *Anticipatory nausea and vomiting* may develop in patients receiving radiation or chemotherapy when these symptoms are poorly controlled. This conditioned response results in the experience of nausea and vomiting when a patient encounters cues associated with the treatment: for example, walking through the doors of the cancer centre or merely seeing the oncologist, even outside of the treatment centre. In some individuals, this response persists after treatment ends. Aggressive emesis control, including the use of prophylactic antiemetics and antianxiety agents, is recommended.

Patients experiencing nausea and vomiting must be assessed for signs and symptoms of dehydration and alkalosis. Fluid intake is recorded to ensure that the volume consumed and retained is adequate. Diarrhea may be a reaction of the bowel mucosa to radiation. The small bowel is extremely sensitive and does not tolerate significant radiation doses. Administering treatments when a patient has a full bladder may serve to move the small bowel out of the treatment field. Nonirritating diets and low-residue diets, as well as antidiarrheal and antispasmodic drugs, are recommended. Lukewarm sitz baths may alleviate discomfort and cleanse the rectal area. The rectal area must be kept scrupulously clean and dry to maintain mucosal integrity. The nurse should inspect the perianal area. Number, volume, consistency, and character of stools per day should be recorded by patients, as should any potentially aggravating or alleviating factors related to bowel movements. Adequate food and fluid intake promote healing and mucosal integrity. Systemic analgesia is warranted for the painful skin irritations that may develop.

Reproductive Effects.

The effects of radiation and chemotherapy on the ovary and testes are determined by the dose delivered and the type of chemotherapy used. The testes are highly sensitive to radiation, and the testicles are protected whenever possible. Doses of 15 to 30 cGy temporarily decrease the sperm count; aspermia

results at 35 to 230 cGy. In some cases, 200 cGy may result in permanent aspermia. In patients receiving 300 to 600 cGy, the sperm count either recovers in 2 to 5 years or does not recover at all. Pretreatment status may be a significant factor because a low sperm count and loss of motility are seen in individuals with testicular cancer and Hodgkin's disease before any therapy. Combined modality treatment or prior chemotherapy with alkylating agents enhances and prolongs the effects of radiation on the testes. When radiation is used alone with conventional doses and appropriate shielding, testicular recovery often occurs. Compromised reproductive function in men may also result from erectile dysfunction after pelvic irradiation and its related vascular and neurological effects.

The radiation dose necessary to induce ovarian failure changes with age. Permanent cessation of menses occurs at 500 to 1000 cGy in 95% of women younger than 40 years, and at 375 cGy, the percentage is higher in women older than 40 years. Unlike the testes, the ovaries have no avenue for repair; therefore, the ovaries are shielded whenever possible. Other factors that influence reproductive or sexual functioning in women include reactions in the cervix and endometrium. These tissues withstand a high radiation dose with minimal sequelae, which accounts for the ability to treat endometrial and cervical cancer with high external and brachytherapeutic doses. Acute reactions such as tenderness, irritation, and loss of lubrication compromise sexual activity. Late effects of combined internal and external therapy include loss of elasticity, loss of lubrication, and vaginal shortening related to fibrosis. Supportive nursing care during brachytherapy for gynecological cancer is critical to the well-being and psychological functioning of women experiencing this treatment; the patient and the patient's partner require information about the expected effects of treatment in relation to reproductive and sexual issues. Potential infertility can be a significant consequence for the individual, and counselling is indicated. Pretreatment harvesting of sperm or ova may be considered. Specific suggestions to manage adverse effects that have an effect on sexual functioning include use of a water-soluble vaginal lubricant and a vaginal dilator after pelvic irradiation. The nurse must be competent in discussing issues related to sexuality, offering specific suggestions and making referrals for ongoing counselling when indicated.

Late Effects of Radiation Treatment and Chemotherapy

Cancer survivors are achieving higher rates of long-term remission and survival because of advancements in treatment modalities. However, these forms of therapy (especially radiation treatment and chemotherapy) may produce long-term sequelae termed *physiological late effects* that occur months to years after cessation of therapy. Every body system can be affected to some extent by chemotherapy and radiation therapy. The effects of radiation on the body's tissues are caused by cellular hypoplasia of stem cells and alterations in the fine vasculature and fibroconnective tissues. In addition to the acute toxic effects, chemotherapy can have long-term effects related to the loss of cells' proliferative reserve capacity. The additive effects of multiagent chemotherapy before, during, or after a course of radiotherapy can significantly increase the risks of physiological late effects.

Cancer survivors may also be at risk for leukemias and other secondary malignancies resulting from therapy for the primary cancer. However, the potential risk for developing a second malignancy does not contraindicate the use of cancer treatment. The overall risk of developing neoplastic complications is low, and the latency period may be long.

The cancer treatments most frequently implicated in causing secondary malignancy are the alkylating chemotherapeutic agents and high-dose radiation, which can induce cancers at the exposure site. The exact mechanism of oncogenesis secondary to irradiation and chemotherapy remains unclear. It could be related to interactions between immuno-suppressive factors, direct cellular damage, and carcinogenic effects, along with other environmental carcinogens.

Acute leukemias occurring as secondary malignancies have been most widely reported after treatment for Hodgkin's disease, but they also occur in survivors of ovarian, lung, and breast cancers. Secondary malignancies other than leukemias include multiple myeloma after radiation therapy for breast cancer; non-Hodgkin's lymphoma after treatment for Hodgkin's disease; and cancers of the bladder, the kidney, and the ureters after the use of cyclophosphamide. Radiation therapy for breast, lung, ovarian, uterine, and thyroid cancers; for non-Hodgkin's lymphoma; and for Hodgkin's disease has been linked to secondary osteosarcoma of the rib, scapula, clavicle, humerus, sternum, ilium, and pelvis. Fibrosarcomas have been reported several years after radiation therapy for malignant glioma and pituitary adenoma. Unfortunately, secondary malignancies are usually resistant to therapy, but supportive care and palliative care are options for the patient.

Biological and Targeted Therapy

Biological therapy is treatment involving the use of biological agents such as interferons, interleukins, monoclonal antibodies, and growth factors to modify the relationship between the host and the tumour. Biological agents are assuming a larger role in cancer treatment, either alone or in combination with surgery, radiation therapy, and chemotherapy. An understanding of the principles of cellular interaction underlies the development of agents that modify the relationship between the host and the tumour by altering the biological response of the host to the tumour cells. Biological agents may affect host–tumour response in three ways: (a) They have direct antitumour effects; (b) they restore, augment, or modulate host immune system mechanisms; and (c) they have other biological effects, such as interfering with the cancer cells' ability to metastasize or differentiate (Table 18-16; Figure 18-17).

TABLE 18-16

DRUG THERAPY
Biological and Targeted Therapy

Drug	Mechanism of Action	Indications	Adverse Effects
Cytokines and Immuno-modulators			
Interferon alfa-2b (Intron A)	Inhibits DNA and protein synthesis Suppresses cell proliferation Increases cytotoxic effects of NK cells	Hairy cell leukemia, chronic myelogenous leukemia, malignant melanoma, renal cell carcinoma, non-Hodgkin's lymphoma, ovarian cancer, multiple myeloma, Kaposi's sarcoma, pancreatic carcinoma	Flu-like syndrome (fever, chills, myalgia, headache), cognitive changes, fatigue, nausea, vomiting, anorexia, weight loss
Interleukin-2 (aldesleukin [Proleukin])	Stimulates proliferation of T and B cells Activates NK cells	Metastatic renal cell cancer, metastatic melanoma	Same as those of interferon alfa-2b; capillary leak syndrome, resulting in hypotension; bone marrow suppression
Levamisole	Potentiates monocytes and macrophage function	Stage III colon cancer (given in combination with 5-fluorouracil)	Diarrhea, metallic taste, nausea, fever, chills, mouth sores, headache
Bacille Calmette-Guérin vaccine	Induces an immune response that prevents angiogenesis of tumour	In situ bladder cancer	Flu-like syndrome, nausea, vomiting, rash, cough
Tyrosine Kinase Inhibitors			
Cetuximab (Erbitux)	Inhibits epidermal growth factor receptor, which is coupled with tyrosine kinase	Colorectal cancer, in combination with radiotherapy for head and neck carcinoma	Rash, dry skin, infusion reactions, interstitial lung disease, fatigue, fever
Erlotinib (Tarceva) and gefitinib (Iressa)	Same as for cetuximab	Non–small cell lung cancer	Rash, diarrhea, interstitial lung disease
Imatinib (Gleevec)	Inhibits *bcr-abl* tyrosine kinase	Chronic myeloid leukemia	Nausea, diarrhea, myalgia, fluid retention
Sorafenib (Nexavar)	Inhibits several tyrosine kinases, some of which are involved in angiogenesis	Advanced renal cell carcinoma	Rash, diarrhea, hypertension; redness, pain, swelling, or blisters on hands and feet
Monoclonal Antibody to CD20			
Rituximab (Rituxan)	Binds CD20 antigen, causing cytotoxicity	Non-Hodgkin's lymphoma (B cell)	Fever, chills, nausea, headache, angioedema
Ibritumomab tiuxetan–yttrium-90 (Zevalin)	Binds CD20 antigen, causing cytotoxicity and radiation injury	Non-Hodgkin's lymphoma (B cell)	Bone marrow suppression, fatigue, nausea, chills
Angiogenesis Inhibitor			
Bevacizumab (Avastin)	Binds vascular endothelial growth factor, thereby inhibiting angiogenesis	Colorectal cancer	Hypertension, colon bleeding and perforation, impaired wound healing, thrombo-embolism, diarrhea
Proteosome Inhibitor			
Bortezomib (Velcade)	Inhibits proteasome activity, which functions to regulate cell growth	Multiple myeloma	Bone marrow suppression, nausea, vomiting, diarrhea, peripheral neuropathy, fatigue
Monoclonal Antibodies			
Gemtuzumab ozogamicin (Mylotarg)	Binds CD33 antigen (expressed on leukemic cells) to deliver cytotoxic drug into the DNA	Acute myeloid leukemia	Bone marrow suppression, fever, chills, nausea
Alemtuzumab (Campath)	Binds CD52 antigen (found on T and B cells, monocytes, NK cells, neutrophils)	Chronic lymphocytic leukemia (B cell)	Bone marrow suppression, chills, fever, vomiting, diarrhea, fatigue
Trastuzumab (Herceptin)	Binds HER2	Breast cancer (HER2 positive)	Cardiotoxicity

HER2, human epidermal growth factor receptor 2; *NK*, natural killer.

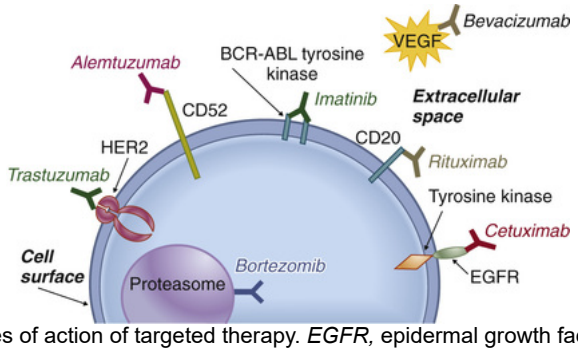

FIGURE 18-17 Sites of action of targeted therapy. *EGFR*, epidermal growth factor receptor; *HER2*, human epidermal growth factor receptor 2; *VEGF*, vascular endothelial growth factor.

Tumour cells express tumour antigens on their surfaces that can be recognized and destroyed by the body's immune cells. Cytokines are glycoprotein products of immune cells, such as lymphocytes and macrophages, and are capable of defence functions. Cytokines include interferons, interleukins, colony-stimulating factors, and TNF. Interferons were the first type of cytokine to be studied as a cancer therapy. Interferons protect cells infected by viruses from attack by other viruses and inhibit replication of viral DNA. The antiproliferative effects of interferons are not completely understood. However, they have been shown to inhibit DNA and protein synthesis in some tumour cells and to stimulate the expression of tumour antigens on tumour cell surfaces. Because the interferons have antiviral and antitumour effects, they are used to treat a number of medical conditions, including hepatitis C and Kaposi's sarcoma. The severity of adverse effects of interferons depends on the dose and the route of administration. One of the most common adverse effects is flu-like syndrome, which includes fever, chills, myalgia, and headache. Targeted therapy interferes with cancer growth by targeting specific cellular receptors and pathways that are important for tumour growth. The targeted therapies are more selective for specific molecular targets than are cancer drugs and are thus able to kill cancer cells without damaging normal cells. Targeted therapies include tyrosine kinase inhibitors, monoclonal antibodies, antiangiogenic agents such as VEGF receptor inhibitors, and interleukins.

Tyrosine kinases are important enzymes that activate the signalling pathways regulating cell proliferation and survival. For example, epidermal growth factor receptor (EGFR) is expressed in cells of epithelial origin, which rely on these receptors for repair and maintenance. EGFR is overexpressed in a wide variety of tumours, including non–small cell lung cancer, head and neck cancers, and pancreatic tumours and gliomas. Overexpression of EGFR is correlated with poor prognosis, increased recurrence rates, and resistance to chemotherapy. As such, it is an appealing target for cancer therapy. Erlotinib (Tarceva) and gefitinib (Iressa) are examples of EGFR tyrosine kinase inhibitors used in the treatment of non–small cell lung cancer.

Produced by B lymphocytes, monoclonal antibodies are antibodies (immunoglobulins) that are capable of binding to specific target cells, including tumour cells. Monoclonal antibodies can be unconjugated or conjugated. Unconjugated monoclonal antibodies are used alone to attack tumour cells directly. Conjugated monoclonal antibodies are attached to agents such as radioisotopes, toxins, chemotherapeutic agents, and other biological agents. The goal of this approach is to deliver the monoclonal antibody complex directly to the targeted cancer cells for their ultimate destruction. The antibodies also may stimulate an immune response in patients. Hybridoma technology for the production of monoclonal antibodies is described in Chapter 16.

The first monoclonal antibody approved for use in oncological treatment was rituximab (Rituxan), an unconjugated monoclonal antibody directed against the CD20 antigen found on the surface of B lymphocytes. Human epidermal growth factor receptor 2 (HER2) is overexpressed in certain cancers (especially breast cancer) and is associated with more aggressive disease and decreased rates of survival. Trastuzumab (Herceptin) is an unconjugated monoclonal antibody that binds to HER2 and inhibits the growth of breast cancer cells that express the HER2 protein.

The most common type of conjugated monoclonal antibody is an immunotoxin, a molecule formed when a monoclonal antibody is conjugated to a plant or bacterial cell toxin. The most frequently used bacterial toxins to date have been *Pseudomonas* exotoxin and diphtheria toxin. Unfortunately, immunotoxins have shown poor clinical efficacy thus far and are associated with significant toxic effects.

Monoclonal antibodies are administered by infusion. Patients may experience infusion-related symptoms, which can include fever, chills, urticaria, mucosal congestion, nausea, diarrhea, and myalgias. There is also a risk, although rare, of anaphylaxis associated with the administration of monoclonal antibodies. This potential exists because most monoclonal antibodies are produced by mouse lymphocytes and thus represent a foreign protein to the human body. Onset of anaphylaxis can occur within 5 minutes of administration and can be a life-threatening event. (See Chapter 16 for a discussion of nursing management of anaphylaxis.) Other toxic effects of monoclonal antibodies may include hepatotoxicity, bone marrow depression, and CNS effects. Patients who receive trastuzumab may also experience cardiac dysfunction, especially when it is administered in higher doses or in combination with anthracycline antibiotics such as doxorubicin (Adriamycin).

Angiogenesis inhibitors work by preventing the mechanisms and pathways necessary for the vascularization of tumours. Bevacizumab (Avastin), a recombinant human monoclonal antibody, is active against the VEGF molecule, a crucial regulator of normal and pathological angiogenesis. Adverse effects of bevacizumab include hypertension, hemorrhage, and thromboembolic events. Its use is indicated in the treatment of colorectal cancer, and trials are being conducted to treat a number of other cancers.

Interleukins are a family of cytokines that act primarily between lymphocytes to induce activation of the immune system or alteration in the functional capacity of tumour cells. To date, 29 interleukins have been discovered, and each is designated by number, but only IL-2 has been approved as an anticancer agent. Aldesleukin (Proleukin) is a recombinant form of IL-2 used in the treatment of metastatic renal cell carcinoma, acute myelogenous leukemia, and lymphoma.

A major toxic effect of IL-2 therapy is capillary leak syndrome, which occurs as a result of changes in capillary permeability and vascular tone. As a consequence of the increase in capillary permeability, fluids shift from intravascular to extravascular compartments. This causes intravascular fluid depletion. Manifestations of capillary leak syndrome include hypotension, peripheral edema, ascites, interstitial pulmonary infiltrates, weight gain, and decreased systemic vascular resistance. Additional toxic effects of IL-2 therapy include renal, cardiovascular, pulmonary, GI, and integumentary toxic effects; bone marrow suppression; and changes in cognitive function. (Note: Provincial and territorial care programs and drug benefits programs may vary; the nurse should consult the employer's protocols and formulary.)

Hematopoietic Growth Factors

Colony-Stimulating Factors.

Colony-stimulating factors are a family of glycoproteins produced by various cells. These glycoproteins stimulate production, maturation, regulation, and activation of cells of the hematological system. After release, colony-stimulating factors attach to receptors on the cell surface of peripheral blood cells and hematopoietic precursors (precursors of mature blood cells). They then stimulate production, maturation, release from the bone marrow, and functional ability of blood cells. The name of the colony-stimulating factor is based on the specific cell line it affects: granulocyte colony–stimulating factor (G-CSF), granulocyte-macrophage colony–stimulating factor (GM-CSF), macrophage colony–stimulating factor (M-CSF), and multicolony-stimulating factor, also known as *interleukin-3* (IL-3).

Colony-stimulating factors have a number of potential clinical uses. They may hasten recovery from bone marrow depression after standard and high-dose chemotherapy and bone marrow transplantation or decrease bone marrow suppression associated with administration of chemotherapeutic agents. Colony-stimulating factors may also re-establish bone marrow function in aplastic anemia, myelodysplastic syndrome, and leukemia and may be effective in the management of sepsis.

G-CSF is available as filgrastim (Neupogen) for the treatment of neutropenia. Pegfilgrastim (Neulasta) is a longer-acting form of filgrastim. G-CSF stimulates the production and function of neutrophils. It can be administered subcutaneously or by intravenous infusion. The most commonly reported adverse effect of G-CSF therapy is medullary bone pain, which occurs most often in the lower back, the pelvis, and the sternum. This pain generally develops at the time the neutrophil count begins to recover and lasts for about 24 hours. The pain associated with G-CSF therapy is usually relieved with nonopioid analgesics.

GM-CSF is available as sargramostim (Leukine, Prokine) for the treatment of (a) neutropenia associated with bone marrow transplantation, (b) bone marrow transplant failure or delay in bone

marrow engraftment, and (c) acute myelogenous leukemia after chemotherapy. GM-CSF stimulates the production and function of neutrophils, eosinophils, and monocytes. In addition, GM-CSF stimulates these cells to produce cytokines. GM-CSF can be administered either subcutaneously or by intravenous infusion. The most common adverse effects associated with GM-CSF administration include medullary bone pain (similar to the bone pain associated with G-CSF administration), leukocytosis, and eosinophilia.

IL-3 is a multipotential stimulator of hematopoietic stem cells. IL-3 has been shown to stimulate the growth of neutrophils, monocytes, eosinophils, basophils, and platelet cell lines. IL-3 is being investigated for the treatment of bone marrow failure and for its ability to enhance myeloid recovery after chemotherapy, radiotherapy, and bone marrow transplantation. M-CSF is also undergoing investigation for its potential role in cancer treatment.

Erythropoietin.

Erythropoietin is a colony-stimulating factor responsible for stimulating growth of the erythroid precursor cells that ultimately mature into RBCs. Erythropoietin is produced naturally by the kidneys. Erythropoietin was initially approved for the management of chronic anemia associated with end-stage renal disease. Subsequently, approval was expanded to include the use of erythropoietin (Eprex) for the management of chemotherapy-related anemia. Darbepoetin alfa (Aranesp), a long-acting form of erythropoietin, is now available.

Toxic and Adverse Effects of Biological Agents

The administration of one biological agent usually induces the endogenous release of others. The release and action of these biological agents result in systemic immune and inflammatory responses. The toxic effects and adverse effects of biological agents are related to dose and schedule. Common adverse effects, especially with interferons, include constitutional flu-like symptoms such as headache, fever, chills, myalgias, fatigue, malaise, weakness, photosensitivity, anorexia, and nausea. The severity of the flu-like symptoms associated with interferon therapy generally decreases over time. Acetaminophen administered every 4 hours, as prescribed, often reduces the severity of the flu-like syndrome. Many patients undergoing treatment with biological agents receive premedication with acetaminophen in an attempt to prevent or decrease the intensity of these symptoms. In addition, large amounts of fluids help decrease the intensity of symptoms.

Tachycardia and orthostatic hypotension are also commonly reported. IL-2 and monoclonal antibodies can cause capillary leak syndrome, with resulting pulmonary edema. Other toxic and adverse effects may involve the CNS and the renal, hepatic, and cardiovascular systems. These effects are found particularly with interferons and IL-2.

Nursing Management Biological Therapy

Problems experienced by patients receiving biological therapy may differ in type or severity from those observed with more traditional forms of cancer therapy. For example, capillary leak syndrome and pulmonary edema are problems that necessitate expertise in critical care nursing. Bone marrow depression occurring with administration of biological agents is generally more transient and milder than that observed with chemotherapy, but fatigue associated with biological therapy can be so severe that it may constitute a dose-limiting toxic effect.

Nursing interventions for flu-like syndrome include the administration of acetaminophen before treatment and every 4 hours after treatment. Intravenous meperidine (Demerol) has been used to control the severe chills associated with some biological agents. Other nursing measures include monitoring of vital signs and temperature, planning for periods of rest for patients, and assisting with activities of daily living.

With interferon and IL-2 therapy, numerous neurological deficits have been observed. The nature and extent of these problems have not been completely elucidated. However, these problems are frightening to patients and the family, who must be taught to observe for neurological problems (e.g., confusion, memory loss, difficulty making decisions, insomnia), report their occurrence, and institute appropriate safety and support measures. (Note: Provincial care programs and drug benefits programs may vary: the nurse should consult the employer's protocols and formulary.)

Bone Marrow and Stem Cell Transplantation

Bone marrow transplantation (BMT) is an effective, lifesaving procedure for a number of malignant and nonmalignant diseases (Table 18-17). BMT allows for the safe use of very high doses of chemotherapeutic agents or radiation to patients whose tumours are resistant or unresponsive to standard doses of chemotherapeutic agents and radiation. BMT offers hope to many patients whose disease is responsive to increased doses of systemic therapy. The numbers of BMT and transplantation programs in Canada have increased dramatically since 2005.

TABLE 18-17

Uses for Bone Marrow Transplantation

Malignant Diseases	Nonmalignant Diseases
• Acute and chronic myelogenous leukemia • Acute lymphocytic leukemia • Hodgkin's lymphoma • Multiple myeloma • Myelodysplastic syndrome • Neuroblastoma • Non-Hodgkin's lymphoma • Ovarian cancer • Sarcoma • Testicular cancer	• Aplastic anemia • Immunodeficiency diseases • Severe autoimmune diseases • Sickle cell disease • Thalassemia

Whether the diagnosis is a malignant or nonmalignant disease, the goal of BMT is cure. Cure rates are still low but are steadily increasing. Even if there is no cure, most transplantation procedures result in a period of remission. BMT is an intensive procedure with many risks, and some patients die from complications of BMT or from relapse of the original disease. Because it is a highly toxic therapy, patients must weigh the significant risks of treatment-related death or treatment failure (relapse) against the hope of cure.

Types of Bone Marrow Transplants

Bone marrow transplants can be allogeneic, autologous, or syngeneic. In *allogeneic marrow transplantation,* the infused bone marrow is acquired from a donor who has been matched to the recipient in terms of human leukocyte antigen (HLA) tissue typing. HLA typing involves testing WBCs to identify genetically inherited antigens common to both donor and recipient that are important in compatibility of transplanted tissue. (HLA tissue typing is discussed in Chapter 16.) The donor is often a family member, but an unrelated donor may be found through a bone marrow registry. The goal is to administer large doses of systemic therapy and then "rescue" the bone marrow through the engraftment and subsequent normal proliferation and differentiation of the donated marrow in the recipient. The most common indication for allogeneic transplantation is leukemia.

In *autologous marrow transplantation,* patients receive their own bone marrow. The aim of this approach is to enable patients to receive intensive chemotherapy or radiation while supporting them with their own bone marrow. In this type of BMT, the patient's own marrow is removed, treated, stored, and reinfused.

A third type of BMT, *syngeneic marrow transplantation,* involves obtaining stem cells from one identical twin and infusing them into the other. Identical twins have identical HLA types and are a perfect match.

Procedures

Harvest Procedures.

Bone marrow can be "harvested" through a procedure conducted in the operating room with the patient under general or spinal anaesthesia in which multiple bone marrow aspirations are carried out, usually from the iliac crest but also from the sternum. The entire harvesting procedure usually takes 1 to 2 hours, and the patient can be discharged after recovery. After the procedure, the donor may experience pain at the collection site, which can be treated with mild analgesics. The donor's body replaces the bone marrow in a few weeks.

After harvesting, autologous bone marrow may be treated *(purged)* to remove cancer cells. Many different pharmacological, immunological, physical, and chemical agents have been used for this purpose. The bone marrow is then frozen *(cryopreserved)* and stored until it is used for transplantation. In allogeneic transplantation, the marrow can be harvested, processed, and infused into the recipient within a few hours of donation.

Preparative Regimens.

In malignant diseases, the goal of BMT is to rescue the marrow after the patient has received high doses of chemotherapeutic agents, with or without radiation, aimed at treating the underlying disease. After harvesting of the marrow, the patient is given high-dose chemotherapy with or without radiation therapy. Total body irradiation can be used for immuno-suppression or to treat the disease.

After the therapy, the marrow that was removed is thawed and administered to the patient intravenously to replace the destroyed marrow. The stem cells reconstitute, or "rescue," the recipient's hematopoietic system. Usually 2 to 4 weeks are required for the transplanted marrow to start producing hematopoietic blood cells. During this pancytopenic period, it is critical for the patient to be in a protective isolation environment and receive supportive care. RBC and platelet transfusions are usually necessary to maintain the necessary quantity of circulating RBCs and platelets.

Complications.

Bacterial, viral, and fungal infections are common after BMT. Prophylactic antibiotic therapy may reduce their incidence. A potentially serious complication of allogeneic transplant is graft-versus-host disease. This occurs when the T lymphocytes from the donated marrow (graft) respond to the recipient (host) cells as if they were foreign and begin to attack certain organs such as the skin, the liver, and the intestines. Graft-versus-host disease is discussed in Chapter 16. Another major adverse event is inadequate oral intake, which results in dehydration and malnutrition and thereby necessitates intensive nutritional support through a variety of interventions, such as oral supplementation and enteral feeding.

Peripheral Stem Cell Transplantation

An alternative to the harvest procedure is *peripheral stem cell transplantation* (PSCT). Peripheral (circulating) stem cells are capable of repopulating the bone marrow. PSCT is a type of transplantation that differs from BMT primarily in the method of stem cell collection. Because the blood contains fewer stem cells than does the bone marrow, stem cells from the bone marrow can be mobilized into the peripheral blood through chemotherapy or hematopoietic growth factors. Common growth factors that are used are GM-CSF and G-CSF. The donor's blood is collected, the peripheral stem cells are separated by means of a cell separator machine, and then the blood is returned through a venous line to the patient. This procedure is called *leukapheresis* and usually takes 2 to 4 hours to complete. In autologous transplantation, the stem cells are purged to kill any cancer cells and then frozen and stored until used for transplantation. Although many of the same steps (harvesting, intensive chemotherapy, reinfusion) of BMT are used in PSCT, the hematological recovery period in PSCT is shorter and produces fewer, less severe complications.

Cord Blood Stem Cells

Umbilical cord blood is rich in hematopoietic stem cells, and successful allogeneic transplantation has been performed with the use of this source. Cord blood can be HLA typed and cryopreserved. A disadvantage of cord blood is the possibly insufficient numbers of stem cells for transplantation into adults.

Gene Therapy

Gene therapy involves the transfer of exogenous genes (transgenes) into the cells of patients in an effort to correct the defective gene. The effect of gene therapy for cancer can be a temporary gene transfer with the additional goal of instigating an immune response to the transgene. The use of this new therapeutic approach for cancer is currently investigational. Several clinical trials are under way to evaluate the safety, tolerability, and efficacy of gene therapy for malignancies such as melanoma, brain tumours, and mesothelioma. (Gene therapy is discussed in Chapter 15.)

Complications Resulting From Cancer

Patients may develop complications related to the continual growth of the malignancy or the adverse effects of treatment.

Nutritional Problems

Malnutrition.

Many patients with cancer experience protein and calorie malnutrition, characterized by depletion of fat and muscle. (Assessment of the degree of malnutrition is discussed in Chapter 42.) See the Resources at the end of this chapter for lists of foods suggested for increasing the protein intake to facilitate repair and regeneration of cells; high-caloric foods that provide energy and minimize weight loss; and a sample high-calorie, high-protein diet.

The nurse should suggest a referral to a dietitian as soon as a 5% weight loss is noted or if the patient has the potential for protein and caloric malnutrition. Albumin and prealbumin levels should be monitored. Once a 4.5-kg weight loss occurs, it is difficult to maintain optimal nutritional status. The patient can be taught to use nutritional supplements in place of milk when cooking or baking. Foods to which nutritional supplements can be easily added include scrambled eggs, pudding, custard, mashed potatoes, cereal, and cream sauces. Packages of instant breakfast can be used as indicated or sprinkled on cereals, desserts, and casseroles.

Malnutrition may occur as a result of the effects of cancer and cancer treatments. Patients may also radically alter their diets because of beliefs that certain foods support the growth or treatment of cancer. A discussion about the patient's dietary practices thus facilitates mutual understanding and education.

If the malnutrition cannot be treated with dietary intake, it may be necessary to use enteral or parenteral supplementation as an adjunct nutritional measure. (Enteral and parenteral nutrition are discussed in Chapter 42.)

Altered Taste Sensation.

It is theorized that cancer cells release substances that resemble amino acids and stimulate the bitter taste buds. Patients may also experience an alteration in the sweet, sour, and salty taste sensations. Meat may taste bitter to patients. The physiological basis of these taste alterations is unclear. It is important to help patients (a) understand the changes that will be experienced and (b) find foods that are appealing. Many Canadians are from different cultural and ethnic groups, and the nurse must be aware of possible differences in meal preparation and selection that are acceptable to patients. Patients can be encouraged to experiment with spices and other seasoning agents to taste in an attempt to mask the taste alterations.

Infection

Infection can cause death in a patient whose immune system is suppressed as a result of cancer treatment. The usual sites of infection include the lungs, genitourinary system, mouth, rectum, peritoneal cavity, and blood (septicemia). Infection occurs as a result of the ulceration and necrosis caused by the tumour, compression of vital organs by the tumour, and neutropenia caused by the disease process or the treatment of cancer. A critical aspect of nursing care is teaching about infection risk associated with neutropenia. A patient with a body temperature of 38°C (100.5°F) or higher should be seen at the hospital or cancer centre as soon as possible. Assessment most often includes signs and symptoms of fever, determination of possible cause, and complete blood cell count.

Many patients are neutropenic when an infection develops. In such individuals, infection causes significant morbidity and may be rapidly fatal if not treated promptly. The classical manifestations of infection are often not present in a patient with neutropenia and a depressed immune system. (Neutropenia is discussed in Chapter 33.)

Oncological Emergencies

Oncological emergencies are life-threatening events that can occur as a result of cancer or cancer treatment. These emergencies can be obstructive, metabolic, or infiltrative.

Obstructive Emergencies.

Obstructive emergencies are caused primarily by tumour obstruction of an organ or a blood vessel. Obstructive emergencies include superior vena cava syndrome, spinal cord compression syndrome, third space syndrome, and intestinal obstruction.

Superior Vena Cava Syndrome.

Superior vena cava syndrome results from obstruction of the superior vena cava by a tumour. The clinical manifestations include facial edema, periorbital edema, distension of veins of the neck and chest, headache, and seizures. A mediastinal mass is often visible on chest radiographs. The most common causes are Hodgkin's disease, non-Hodgkin's lymphoma, and lung cancer. Superior vena cava syndrome is considered a serious medical problem, and management usually involves radiation therapy to the site of obstruction and treatment of the primary tumour. Chemotherapeutic agents may be administered concurrently with the radiation therapy

Spinal Cord Compression.

Spinal cord compression is a neurological emergency caused by the presence of a malignant tumour in the epidural space of the spinal cord. The most common primary tumours that produce this problem are melanoma and cancers of the breast, lung, prostate, GI system, and kidneys. Lymphomas also pose a risk if diseased lymph tissue invades the epidural space. The manifestations are back pain that is intense, localized, and persistent, accompanied by vertebral tenderness and aggravated by the Valsalva manoeuvre; motor weakness and dysfunction; sensory paresthesia and loss; and autonomic dysfunction. One of the clinical symptoms that reflect autonomic dysfunction is a change in bowel or bladder function. The nurse should carefully assess for potential signs or symptoms related to cord compression. Radiation therapy is used for patients with slowly progressive neurological deficits and radiosensitive tumours. Surgery is usually recommended for patients with rapidly progressive neurological signs, especially if the tumours are relatively radiologically resistant.

Third Space Syndrome.

Third space syndrome involves a shifting of fluid from the vascular space to the interstitial space that results primarily from extensive surgical procedures, biological therapy, or septic shock. Initially, affected patients exhibit signs of hypovolemia, including hypotension, tachycardia, low central venous pressure, and decreased urine output. Treatment includes fluid, electrolyte, and plasma protein replacement. During recovery, hypervolemia can occur, resulting in hypertension, elevated central venous pressure, weight gain, and shortness of breath. Treatment generally involves reduction in fluid administration and fluid balance monitoring.

Intestinal Obstruction.

Intestinal obstruction occurs when partial or complete obstruction of the intestine prevents the passage of the intestinal contents through the GI tract. This can cause nausea, vomiting, abdominal pain, or even more serious problems, such as bowel necrosis. It necessitates prompt treatment. Chapter 45 contains a complete discussion of intestinal obstruction.

Metabolic Emergencies.

Metabolic emergencies are caused by the production of ectopic hormones directly from the tumour or are secondary to cancer treatment. Ectopic hormones can arise in tumours because their cells are less differentiated than normal cells, enabling re-expression of genes that are suppressed in normal development. Metabolic emergencies include syndrome of inappropriate antidiuretic hormone (SIADH), hypercalcemia, tumour lysis syndrome (TLS), septic shock, and disseminated intravascular coagulation.

Syndrome of Inappropriate Antidiuretic Hormone.

SIADH results from abnormal or sustained production of antidiuretic hormone (see Chapter 51). SIADH occurs most frequently with carcinoma of the lung but can also occur with cancers of the pancreas, duodenum, brain, esophagus, colon, ovary, prostate, bronchus, and nasopharynx and with leukemia, mesothelioma, reticulum cell sarcoma, Hodgkin's disease, thymoma, and lymphosarcoma. Cancer cells in these tumours are actually able to manufacture, store, and release antidiuretic hormone. The chemotherapeutic agents vincristine and cyclophosphamide (Procytox) also stimulate the release of antidiuretic hormone from the pituitary or tumour cells. Symptoms of SIADH include weight gain, weakness, anorexia, nausea, vomiting, personality changes, seizures, and coma. Treatment of SIADH includes fluid restriction and, in severe cases, intravenous administration of 3% sodium chloride solution.

Hypercalcemia.

Hypercalcemia can occur in the presence of cancer that involves the bone, as in metastatic disease of the bone or multiple myeloma, or when a parathyroid hormone–like substance is secreted by cancer cells in the absence of bone metastasis (Kurtin, 2014). Hypercalcemia resulting from malignancies that have metastasized occurs most frequently in patients with lung, breast, kidney, colon, ovarian, or thyroid cancer. Hypercalcemia resulting from secretion of parathyroid hormone–like substance occurs most frequently in patients with hypernephromas; squamous cell carcinoma of the lung; head and neck, cervical, and esophageal cancers; lymphomas; and leukemia. Immobility and dehydration can contribute to or exacerbate hypercalcemia.

The primary manifestations of hypercalcemia include apathy, depression, fatigue, muscle weakness, electrocardiographic changes, polyuria and nocturia, anorexia, nausea, and vomiting. Serum levels of calcium in excess of 3 mmol/L can be life-threatening. Chronic hypercalcemia can result in nephrocalcinosis and irreversible renal failure. The long-term treatment of hypercalcemia is aimed at the primary disease. Acute hypercalcemia is treated by hydration (3 L/day), diuretic administration (particularly loop diuretics), and a bisphosphonate, a drug that inhibits the action of osteoclasts. Infusion of a bisphosphonate is the treatment of choice.

Tumour Lysis Syndrome.

Acute TLS is a metabolic complication that occurs in some patients with cancer and is frequently triggered by chemotherapy. It results from the rapid destruction of a large number of tumour cells, which can cause fatal biochemical changes. TLS is often associated with tumours that have high growth rates and are sensitive to the effects of chemotherapy. If not identified and treated quickly, TLS can result in acute renal failure.

The four hallmark signs of TLS are hyperuricemia, hyperphosphatemia, hyperkalemia, and hypocalcemia. TLS usually occurs within the first 24 to 48 hours after the initiation of chemotherapy and may persist for approximately 5 to 7 days. The primary goal of TLS management is preventing renal failure and severe electrolyte imbalances. The primary treatment includes increasing urine production through hydration therapy and decreasing uric acid concentrations through administration of allopurinol (Lydon, 2011).

Septic Shock and Disseminated Intravascular Coagulation.

Septic shock is discussed in Chapter 69, and disseminated intravascular coagulation is discussed in Chapter 33.

Infiltrative Emergencies.

Infiltrative emergencies occur when malignant tumours infiltrate major organs secondary to cancer therapy. The most common infiltrative emergencies are cardiac tamponade and carotid artery rupture.

Cardiac Tamponade.

Cardiac tamponade results from fluid accumulation in the pericardial sac, constriction of the pericardium by tumour, or pericarditis secondary to radiation therapy for the chest. Manifestations include a heavy feeling over the chest, shortness of breath, tachycardia, cough, dysphagia, hiccups, hoarseness, nausea, vomiting, excessive perspiration, decreased level of consciousness, pulsus paradoxus, distant or muted heart sounds, and extreme anxiety. Emergency management is aimed at

reduction of fluid around the heart and includes surgical establishment of a pericardial window or an indwelling pericardial catheter. Supportive therapy includes administration of oxygen therapy, intravenous hydration, and vasopressor therapy.

Carotid Artery Rupture.

Rupture of the carotid artery occurs most frequently in patients with cancer of the head and neck as a result of invasion of the arterial wall by tumour or erosion after surgery or radiation therapy. Bleeding can manifest as minor oozing or, in the case of a bursting of the artery, spurting of blood. In the presence of bursting, pressure should be applied to the site with a finger. Intravenous fluid and blood products are administered in an attempt to stabilize the patient for surgery. Surgical management involves ligation of the carotid artery above and below the rupture site and reduction of local tumour.

Management of Cancer Pain

Moderate to severe pain occurs in approximately 50% of patients receiving active treatment for cancer and in 80% of those with advanced cancer. Despite progress made in cancer therapies, the incidence of cancer-related pain has not changed in decades. Cancer pain is commonly undertreated for a number of reasons, and this has a profound effect on patients' mood, functional status, and quality of life (Brant, 2011).

Inadequate pain assessment is a significant barrier to effective pain management. Data such as vital signs and patient behaviours are not reliable indicators of pain, especially longstanding, chronic pain. Therefore, it is essential that every patient with cancer be assessed for pain by the question "Do you have pain?" If the patient's self-report is affirmative, further data are obtained and documented initially and at regular intervals regarding the onset, the location, and the intensity of the pain, what it feels like, and how it is relieved. Patterns of change also should be assessed. The patient's pain report must be accepted as the primary source of assessment data. Drug therapy includes nonsteroidal anti-inflammatory medications, opioids, and adjuvant pain medications. Analgesic medications should be administered on a regular schedule, around the clock, with additional doses as needed for breakthrough pain. Oral administration of the medication is preferred. It is important to remember that with opioid drugs, such as morphine, the appropriate dose is whatever is necessary to control the pain with the least intrusive adverse effects. Principles of patient-controlled analgesia should also be followed. Fear of addiction is not warranted but must be addressed as part of patient teaching relevant to pain control because for both the patient and the nurse, it represents a significant barrier to appropriate pain management.

Nonpharmacological interventions, including relaxation therapy and imagery, can be effectively used to manage pain (see Chapter 12). (Additional strategies to relieve pain are discussed in Chapter 10.) More information on cancer pain management is available from cancer agency clinical practice guidelines, such as those on the BC Cancer Agency website (see the Resources at the end of this chapter).

Psychosocial Care

Psychosocial care is an important aspect of cancer care. Supportive care includes services and strategies to help cancer patients and their families cope with the cancer experience. Because of the effectiveness of cancer treatment, cancer is cured in many patients, or the disease is controlled for long periods. In view of this trend in survival, an optimal quality of life must be maintained after the diagnosis of cancer. By understanding the effect of cancer on the patient and the family and by promoting services that can provide financial, social, and psychological counselling, the nurse can be more effective in assisting patients and families throughout their cancer experience.

A diagnosis of cancer may precipitate a crisis in the lives of the patient and his or her family, and repercussions may affect all aspects of their lives. Common fears experienced by the patient with cancer include disfigurement, dependency, unrelieved pain, financial depletion, abandonment, and death.

To cope with these fears, patients with cancer may use and experience different behavioural patterns: shock, anger, denial, bargaining, depression, helplessness, hopelessness, rationalization, acceptance, and intellectualization. These behavioural patterns may occur at any time during the process of cancer. However, some patterns appear to occur more frequently or at a greater intensity at certain specific stages of the disease process. The following factors may determine how a patient will cope with the diagnosis of cancer:

1. *Ability to cope with stressful events in the past* (e.g., loss of job, major disappointment): By simply asking how the patient has coped with stressful events, the nurse can obtain an understanding of the patient's coping patterns, the effectiveness of the usual coping patterns, and the usual coping time framework.
2. *Availability of significant others:* Patients who have effective support systems tend to cope more effectively than do patients who do not have a meaningful, available support system.
3. *Ability to express feelings and concerns:* Patients who are able to express feelings and needs and who seek and ask for help appear to cope more effectively than do patients who internalize feelings and needs.
4. *Age at the time of diagnosis:* Age determines the coping strategies to a great degree. For example, a young mother with cancer may have concerns that differ from those of a 70-year-old woman with cancer.
5. *Extent of disease:* Cure or control of the disease process is usually easier to cope with than the reality of terminal illness.
6. *Disruption of body image:* Such disruption (e.g., by radical neck dissection, alopecia, mastectomy) may intensify the psychological effect of cancer.
7. *Presence of symptoms:* Symptoms such as fatigue, nausea, diarrhea, and pain may intensify the psychological effect of cancer.
8. *Past experience with cancer:* If past experiences with cancer have been negative, the patient will probably view his or her current status as negative.
9. *Attitude associated with the cancer:* A patient who feels in control and has a positive attitude about cancer and cancer treatment is better able to cope with the diagnosis and treatment of cancer than is a patient who feels hopeless, helpless, and out of control.

To facilitate the development of a hopeful attitude about cancer and to support the patient and the family during the various stages of the process of cancer, the nurse should act on the following suggestions:

1. Be available and continue to be available for discussion with the patient and family, especially during difficult times.
2. Actively assess the patient's needs for counselling and refer him or her to appropriate services when necessary.
3. Listen actively to fears and concerns.
4. Offer strategies to enhance coping behaviours.
5. Provide essential information as the patient asks for it, and be sensitive to information overload.

6. Establish a therapeutic relationship based on trust and confidence; be open, honest, and caring in the approach.
7. Be "present" with the patient to offer comfort and assurance that the nurse cares about him or her.
8. Understand and collaborate with the patient to set realistic, reachable short- and long-term goals.
9. Encourage the patient to maintain usual lifestyle patterns.
10. Maintain hope. Hope varies, depending on the status of the patient: hope that the symptoms are not serious, hope that the treatment is curative, hope for independence, hope for relief of pain, hope for a longer life, or hope for a peaceful death. Hope provides control over what is occurring and is the basis of a positive attitude toward cancer and cancer care. The development of an advanced care plan may help to clarify patients' attitudes and provide reassurance that their wishes for future care will be respected. Consider the spiritual aspects of care; support patients in exploring their belief systems and in finding meaning that transcends cultural and religious boundaries. Nurses can assist patients in identifying their strengths and developing skills to cope with the emotional aspects of having cancer.
11. Encourage and facilitate patients' participation in their care. This may include considering their interest in the use of integrative therapies such as support groups, mind–body modalities, nutritional supplements, and herbal therapies. The "unofficial" use of complementary and alternative medicines in oncology is widespread and has the potential to help (e.g., by relieving symptoms) or to harm (e.g., through associated toxic effects or by preventing or diminishing the effects of proven therapies). Patients may need support in understanding the difference between complementary and alternative therapies and the risks and benefits associated with complementary and alternative medicine.

Organizations and journals available as resources for the nurse are listed in the Resources section at the end of this chapter. The "Ethical Dilemmas" box is a description of considerations of nurse–family interactions when treatment is considered medically futile.

Ethical Dilemmas

Medical Futility

Situation

A 65-year-old woman has breast cancer with metastasis to the liver and bone. The family asks the nurse why their mother is not receiving chemotherapy. In addition, family members want to make certain that she will be resuscitated should her heart stop. They are aware of her diagnosis and that she may have less than 1 month to live. The nurse was told in morning rounds that the woman does not want any treatment that would prolong her life.

Important Points for Consideration

- If the patient is competent, the patient is legally and ethically the decision maker with regard to his or her own care in consultation with the patient's family and the health care team as desired.
- Members of the health care team have no obligation to provide care that is medically futile. Care that is futile may be inappropriate, prolong dying, or provide little or no benefit to the patient.
- Palliative care is health care that would provide comfort, control pain, reduce symptoms, or improve the quality of her remaining life, as defined by the patient.
- Patients or families do not have a right to demand treatment that offers no clear benefit to the patient.
- The nurse should work in collaboration with other members of the health care team to have discussions with the family members, ease the acceptance of their mother's diagnosis, incorporate their mother's goals into the plan of care, discuss a do-not-resuscitate (DNR) order and a referral to hospice, and plan for her eventual death.

Clinical Decision-Making Questions

1. How can the nurse help the patient communicate her wishes to her family?
2. How can the nurse and the health care team help the family plan end-of-life care that incorporates the wishes of their mother?

Age-Related Considerations

Cancer

Cancer is usually a disease of aging. Most cancers occur in people older than 65 years. Cancer is the leading cause of death in people 65 to 74 years of age. Clinical manifestations of cancer in an older adult may be mistakenly attributed to age-related changes and ignored by the person.

Older adults are particularly vulnerable to the complications of both cancer and cancer therapy. This is because of their decline in physiological functioning, social and emotional resources, and cognitive function. The functional status and comorbid conditions of an older adult should be taken into consideration when a treatment plan is selected (Puts, Hardt, Monette, et al., 2012). Age alone is not a sufficient predictor of tolerance or response to treatment (Cheung, Le, Gagliese, et al., 2011).

Because of advances in the treatment of cancer, cancer therapies benefit an increasing number of older adults, including patients with suboptimal health. Some important questions to consider when cancer is diagnosed in an older person include the following: Will the treatment provide more benefit than harm? Will the patient be able to tolerate the treatment safely? What is the patient's choice of therapy?

Review Questions

The number of the question corresponds to the same-numbered objective at the beginning of the chapter.

1. Which of the following is consistent with trends in the incidence and death rates of cancer?
   a. Lung cancer is the most common type of cancer in men.
   b. Breast cancer is the leading cause of cancer deaths in women.
   c. A higher percentage of women than men have lung cancer.
   d. The incidence of cancer increases as the population ages.
2. What features of cancer cells distinguish them from normal cells? *(Select all that apply.)*
   a. Cells lack contact inhibition.
   b. Cells return to a previous undifferentiated state.
   c. Oncogenes maintain normal cell expression.
   d. Proliferation occurs when there is a need for more cells.
   e. New proteins characteristic of embryonic stage emerge on cell membrane.
3. Which is a characteristic feature of the stage of progression in the development of cancer?
   a. Oncogenic viral transformation of target cells
   b. A reversible steady growth facilitated by carcinogens
   c. A period of latency before clinical detection of cancer
   d. The proliferation of cancer cells in spite of host control mechanisms
4. What is the primary protective role of the immune system in relation to malignant cells?
   a. Surveillance for cells with tumour-associated antigens
   b. The binding with free antigen released by malignant cells
   c. The production of blocking factors that immobilize cancer cells
   d. The response to a new set of antigenic determinants on cancer cells
5. What is the primary difference between benign and malignant neoplasms?
   a. The rate of cell proliferation
   b. The site of malignant tumour
   c. The requirements for cellular nutrients
   d. The characteristic of tissue invasiveness
6. Which nursing roles are important for the prevention and detection of cancer?
   a. Health promotion in relation to eating low-fibre, refined-carbohydrate diets
   b. Teaching about cancer risk factors
   c. Encouraging the public to participate in regular screening tests for all detectable cancer sites
   d. Using people's natural fear of cancer to motivate changes in unhealthy lifestyles
7. Which principle underpins a therapeutic approach to cancer?
   a. Surgery is the single most effective treatment for cancer.
   b. Initial treatment is always directed toward cure of the cancer.
   c. A combination of treatment modalities is effective for controlling many cancers.
   d. None of the above.
8. Which points would be part of nursing teaching for a client undergoing brachytherapy of the cervix?
   a. The client will learn that she must undergo simulation to locate the treatment area.
   b. The client will be taught about the treatment and need for staff time limitations in relation to her care.

c. The client will be taught that she may experience desquamation of the skin on the abdomen and upper legs.
d. The client will require shielding of the ovaries during treatment to prevent ovarian damage.

9. Which is the most effective method of administering a chemotherapeutic agent that is a vesicant?
a. Giving it orally.
b. Giving it intra-arterially.
c. Using an Ommaya reservoir.
d. Using a central venous access device.

10. Why does stomatitis, a common adverse effect of chemotherapeutic agents, occur?
a. The site of the malignancy is near the oral cavity.
b. The general health of the client with cancer is poor.
c. Chemotherapeutic drugs have a local and irritating effect on epithelial cells.
d. Rapidly dividing cells of the mucous membranes of the mouth are being destroyed.

11. In teaching the client about IL-2, which information will the nurse include?
a. It stimulates the immune system.
b. It inhibits DNA and protein synthesis in tumour cells.
c. It decreases the antigenic expression of antigens on tumour cell surfaces.
d. It prevents bone marrow suppression associated with chemotherapy.

12. Which information will the nurse provide to a client receiving radiation therapy or chemotherapy?
a. Effective birth control methods should be used for the rest of the client's life.
b. Notify the health care team if nausea and vomiting are experienced during treatment so that these can be managed.
c. After successful treatment, the client returns to previous functional level.
d. The cycle of fatigue-depression-fatigue that may occur during treatment can be reduced by restricting activity.

13. Which is an inappropriate nursing intervention to promote nutrition in the client with cancer?
a. Providing bland, pureed food because the person's taste sensation is altered
b. Providing increased protein for normal cell recovery and immune system function
c. Encouraging the client to eat a high-calorie, high-protein snack every few hours to prevent weight loss
d. Alerting the physician that nutritional supplements may be needed when the client has a 4-kg weight loss

14. What is the primary cause of syndrome of SIADH in cancer?
a. Autoimmune reaction
b. Gram-negative septicemia
c. Invasiveness of cancer cells
d. Ectopic hormonal production

15. A client has recently received a diagnosis of early-stage breast cancer. Which of the following is most appropriate for the nurse to focus on?
a. Maintaining the client's hope
b. Preparing a will and advance directives
c. Discussing replacement child care for client's children
d. Discussing the client's past experiences with her grandmother's cancer

1. d; 2. a, b, e; 3. d; 4. a; 5. d; 6. b; 7. c; 8. b; 9. d; 10. d; 11. a; 12. b; 13. a; 14. d; 15. a

CHAPTER 19

Fluid, Electrolyte, and Acid–Base Imbalances

Written by, Mariann M. Harding

Adapted by, Jana Lok

LEARNING OBJECTIVES

1. Describe the composition of the major body fluid compartments.
2. Define processes involved in the regulation of the movement of water and electrolytes between the body fluid compartments.
3. Describe the etiology, laboratory diagnostic findings, clinical manifestations, and nursing and collaborative management of the following disorders:
    a. Water excess and deficit
    b. Sodium and volume imbalances: hypernatremia and hyponatremia
    c. Potassium imbalance: hyperkalemia and hypokalemia
    d. Magnesium imbalance: hypermagnesemia and hypomagnesemia
    e. Calcium imbalance: hypercalcemia and hypocalcemia
    f. Phosphate imbalance: hyperphosphatemia and hypophosphatemia
4. Identify the processes of acid–base regulation.
5. Discuss the etiology, laboratory diagnostic findings, clinical manifestations, and nursing and collaborative management of the following acid–base imbalances: metabolic acidosis, metabolic alkalosis, respiratory acidosis, and respiratory alkalosis.
6. Describe the composition and indications for use of common intravenous fluid solutions.
7. Discuss types and nursing management of commonly used central venous access devices.

Homeostasis

Body fluids and electrolytes play an important role in homeostasis. **Homeostasis** is the state of equilibrium in the internal environment of the body, naturally maintained by adaptive responses that promote healthy survival (Mosby, 2016). Maintenance of the composition and volume of body fluids within narrow normal limits is necessary to maintain homeostasis (McCance & Huether, 2014). During normal metabolism, the body produces many acids. These acids alter the internal environment of the body, including fluid and electrolyte balances, and must also be regulated to maintain homeostasis. Many diseases and their treatments have the ability to affect fluid and electrolyte balance. For example, a patient with metastatic breast cancer may develop hypercalcemia. Chemotherapy prescribed to treat the cancer may result in nausea and vomiting and, subsequently, dehydration and acid–base imbalances. Correction of the dehydration with intravenous (IV) fluids must be monitored closely to prevent fluid overload.

It is important for the nurse to anticipate the potential for alterations in fluid and electrolyte balance associated with certain disorders and medical therapies, to recognize the signs and symptoms of imbalances, and to intervene with the appropriate actions. This chapter describes the normal control of fluids, electrolytes, and acid–base balance; etiologies that disrupt homeostasis and resultant manifestations; and actions that the health care provider can take to prevent imbalance or restore fluid, electrolyte, and acid–base balance.

Water Content of the Body

Water is the primary component of the body, accounting for approximately 60% of adult body weight. Water content varies with sex, body mass, and age (Figure 19-1). Lean body mass has a higher percentage of water than does adipose tissue; therefore, the more fat present in the body, the less the total water content. Women generally have a lower percentage of body water because they tend to have less lean body mass than do men. In older adults, the body water content is lower as a result of decreased lean body mass. Thus older adults are at an increased risk for fluid-related problems.

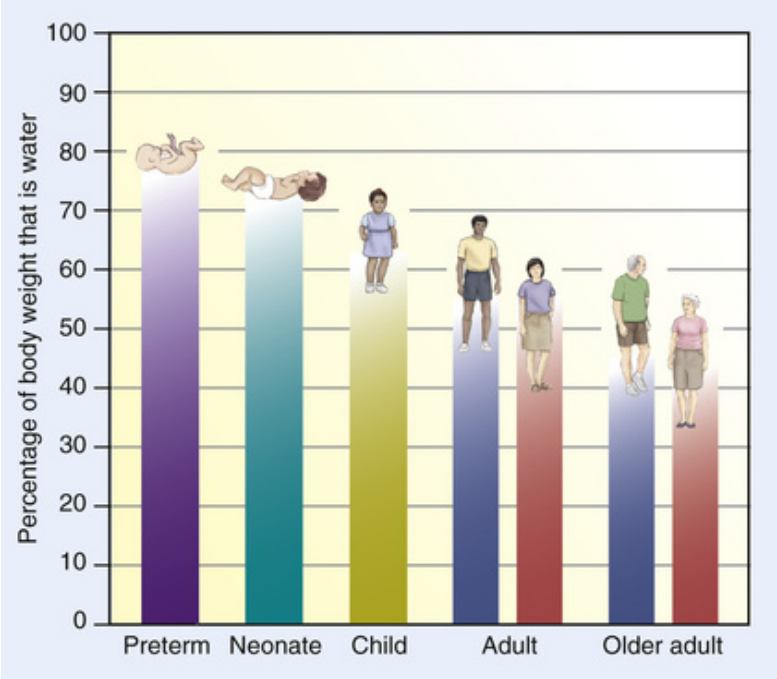

FIGURE 19-1 Levels of body water over the lifespan.

Body Fluid Compartments

The two major fluid compartments in the body are intracellular spaces (inside the cells) and the extracellular spaces (outside the cells) (Figure 19-2). Approximately two-thirds of body water is located within cells and is called *intracellular fluid* (ICF); the ICF constitutes approximately 42% of body weight. The body of a 70-kg man would contain approximately 42 L

of water, of which 30 L would be intracellular. *Extracellular fluid* (ECF) consists primarily of interstitial fluid and intravascular fluid (plasma). The ECF constitutes one-third of the body water, or approximately 17% of the total weight; this would amount to approximately 11 L in a 70-kg man. Approximately one-third of the ECF is in the plasma space (3 L in a 70-kg man), and two-thirds is in the interstitial space (8 L in a 70-kg man). Other ECF components include lymph and transcellular fluids. Transcellular fluids account for approximately 1 L and include cerebro-spinal fluid; fluid in the gastro-intestinal (GI) tract and joint spaces; and pleural, peritoneal, intraocular, and pericardial fluid.

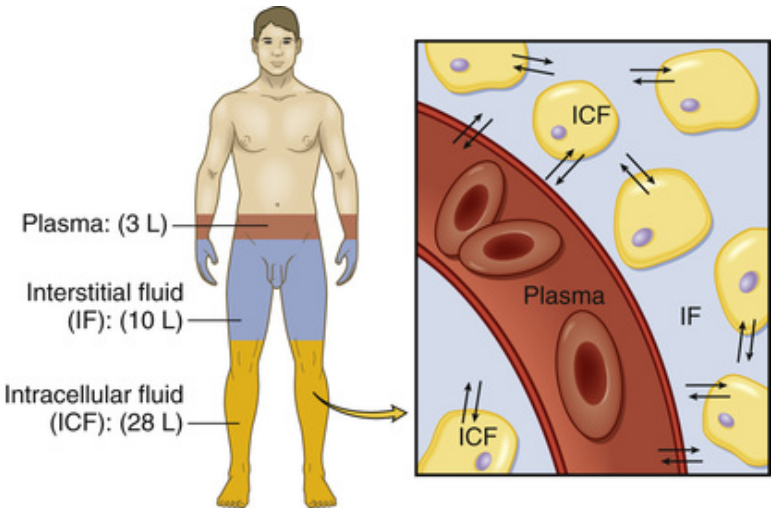

FIGURE 19-2 Relative volumes of three body fluids. Values represent fluid distribution in a young male adult. *ICF,* intercellular fluid; *IF,* interstitial fluid.

Calculation of Fluid Gain or Loss

One litre of water weighs 1 kg. Body weight change, especially sudden change, is an excellent indicator of overall fluid volume loss or gain. For example, if a patient drinks 240 mL of fluid, weight gain will be 0.24 kg. A patient receiving diuretic therapy who loses 2 kg in 24 hours has experienced a fluid loss of approximately 2 L. An adult patient who is fasting might lose approximately 0.5 to 1 kg per day. A weight loss exceeding this is probably caused by loss of body fluid.

Electrolytes

Electrolytes are substances whose molecules dissociate or split into ions when placed in solution. **Ions** are electrically charged molecules. **Cations** are positively charged ions. Examples include sodium (Na^+), potassium (K^+), calcium (Ca^{2+}), and magnesium (Mg^{2+}) ions. **Anions** are negatively charged ions. Examples include bicarbonate (HCO_3^-), chloride (Cl^-), and phosphate (PO_4^{3-}) ions. Most proteins bear a negative charge and are thus anions. The electrical charge of an ion is termed its **valence.** Cations and anions combine according to their valences.

Measurement of Electrolytes

The measurement of electrolytes is important to the nurse in evaluating electrolyte balance, as well as in determining the composition of electrolyte preparations. The concentration of electrolytes can be expressed in milligrams per decilitre (mg/dL), millimoles per litre (mmol/L), or milliequivalents per litre (mEq/L). The international standard symbol for measuring electrolytes is mmol/L. One mole (mol) of a substance is the molecular (or atomic) weight of that substance expressed in grams; hence, a millimole (mmol) of a substance is the atomic weight in milligrams. Sodium's atomic weight is 23 mg; therefore, 23 mg of sodium is 1 mmol of sodium. Sodium and chloride are monovalent elements that carry one electron and will match one to one: 1 mmol of sodium combines with 1 mmol of chloride.

An element with two electrons, such as calcium, requires two monovalent partners. To avoid keeping track of how to match millimoles, the milliequivalent is the favoured unit of measure for electrolytes. The following formula is used to convert millimoles to milliequivalents:

$$\text{mEq} = (\text{mmol/L}) \times \text{valence}$$

Electrolytes in body fluids are active chemicals that unite in varying combinations. Thus it is more practical to express their concentration as a measure of chemical activity (or milliequivalents) rather than as a measure of weight. Ions combine milliequivalent for milliequivalent: they match 1 to 1. For example, 1 mEq (1 mmol) of sodium combines with 1 mEq (1 mmol) of chloride, and 1 mEq (0.5 mmol) of calcium combines with 1 mEq

(1 mmol) of chloride. This combining power of electrolytes is important for maintaining the balance of positively charged ions (cations) and negatively charged ions (anions) within body fluids.

Electrolyte Composition of Fluid Compartments

Electrolyte composition varies between the ECF and the ICF. The overall concentration of the electrolytes is approximately the same in the two compartments. However, concentrations of specific ions differ greatly (Figure 19-3). In the ECF, the main cation is sodium, with small amounts of potassium, calcium, and magnesium. The primary ECF anion is chloride, with small amounts of bicarbonate, sulfate, and phosphate anions. In the ICF, the most prevalent cation is potassium, with small amounts of magnesium and sodium. The predominant ICF anion is phosphate, with some protein and a small amount of bicarbonate.

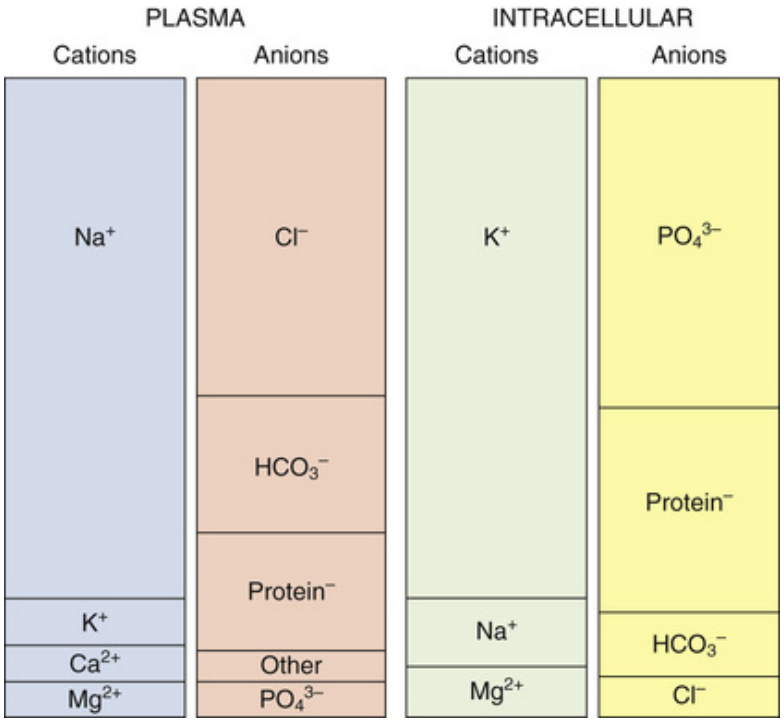

FIGURE 19-3 The relative concentrations of the major cations and anions in the intracellular space and the plasma.

Mechanisms Controlling Fluid and Electrolyte Movement

Different processes—such as simple diffusion, facilitated diffusion, and active transport—are involved in the movement of electrolytes and water between the ICF and the ECF. Water movement is driven by two forces: hydrostatic pressure and osmotic pressure.

Diffusion

Diffusion is the movement of molecules from an area of high concentration to one of low concentration (Figure 19-4). The membrane separating the two areas must be permeable by the diffusing substance for the process to occur. Net movement of molecules stops when the concentrations are equal in both areas. Simple diffusion requires no external energy. Gases (e.g., oxygen, nitrogen, carbon dioxide) and substances (e.g., urea) can permeate cell membranes and are distributed throughout the body.

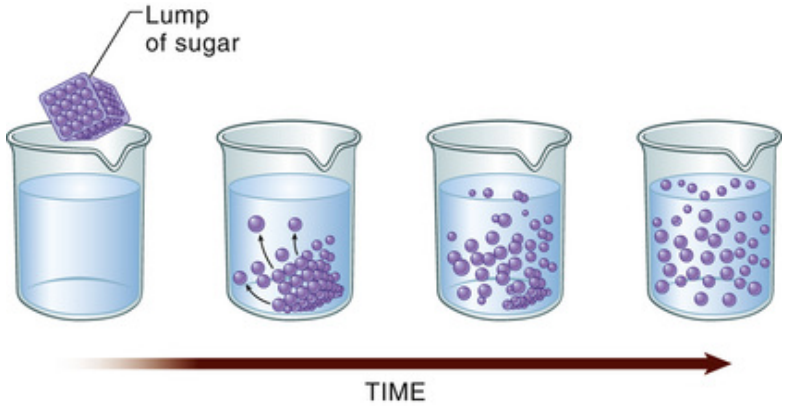

FIGURE 19-4 Diffusion is the movement of molecules from an area of high concentration to an area of low concentration. In this example, the sugar molecules eventually are evenly distributed.

Source: Patton, K. T., & Thibodeau, G. A. (2016). *Anatomy and physiology* (9th ed., p. 99). St. Louis: Mosby.

Facilitated Diffusion

Facilitated diffusion involves the use of a protein carrier in the cell membrane. The protein carrier combines with a molecule, especially one too large to pass easily through the cell membrane, and assists in moving the molecule across the membrane from an area of high concentration to one of low concentration. Like simple diffusion, facilitated diffusion is passive and requires no energy. An example of facilitated diffusion is glucose transport into the cell. The large glucose molecule must combine with a carrier molecule to be able to cross the cell membrane and enter most cells.

Active Transport

Active transport is a process requiring energy in which molecules move against the concentration gradient. An example is the sodium–potassium pump. The intracellular and extracellular concentrations of sodium and potassium differ greatly (see Figure 19-3). To maintain this concentration difference, the cell uses active transport to move sodium out of the cell and potassium into the cell (Figure 19-5). The energy source for the sodium–potassium pump is adenosine triphosphate (ATP).

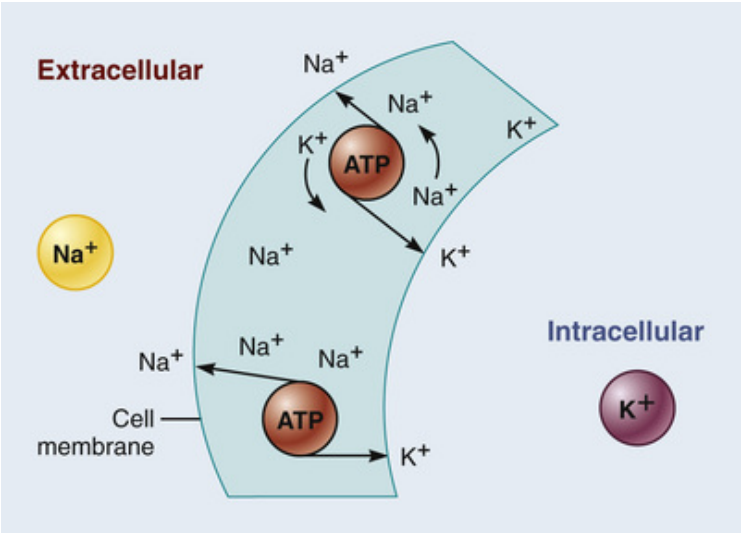

FIGURE 19-5 Sodium–potassium pump. As sodium (Na^+) diffuses into the cell and potassium (K^+) diffuses out of the cell, an active transport system supplied with energy from adenosine triphosphate (ATP) delivers Na^+ back to the extracellular compartment and K^+ to the intracellular compartment.

Osmosis

Osmosis is the movement of water between two compartments separated by a semipermeable membrane, one that allows the movement of water but not solute. Water moves through the membrane from an area of low solute concentration to an area of high solute concentration (Figure 19-6). Osmosis requires no outside energy sources and stops when the concentration differences disappear or when hydrostatic pressure builds and is sufficient to oppose any further movement of water. Diffusion and osmosis are important in maintaining the fluid volume of body cells and the concentration of the solute.

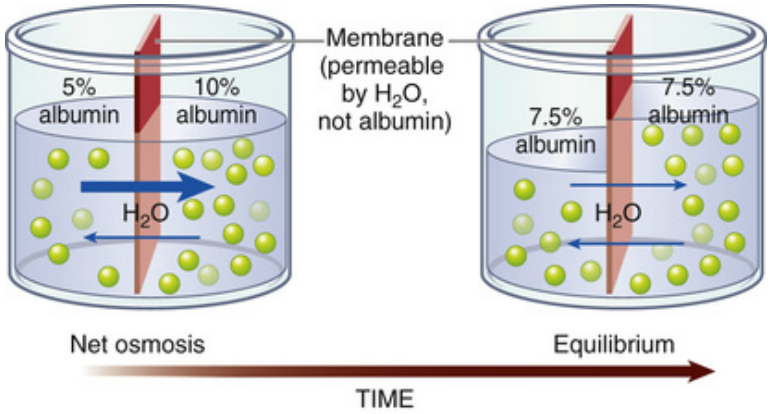

FIGURE 19-6 Osmosis is the process of water movement through a semipermeable membrane from an area of low solute concentration to an area of high solute concentration. Source: Patton, K. T., & Thibodeau, G. A. (2016). *Anatomy and physiology* (9th ed., p. 102). St. Louis: Mosby.

Osmotic pressure is the amount of pressure necessary to stop the osmotic flow of water. Osmotic pressure can be understood by imagining a chamber in which two compartments are separated by a semipermeable membrane (see Figure 19-6). Water moves to the more concentrated side of the chamber until the pressure generated by the height of the higher column of water opposes further movement.

Osmotic pressure is determined by the concentration of solutes in solution. It is measured in milliosmoles (mOsm) and may be expressed as either fluid osmolarity or fluid osmolality. Although the terms *osmolarity* and *osmolality* are often used interchangeably, they are different measurements. **Osmolarity** is a measure of the total milliosmoles of solute per unit of total volume of solution: that is, the total milliosmoles per litre of solution (mOsm/L), or the concentration of molecules per volume of

solution. **Osmolality** is a measure of the osmotic force of solute per unit of weight of solvent: that is, the number of milliosmoles per kilogram of water (mOsm/kg, or mmol/kg), or the concentration of molecules per weight of water. Osmolality is the preferred measure for evaluating the concentration of plasma, urine, and body fluids (McCance & Huether, 2014).

Measurement of Osmolality.

Osmolality is approximately the same in the various body fluid spaces. Determining osmolality is important because it indicates the water balance of the body. To assess the state of the body water balance, the clinician can measure or estimate plasma osmolality. Normal plasma osmolality is between 280 and 300 mmol/kg. A value greater than 295 mmol/kg indicates that the concentration of particles is too great or that the water content is too little. This condition is termed *water deficit.* A value less than 285 mmol/kg indicates too little solute for the amount of water or too much water for the amount of solute. This condition is termed *water excess.* Both conditions are clinically significant.

Plasma and urine osmolality can be measured in most clinical laboratories. Because the major determinants of the plasma osmolality are sodium, glucose, and urea, the effective plasma osmolality can be calculated from the concentrations of those compounds with the following equation:

$$\text{Effective osmolality} = 2 \times (Na^-)p + (\text{glucose})p/18$$

where $(Na^-)p$ and (glucose)p are the plasma concentrations of sodium and glucose in milliequivalents per litre (mEq/L) and milligrams per decilitre (mg/dL), respectively. The sodium concentration is multiplied by 2 to account for the presence of an equivalent number of anions. Glucose concentration is divided by one-tenth of its molecular weight to calculate the number of osmotically active particles per litre.

It is sometimes recommended that the measurement of blood urea nitrogen (BUN)* be included in the calculation of plasma osmolality. This is done by adding a third term to the effective osmolality equation (+ BUN/2.8), with the BUN expressed in milligrams per decilitre. However, the urea moves freely between body fluid compartments; it has no lasting effect on water movement across cell boundaries and is sometimes dubbed an "ineffective osmole." The actual osmolality is calculated more

accurately if the BUN is used. However, the measure of the effective plasma osmolality without consideration of the BUN term is the more physiologically meaningful estimate. Osmolality of urine can range from 100 to 1 300 mmol/kg, depending on the amount of antidiuretic hormone (ADH) and the renal response to it.

Osmotic Movement of Fluids.

Cells are affected by the osmolality of the fluid that surrounds them. Fluids with the same osmolality as the cell interior are **isotonic.** Solutions in which the solutes are less concentrated than they are in cells are **hypotonic** (hypo-osmolar). Those with solutes more concentrated than they are in cells are **hypertonic** (hyperosmolar).

Normally, the ECF and the ICF are isotonic to one another; so no net movement of water occurs. In the metabolically active cell, there is a constant exchange of substances between the compartments, but no net gain or loss of water occurs.

If a cell is surrounded by hypotonic fluid, water moves into the cell, causing it to swell and possibly to burst. If a cell is surrounded by hypertonic fluid, water leaves the cell to dilute the ECF; the cell shrinks and may eventually die (Figure 19-7).

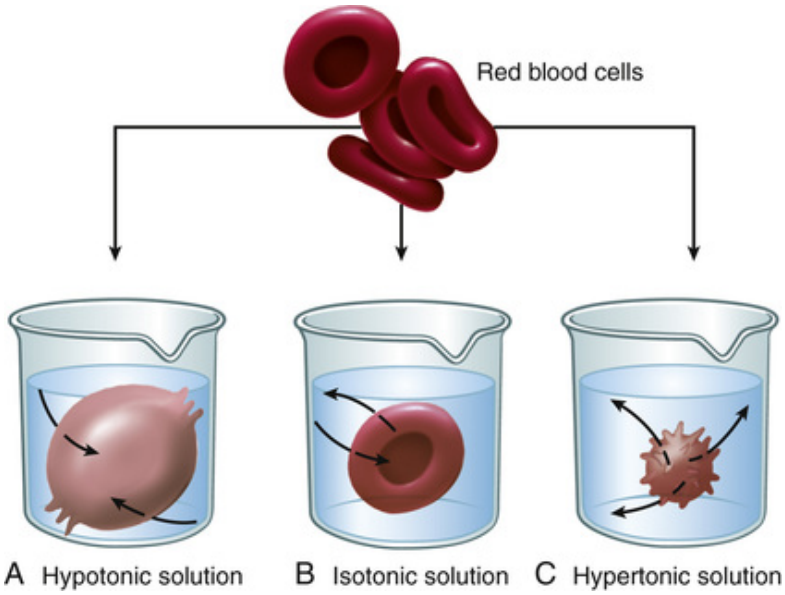

FIGURE 19-7 Effects of water status on red blood cells. **A,** Hypotonic solution (H_2O excess) results in cellular swelling. **B,** Isotonic solution (normal H_2O balance) results in no change. **C,** Hypertonic solution (H_2O deficit) results in cellular shrinking. Source: Patton, K. T., & Thibodeau, G. A. (2016). *Anatomy and physiology* (9th ed., p. 102). St. Louis: Mosby.

Hydrostatic Pressure

Hydrostatic pressure is the force within a fluid compartment. In the blood vessels, hydrostatic pressure is the blood pressure generated by the contraction of the heart. Hydrostatic pressure in the vascular system gradually decreases as the blood moves through the arteries until it is approximately 40 mm Hg at the arterial end of a capillary. Because of the size of the capillary bed and fluid movement into the interstitium, the pressure decreases to approximately 10 mm Hg at the venous end of the capillary. Hydrostatic pressure is the major force that pushes water out of the vascular system at the capillary level.

Oncotic Pressure

Oncotic pressure (colloidal osmotic pressure) is osmotic pressure exerted by colloids in solution. The major colloid in the vascular system contributing to the total osmotic pressure is protein. Protein molecules attract water, pulling fluid from the tissue space to the vascular space (Porth, 2013). Unlike electrolytes, proteins have large molecular sizes,

which prevents them from leaving the vascular space through pores in capillary walls. Plasma oncotic pressure is approximately 25 mm Hg. Some proteins are found in the interstitial space; they exert an oncotic pressure of approximately 1 mm Hg.

Fluid Movement in Capillaries

There is normal movement of fluid between the capillary and the interstitium. The amount and direction of movement are determined by the interaction of (1) capillary hydrostatic pressure, (2) plasma oncotic pressure, (3) interstitial hydrostatic pressure, and (4) interstitial oncotic pressure.

Capillary hydrostatic pressure and interstitial oncotic pressure cause the movement of water out of the capillaries. Plasma oncotic pressure and interstitial hydrostatic pressure cause the movement of fluid into the capillary. At the arterial end of the capillary (Figure 19-8), capillary hydrostatic pressure exceeds plasma oncotic pressure, and fluid is moved into the interstitium. At the venous end of the capillary, the capillary hydrostatic pressure is lower than plasma oncotic pressure, and fluid is drawn back into the capillary by the oncotic pressure created by plasma proteins.

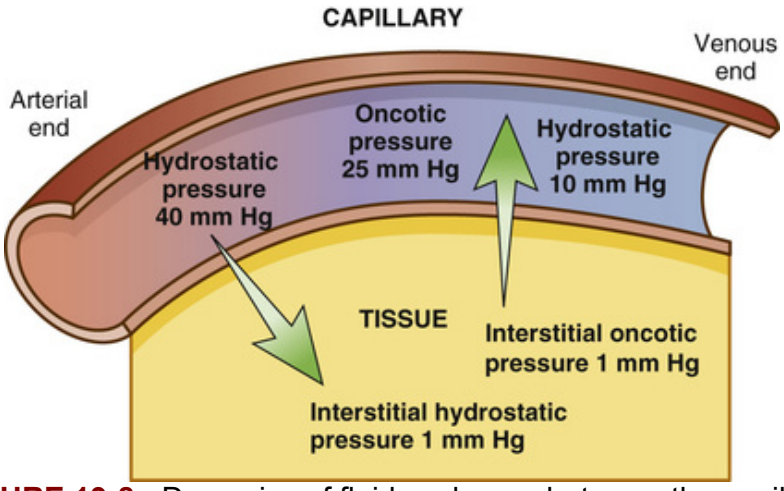

FIGURE 19-8 Dynamics of fluid exchange between the capillary and the tissue. Equilibrium exists between forces filtering fluid out of the capillary and forces absorbing fluid back into the capillary. Note that the hydrostatic pressure is greater at the arterial end of the capillary than at the venous end. The net effect of pressures at the arterial end of the capillary causes a movement of fluid into the tissue. At the venous end of the capillary, there is net movement of fluid back into the capillary.

Fluid Shifts

If capillary or interstitial pressures are altered, fluid may abnormally shift from one compartment to another, which results in edema or dehydration.

Shifts of Plasma to Interstitial Fluid.

Accumulation of fluid in the interstitium *(edema)* occurs if venous hydrostatic pressure rises, plasma oncotic pressure decreases, or interstitial oncotic pressure rises. Edema may also develop if the lymphatic outflow is obstructed, which causes decreased removal of interstitial fluid.

Elevation of Venous Hydrostatic Pressure.

Increasing the pressure at the venous end of the capillary inhibits fluid movement back into the capillary. Causes of increased venous pressure include fluid overload, heart failure, liver failure, obstruction of venous return to the heart (e.g., by tourniquets, restrictive clothing, venous thrombosis), and venous insufficiency (e.g., manifested by varicose veins).

Decrease in Plasma Oncotic Pressure.

Fluid remains in the interstitium if the plasma oncotic pressure is too low to draw fluid back into the capillary. Decreased oncotic pressure is seen when the plasma protein content is low. This can result from excessive protein loss (renal disorders), deficient protein synthesis (liver disease), and deficient protein intake (malnutrition).

Elevation of Interstitial Oncotic Pressure.

Trauma, burns, and inflammation can damage capillary walls and allow plasma proteins to accumulate in the interstitium. The resultant increased interstitial oncotic pressure draws fluid into the interstitium and holds it there.

Shifts of Interstitial Fluid to Plasma.

Fluid is drawn into the plasma space whenever there is an increase in the plasma osmotic or oncotic pressure. This could happen with administration of colloids, dextran, mannitol, or hypertonic solutions. Fluid is drawn from the interstitium. In turn, water is drawn from cells via osmosis, which causes equilibration of the osmolality between the ICF and the ECF.

Increasing the tissue hydrostatic pressure is another way of causing a shift of fluid into plasma. The wearing of elastic compression gradient

stockings or hose to decrease peripheral edema is a therapeutic application of this effect.

Fluid Movement Between Extracellular Fluid and Intracellular Fluid

Changes in the osmolality of the ECF alter the volume of cells. Increased ECF osmolality (water deficit) pulls water out of cells until the two compartments have a similar osmolality. Water deficit is associated with symptoms that result from cell shrinkage as water is pulled into the vascular system. For example, neurological symptoms are caused by altered central nervous system (CNS) function as brain cells shrink. Decreased ECF osmolality (water excess) develops as the result of gain or retention of excess water. In this case, cells swell. Again, the primary symptoms are neurological as a result of brain cell swelling as water shifts into the cells.

Fluid Spacing

Fluid spacing is a term sometimes used to describe the distribution of body water. *First spacing* describes the normal distribution of fluid in the ICF and ECF compartments. *Second spacing* refers to an abnormal accumulation of interstitial fluid (i.e., edema). *Third spacing* occurs when fluid accumulates in a portion of the body from which it is not easily exchanged with the rest of the ECF. Third-spaced fluid is trapped and essentially unavailable for functional use. Examples of third spacing are ascites, sequestration of fluid in the abdominal cavity with peritonitis, and edema associated with burns, trauma or sepsis.

Regulation of Water Balance

Hypothalamic Regulation

Water balance is maintained by a balance of intake and excretion. A body fluid deficit or an increase in plasma osmolality is sensed by hypothalamic osmoreceptors, which in turn stimulate thirst and ADH release. Thirst causes the patient to drink. Hypothalamic ADH, which is stored in the posterior pituitary gland, induces water reabsorption in the renal distal and collecting tubules. Together, these factors result in increased free water in the body and decreased plasma osmolality. Once plasma osmolality is normalized, secretion of ADH is suppressed, and thus urinary excretion is restored.

An intact thirst mechanism is critical because it is the primary protection against the development of hyperosmolality. The patient who cannot recognize or act on the sensation of thirst is at risk for fluid deficit and hyperosmolality. The sensitivity of the thirst mechanism decreases in older adults.

The desire to consume fluids is also affected by social and psychological factors not related to fluid balance. A dry mouth will cause the patient to drink, even when there is no measurable body water deficit. This is normally compensated by equivalent water excretion. A patient with psychiatric issues may display psychogenic polydipsia that may lead to water intoxication.

Pituitary Regulation

Under hypothalamic control, the posterior pituitary gland releases ADH, which causes the distal tubules and collecting ducts in the kidneys to regulate water retention by becoming more permeable by water. Water is reabsorbed from the tubular filtrate into the blood and not excreted in urine. Factors that stimulate ADH release include increased plasma osmolality, stress, nausea, nicotine, and morphine. For instance, it is common for patients to have a lower serum osmolality after surgery, possibly because of the stress of surgery and opioid analgesia.

A pathological condition seen occasionally is *syndrome of inappropriate antidiuretic hormone* (SIADH; see Chapter 51). Causes of SIADH include abnormal ADH production in CNS disorders (e.g., brain tumours, brain injury) and certain malignancies (e.g., small cell lung cancer). The

inappropriate secretion of ADH causes water retention, which causes plasma osmolality to decrease below the normal value and causes a relative increase in urine osmolality with a decrease in urine volume.

Reduction in the release or action of ADH produces diabetes insipidus (see Chapter 51). A copious amount of dilute urine is excreted because the renal tubules and collecting ducts do not appropriately reabsorb water. A patient with diabetes insipidus exhibits extreme polyuria and, if alert, polydipsia (excessive thirst). Symptoms of dehydration and hypernatremia develop if the water losses are not adequately replaced.

Adrenal Cortical Regulation

ECF volume is maintained by a combination of hormonal influences. ADH affects only water reabsorption. Hormones released by the adrenal cortex help regulate both water and electrolytes. Two groups of hormones secreted by the adrenal cortex are glucocorticoids and mineralocorticoids. The glucocorticoids (e.g., cortisol) have primarily an anti-inflammatory effect and increase serum glucose levels, whereas the mineralocorticoids (e.g., aldosterone) enhance sodium retention and potassium excretion (Figure 19-9). When sodium is reabsorbed, water follows as a result of osmotic changes.

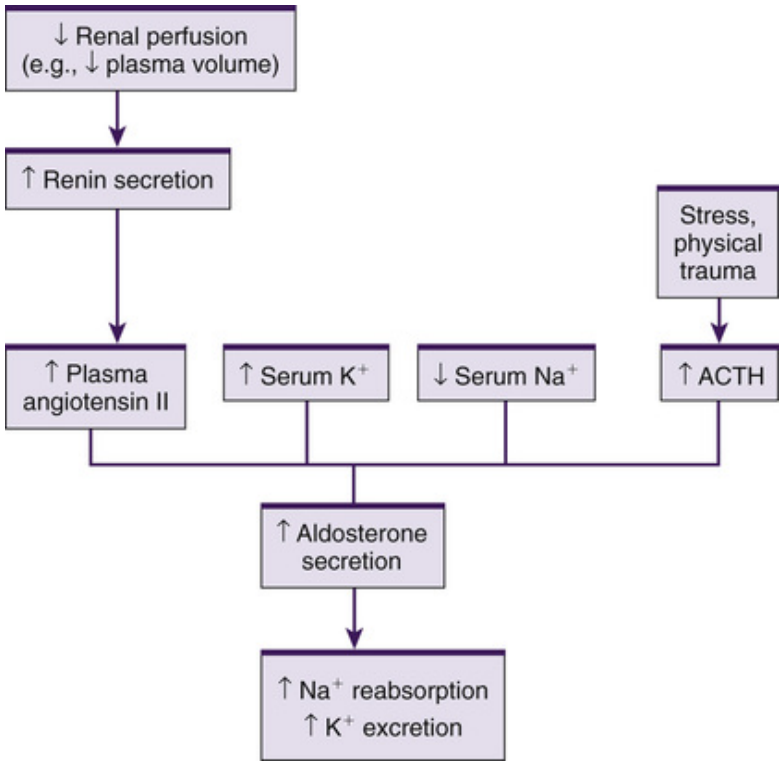

FIGURE 19-9 Factors affecting aldosterone secretion. *ACTH,* adrenocorticotrophic hormone.

Cortisol is the most common example of a naturally occurring glucocorticoid. In large doses, cortisol has both glucocorticoid (glucose level–elevating and anti-inflammatory) and mineralocorticoid (sodium-retaining) properties. The adrenocortical hormone cortisol is secreted normally and whenever stress levels are increased. Many body systems, including fluid and electrolyte balance, are affected by stress (Figure 19-10).

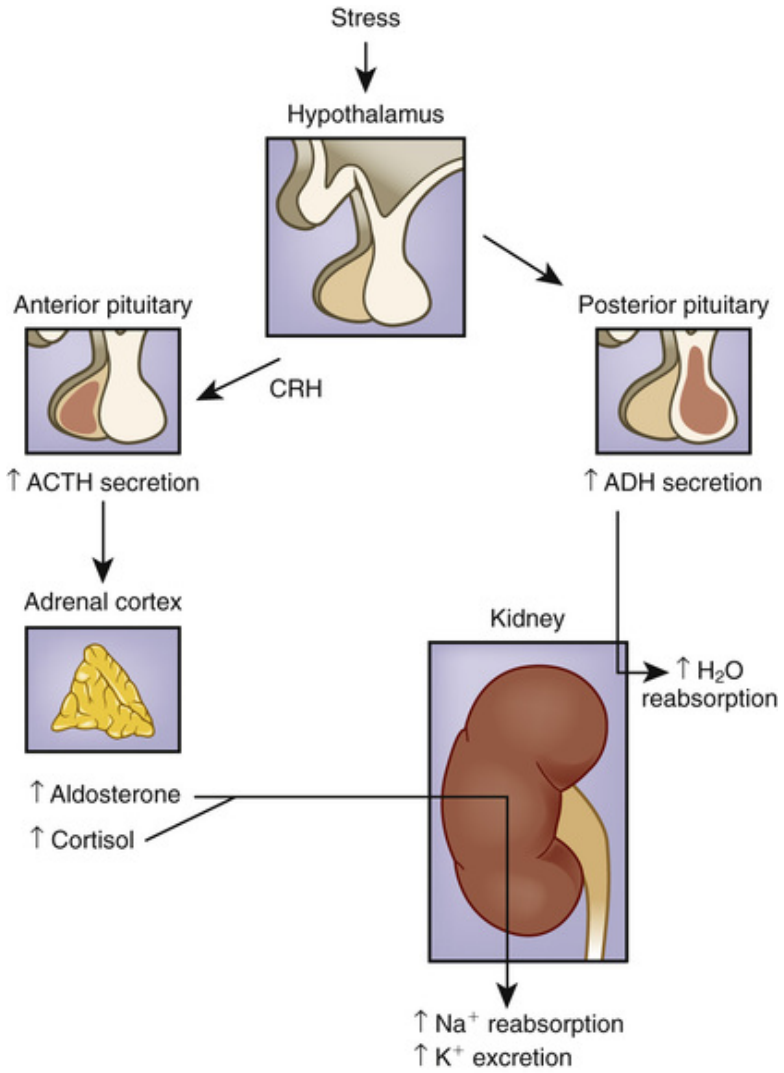

FIGURE 19-10 Effects of stress on fluid and electrolyte balance. *ACTH,* adrenocorticotrophic hormone; *ADH,* antidiuretic hormone; *CRH,* corticotropin-releasing hormone.

Aldosterone is a naturally occurring mineralocorticoid with potent sodium-retaining and potassium-excreting capability. Decreased renal perfusion or decreased sodium in the distal portion of the renal tubule activates the renin-angiotensin-aldosterone system, which results in aldosterone secretion. In addition to this system, increased serum potassium, decreased serum sodium, and adrenocorticotrophic hormone (ACTH) stimulate aldosterone secretion. Aldosterone increases sodium and water reabsorption in the renal distal tubules, which causes plasma osmolality to decrease and fluid volume to be restored (see Figure 19-9).

Renal Regulation

The primary organs for regulating fluid and electrolyte balance are the kidneys (see Chapter 47). The kidneys regulate water balance through adjustments in urine volume. Similarly, urinary excretion of most electrolytes is adjusted so that a balance is maintained between overall intake and output. The total plasma volume is filtered by the kidneys many times each day. In the average adult, the kidneys reabsorb 99% of this filtrate, producing approximately 1.5 L of urine per day. As the filtrate moves through the renal tubules, selective reabsorption of water and electrolytes and secretion of electrolytes result in the production of urine, whose composition and concentration are greatly different from those of the plasma. This process helps maintain normal plasma osmolality, electrolyte balance, blood volume, and acid–base balance. The renal tubules are the site for the actions of ADH and aldosterone.

When renal function is severely impaired, the kidneys cannot maintain fluid and electrolyte balance. This condition results in edema, potassium and phosphorus retention, acidosis, and other electrolyte imbalances (see Chapter 49). Renal function is typically decreased in older adults, which increases their risk for fluid and electrolyte imbalances. In particular, the ability to concentrate urine may be reduced in older adults.

Cardiac Regulation

Atrial natriuretic factor (ANF) is a hormone released by the cardiac atria in response to increased atrial pressure (increased volume, such as what occurs in heart failure) and high serum sodium levels. The primary actions of ANF are vasodilation and increased urinary excretion of sodium and water, which decreases blood volume (McCance & Huether, 2014).

Gastro-intestinal Regulation

Daily water intake and output are between 2 000 and 3 000 mL (Table 19-1). The GI tract accounts for most of the water intake. Water intake includes fluids, water from food metabolism, and water present in solid foods. Lean meat is approximately 70% water, whereas the water content of many fruits and vegetables approaches 100%.

TABLE 19-1
NORMAL FLUID BALANCE IN THE ADULT

Substance	Amount
Intake	
Fluids	1200 mL
Solid food	1000 mL
Water from oxidation	300 mL
Total	2500 mL
Output	
Insensible loss (skin and lungs)	900 mL
Urine	1500 mL
In feces	100 mL
Total	2500 mL

Most of the body's water is excreted by the kidneys, and a small amount of water is normally eliminated by the GI tract in feces. The GI tract normally secretes approximately 8 000 mL of digestive fluids each day, of which most is reabsorbed. This is why diarrhea and vomiting, which prevent GI reabsorption of secreted fluid, can lead to significant fluid and electrolyte loss.

Insensible Water Loss

Insensible water loss, which is invisible vaporization from the lungs and the skin, assists in regulating body temperature. Normally, approximately 900 mL per day is lost. The amount of water loss is increased by accelerated body metabolism, which occurs with increased body temperature and exercise.

Water loss through the skin should not be confused with the vaporization of water excreted by sweat glands. Only water is lost by insensible perspiration. Excessive sweating *(sensible perspiration)* caused by fever or high environmental temperatures may lead to large losses of water and electrolytes.

Age-Related Considerations

Fluid and Electrolytes

Older adults experience normal physiological changes that increase susceptibility to fluid and electrolyte imbalances. Structural changes in the kidneys and a decrease in the renal blood flow lead to a decrease in the glomerular filtration rate, decreased creatinine clearance, the loss of the ability to concentrate urine and conserve water, and narrowed limits for the excretion of water, sodium, potassium, and hydrogen ions. Hormonal changes include decreases in renin and aldosterone and increases in ADH and atrial natriuretic peptide (ANP; Touhy & Jett, 2016). Loss of subcutaneous tissue and thinning of the dermis lead to increased loss of moisture through the skin and an inability to respond to heat or cold quickly. Older adults experience a decrease in the thirst mechanism, which results in decreased fluid intake despite increases in osmolality and serum sodium level. Frail older adults, especially if ill, are at increased risk for free-water loss and subsequent development of hypernatremia secondary to impairment of the thirst mechanism, and increased risk for adverse social and environmental conditions (Hooper, Bunn, Jimoh, et al., 2014).

Healthy older adults usually consume adequate fluids to remain well hydrated. However, functional changes may occur that affect the individual's ability to independently obtain fluids. Musculoskeletal changes, such as stiffness of the hands and fingers, can lead to a decreased ability to hold a glass or cup. Mental status changes, such as confusion or disorientation, or changes in ambulation status may lead to a decreased ability to obtain fluids. As a result of incontinent episodes, an older adult may intentionally restrict fluid intake (Hooper, Bunn, Jimoh, et al., 2014).

To help older adult patients, the health care provider must understand the homeostatic changes that occur in this population. It is important to avoid the pitfalls of ageism, wherein fluid and electrolyte problems may be inappropriately attributed to the natural processes of aging. The nurse needs to adapt assessment and nursing implementation to account for these physiological and functional changes. Suggestions for alterations in nursing care for older adults are presented throughout this chapter and in Chapter 7.

Fluid and Electrolyte Imbalances

Fluid and electrolyte imbalances occur to some degree in most patients with a major illness or injury because illness disrupts the normal homeostatic mechanism. Some fluid and electrolyte imbalances are directly caused by injury or disease (e.g., burns, heart failure). At other times, therapeutic measures (e.g., IV fluid replacement, diuretics) cause or contribute to fluid and electrolyte imbalances.

The imbalances are commonly classified as *deficits* or *excesses*. Each imbalance is discussed separately. Normal values are listed in Table 19-2. In actual clinical situations, more than one imbalance occurring in the same patient is common. For example, a patient undergoing prolonged nasogastric suction will lose Na^+, K^+, H^+, and Cl^-. These imbalances may result in deficiencies of both Na^+ and K^+, as well as metabolic alkalosis and fluid volume deficit.

TABLE 19-2

NORMAL SERUM ELECTROLYTE VALUES

Electrolyte	Normal Value
Anions	
Bicarbonate (HCO_3^-)	21–28 mmol/L
Chloride (Cl^-)	98–106 mmol/L
Phosphate (PO_4^{3-})	0.97–1.45 mmol/L
Protein	64–83 g/L
Cations	
Potassium (K^+)	3.5–5.0 mmol/L
Magnesium (Mg^{2+})	0.74–1.07 mmol/L
Sodium (Na^+)	135–145 mmol/L
Calcium (Ca^{2+}) (total)	2.25–2.75 mmol/L
Calcium (ionized)	1.05–1.30 mmol/L

Sodium and Extracellular Fluid Volume Imbalances

Sodium plays a major role in maintaining the concentration and the volume of the ECF. Sodium is the main cation of the ECF and the primary determinant of ECF osmolality. Sodium imbalances are typically associated with parallel changes in osmolality. Because sodium affects the water distribution between the ECF and the ICF, it affects osmolality. Sodium is also important in the generation and transmission of nerve

impulses and the regulation of acid–base balance. Serum sodium is measured in milliequivalents per litre or millimoles per litre.

The GI tract absorbs sodium from foods. Typically, daily intake of sodium far exceeds the body's daily requirements. Sodium leaves the body through urine, sweat, and feces. The kidneys are the primary regulator of sodium balance. The kidneys regulate the ECF concentration of sodium by excreting or retaining water under the influence of ADH. Aldosterone also plays a part in sodium regulation by promoting sodium reabsorption from the renal tubules. The serum sodium level reflects the ratio of sodium to water, not necessarily the loss or gain of sodium. Thus changes in the serum sodium level may reflect either a primary water imbalance, a primary sodium imbalance, or a combination of the two. Sodium imbalances are typically associated with imbalances in ECF volume (Figures 19-11 and 19-12).

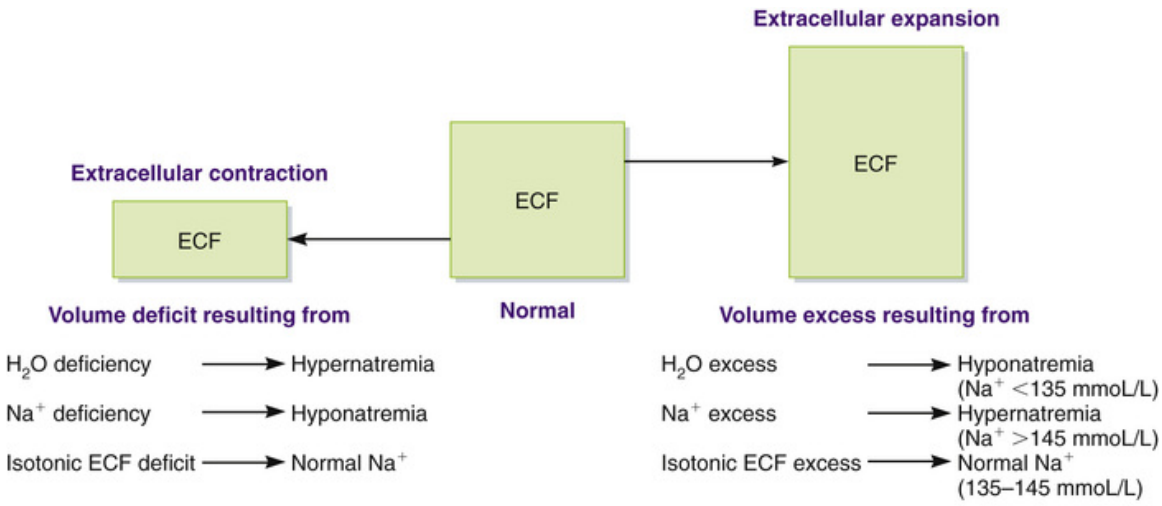

FIGURE 19-11 Differential assessment of extracellular fluid (ECF) volume.

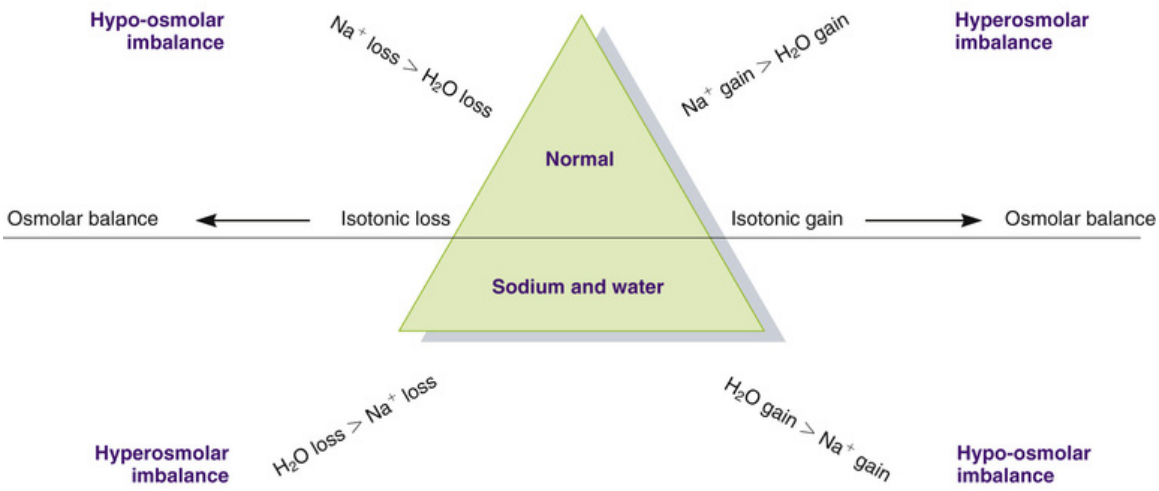

FIGURE 19-12 Isotonic gains and losses affect mainly the extracellular fluid (ECF) compartment, with little or no water movement into the cells. Hypertonic imbalances cause water to move from inside the cell into the ECF to dilute the concentrated sodium, which results in cell shrinkage. Hypotonic imbalances cause water to move into the cell, which results in cell swelling.

Hypernatremia.

The serum sodium level may become elevated as a result of water loss or sodium gain. Because sodium is the major determinant of the ECF osmolality, hypernatremia causes hyperosmolality. In turn, hyperosmolality causes a shift of water out of the cells, which leads to cellular dehydration.

As discussed earlier, the primary protection against the development of hyperosmolality is thirst. As the plasma osmolality increases, the thirst centre in the hypothalamus is stimulated, and the individual seeks fluids.

Hypernatremia is not a problem in an alert person who has access to water, can sense thirst, and is able to swallow. Hypernatremia secondary to water deficiency is often the result of an impaired level of consciousness or an inability to obtain fluids. Unconscious patients and certain cognitively impaired patients are at risk because of an inability to express thirst and act on it.

Several clinical states can produce water loss and hypernatremia (Table 19-3). A deficiency in the synthesis of ADH or in its release from the posterior pituitary gland (central diabetes insipidus) or a decrease in kidney responsiveness to ADH (nephrogenic diabetes insipidus) can result in profound diuresis, causing a water deficit and hypernatremia. Hyperosmolality can result from administration of concentrated

hyperosmolar tube feedings and osmotic diuretics (mannitol), as well as from hyperglycemia associated with uncontrolled diabetes mellitus. These situations result in osmotic diuresis. Dilute urine is lost, leaving behind a high solute load. Other causes of hypernatremia include excessive sweating and increased sensible losses from high fever.

TABLE 19-3

WATER AND SODIUM IMBALANCES: CAUSES AND CLINICAL MANIFESTATIONS

Water Excess: Hyponatremia (Na^+ Level <136 mmol/L)	Water Deficit: Hypernatremia (Na^+ Level >145 mmol/L)
Causes	
Sodium loss • GI losses: diarrhea, vomiting, fistulas, NG suction • Renal losses: diuretics, adrenal insufficiency, Na^+ wasting renal disease • Skin losses: burns, wound drainage	Water loss (sodium concentration) • ↑ Insensible water loss or perspiration (high fever, heatstroke) • Diabetes insipidus • Osmotic diuresis
Water gain (sodium dilution) • SIADH • Heart failure • Excessive hypotonic IV fluids • Primary polydipsia	Sodium gain • IV hypertonic NaCl • IV sodium bicarbonate • IV excessive isotonic NaCl • Primary hyperaldosteronism • Saltwater near-drowning
Clinical Manifestations	
Decreased ECF volume (sodium loss) • Irritability, apprehension, confusion • Postural hypotension • Tachycardia • Rapid, thready pulse • ↓ CVP • ↓ Jugular venous filling • Nausea, vomiting • Dry mucous membranes • Weight loss • Tremors, seizures, coma	Decreased ECF volume (water loss) • Intense thirst; dry, swollen tongue • Restlessness, agitation, twitching • Seizures, coma • Weakness • Postural hypotension, ↓ CVP • Weight loss
Normal or increased ECF volume (water gain) • Headache, lassitude, apathy • Weakness, confusion • Nausea, vomiting • Weight gain • ↑ BP, ↑ CVP • Muscle spasms, seizures, coma	Normal or increased ECF volume (sodium gain) • Intense thirst • Restlessness, agitation, twitching • Seizures, coma • Flushed skin • Weight gain • Peripheral and pulmonary edema • ↑ BP, ↑ CVP

BP, blood pressure; *CVP,* central venous pressure*; ECF,* extracellular fluid; *GI,* gastrointestinal; *IV,* intravenous; *NaCl,* sodium chloride; *NG,* nasogastric; *SIADH,* syndrome of inappropriate antidiuretic hormone.

Sodium intake in excess of water intake can also lead to hypernatremia. Causes of sodium gain include IV administration of hypertonic saline or sodium bicarbonate, use of sodium-containing drugs, excessive oral intake

of sodium (ingestion of seawater), and primary aldosteronism (hypersecretion of aldosterone), which in turn is caused by a tumour of the adrenal glands.

Symptoms are primarily the result of changes in the plasma osmolality that lead to changes in the volume of cellular water (see Table 19-3). Dehydration of neurons leads to neurological manifestations such as intense thirst, lethargy, agitation, seizures, and even coma. Sodium excess also has a direct effect on the irritability and conduction of neurons, causing them to be more easily excited. Patients with hypernatremia will also exhibit the symptoms of any accompanying volume imbalance.

Collaborative Care.

The goal of treatment in hypernatremia that is caused by either water loss or sodium gain is to treat the underlying cause. In the treatment of primary water deficit, fluid is replaced either orally or by IV infusion with isotonic fluids, such as 0.9% sodium chloride (Harring, Deal, & Kuo, 2014). Serum sodium levels must be reduced gradually to prevent too rapid a shift of water back into the cells. Overly rapid correction of hypernatremia can result in cerebral edema. The risk is greatest in patients who have developed hypernatremia over several days or longer.

The goal of treatment for sodium excess is to dilute the sodium concentration with salt-free IV fluids, such as 5% dextrose in water, and to promote excretion of the excess sodium by administering diuretics. Dietary sodium intake is often restricted. (See Chapter 51 for specific treatment of diabetes insipidus.) To prevent hypernatremia in older adults or cognitively impaired patients, it is important to pay close attention to fluid intake and losses. Regular administration of oral fluids must be incorporated into these patients' plan of care (Hooper, Bunn, Jimoh, et al., 2014).

Hyponatremia.

Hyponatremia (low serum sodium) may result from a loss of sodium-containing fluids, water excess in relation to the amount of sodium (dilutional hyponatremia), or a combination of both (see Table 19-3). Hyponatremia is usually associated with ECF hypo-osmolality that results from the excess water. To restore balance, fluid shifts out of the ECF and into the cells, leading to cellular edema. Common causes of hyponatremia caused by water excess are inappropriate use of sodium-free or hypotonic IV fluids. This may occur in patients after surgery or major trauma, during administration of fluids in patients with renal failure, or in patients with

psychiatric disorders associated with excessive water intake. In SIADH, dilutional hyponatremia results from abnormal retention of water. (See Chapter 51 for a discussion of the causes of SIADH.)

Losses of sodium-rich body fluids from the GI tract, the kidneys, or the skin indirectly result in hyponatremia. Because these fluids are either isotonic or hypotonic, sodium is lost with an equal or greater proportion of water. However, hyponatremia develops as the body responds to the fluid volume deficit with activation of the thirst mechanism and by releasing ADH. The resultant retention of water lowers the sodium concentration.

The manifestations of hyponatremia are due to cellular swelling and first appear in the CNS (see Table 19-3). Mild hyponatremia has minor, nonspecific neurological symptoms, including headache, irritability, and difficulty concentrating. More severe hyponatremia can cause confusion, vomiting, seizures, and even coma. If hyponatremia is severe and develops rapidly, irreversible neurological damage or death from brain herniation can occur (Verbalis, Goldsmith, Greenberg, et al., 2013).

Collaborative Care.

In hyponatremia that is caused by water excess, fluid restriction is often all that is needed to treat the problem. If severe symptoms (seizures) develop, small amounts of IV hypertonic saline solution (3% sodium chloride [NaCl]) are administered to restore the serum sodium level while the body is returning to a normal water balance. Treatment of hyponatremia associated with abnormal fluid loss includes fluid replacement with sodium-containing solutions. The nurse must monitor serum sodium levels and the patient's response to therapy to avoid rapid correction or overcorrection. Rapidly increasing levels of sodium can cause osmotic demyelination syndrome with permanent damage to nerve cells in the brain. An accurate record of fluid input and output is essential. Commercially available oral rehydration fluids containing electrolytes may help prevent the development of hyponatremia in the home setting.

Extracellular Fluid Volume Imbalances.
